APPENDIX 10. BENCHMARK DOSE MODELING

This appendix provides the BMD modeling outputs for toxicity data that were amenable to dose-response modeling. All models are run with default parameters and a benchmark response of 5% for dichotomous data and one standard deviation from the control mean for continuous data. When appropriate, some models for continuous data are run with modeled variance instead of the default constant variance. Model selection criteria when comparing outputs of different models for the same endpoint/dataset are: scaled residual ≤ the absolute value of two, goodness of fit p-value ≥ 0.05,[28] the Akaike's information criterion (AIC), and visual inspection of the dose-response curve. The lower limit of the 95% confidence interval of the BMD resulting in the benchmark response, the BMDL, is selected as the POD. The model selected for each study to derive a POD is presented below.

Benchmark Dose Analysis Results for Noncancer Endpoints

Perfluorooctanoic Acid

Figure A10.1. BMD modeling of decreased influenza (Hib) antibody levels in humans from Abraham et al. (2020)

[28] US EPA's Benchmark Dose Technical Guidance (2012) suggests using a goodness of fit p-value ≥ 0.1; however, models with less adequate fit (goodness of fit p-value ≥ 0.05) may be used when other criteria are taken into account, such as variability in the endpoint and visual fit.

Model run output for Figure A10.1: Hill Model for decreased influenza (Hib) antibody levels in humans from Abraham et al. (2020).
Note, the benchmark response factor (BMRF, or user defined benchmark response) was derived by OEHHA as follows:

Power(10, at dose Q1) = power(10, 1.84) = 69.2 mg/dl;

10% decrease = 69.2 mg/dl × 0.90 = 62.3 mg/dl;

Log_{10}(62.3 mg/dl) = 1.79.

So, a 10% decrease from Q1 corresponds to a log_{10} value of 1.79, or a difference of 1.84 – 1.79 = 0.05 on the log_{10} scale.

Thus, the BMRF is an absolute deviation of 0.05.

25.7	18	1.19	1.19	0.6	0.667	0.000231

Model Descriptions for likelihoods calculated
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A3 uses any fixed variance parameters that
were specified by the user

Model R: Yi = Mu + e(i)
Var{e(i)} = Sigma^2

Likelihoods of Interest

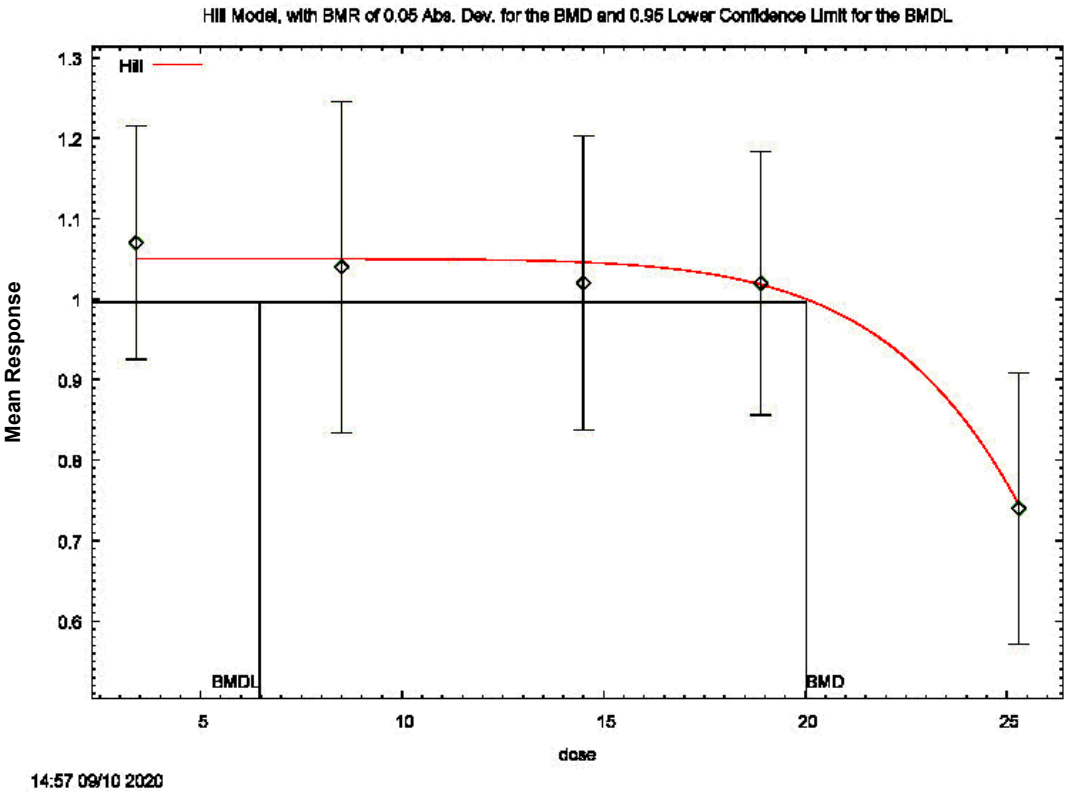
Model	Log(likelihood)	# Param's	AIC
A1	-9.356408	6	30.712816
A2	-7.232118	10	34.464235
A3	-9.356408	6	30.712816
fitted	-9.356848	4	26.713697
R	-16.086495	2	36.172990

Explanation of Tests
Test 1: Do responses and/or variances differ among Dose levels?
(A2 vs. R)
Test 2: Are Variances Homogeneous? (A1 vs. A2)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does the Model for the Mean Fit? (A3 vs. fitted)
(Note: When rho=0 the results of Test 3 and Test 2 will be the same.)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	17.7088	8	0.02352
Test 2	4.24858	4	0.3734
Test 3	4.24858	4	0.3734
Test 4	0.000880611	2	0.9996

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels
It seems appropriate to model the data



The p-value for Test 2 is greater than .1. A homogeneous variance model appears to be appropriate here

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here

The p-value for Test 4 is greater than .1. The model chosen seems to adequately describe the data

Benchmark Dose Computation
Specified effect = 0.05
Risk Type = Absolute deviation
Confidence level = 0.95
BMD = 16.8106
BMDL = 2.75177
BMDU = 19.2936

Figure A10.2. BMD modeling of decreased tetanus antibody levels in humans from Abraham et al. (2020)

Model run output for Figure A10.2: Hill Model for decreased tetanus antibody levels in humans from Abraham et al. (2020).
Note, the BMRF was derived by OEHHA as follows:

Power(10, at dose Q1) = power(10, 1.07) = 11.75 mg/L (mean antibody cocentration at dose Q1);

10% decrease = 11.75 mg/L × 0.90 = 10.57 mg/L;

Log_{10}(10.57 mg/L) = 1.02.
So, a 10% decrease from Q1 corresponds to a log_{10} value of 1.02, or a difference of 1.07 – 1.02 = 0.05 on the log_{10} scale.
Thus, the BMRF is an absolute deviation of 0.05.

Likelihoods of Interest

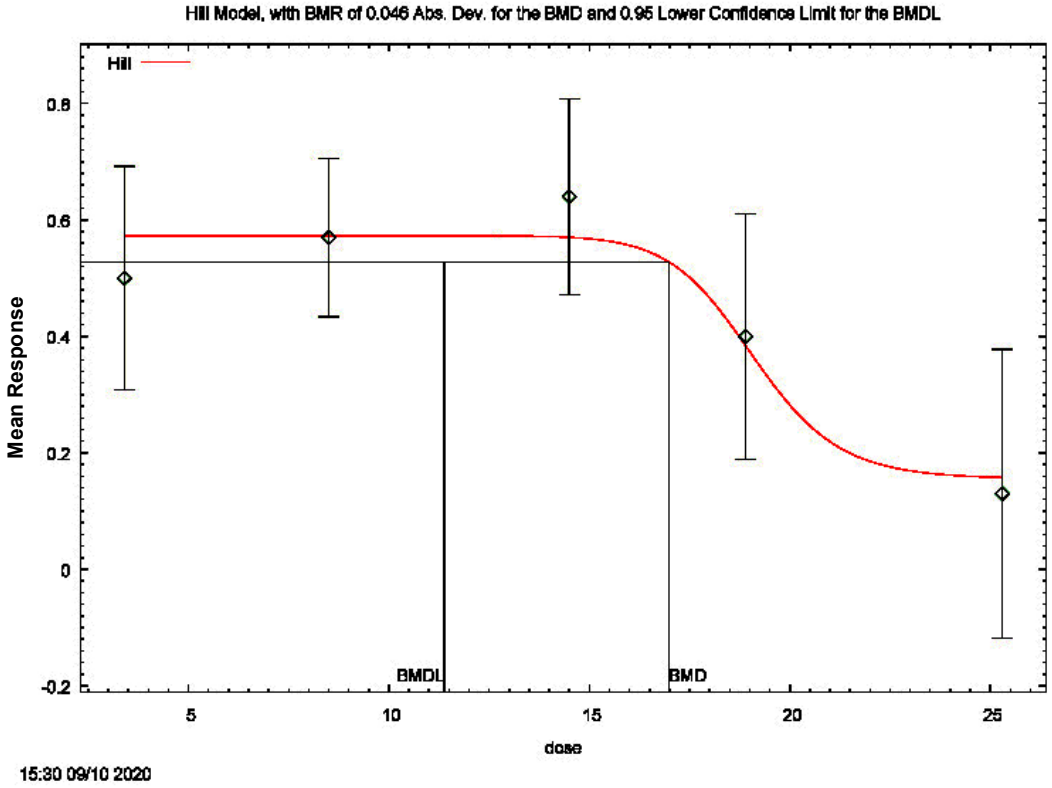
Model	Log(likelihood)	# Param's	AIC
A1	51.307931	6	-90.615863
A2	52.669574	10	-85.339147
A3	51.307931	6	-90.615863
fitted	51.222612	5	-92.445225
R	46.092155	2	-88.184310

Explanation of Tests
Test 1: Do responses and/or variances differ among Dose levels?
(A2 vs. R)
Test 2: Are Variances Homogeneous? (A1 vs. A2)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does the Model for the Mean Fit? (A3 vs. fitted)
(Note: When rho=0 the results of Test 3 and Test 2 will be the same.)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	13.1548	8	0.1066
Test 2	2.72328	4	0.6051
Test 3	2.72328	4	0.6051
Test 4	0.170638	1	0.6795

The p-value for Test 1 is greater than .05. There may not be a
diffence between responses and/or variances among the dose levels
Modelling the data with a dose/response curve may not be appropriate



The p-value for Test 2 is greater than .1. A homogeneous variance
model appears to be appropriate here

The p-value for Test 3 is greater than .1. The modeled variance appears
to be appropriate here

The p-value for Test 4 is greater than .1. The model chosen seems to adequately describe the data

Benchmark Dose Computation
Specified effect = 0.05
Risk Type = Absolute deviation
Confidence level = 0.95
BMD = 20.0211
BMDL = 6.4617
BMDU = 23.8054

Figure A10.3. BMD modeling of decreased diphtheria antibody levels in humans from Abraham et al. (2020)

Model run output for Figure A10.3: Hill Model for decreased diphtheria antibody levels in humans from Abraham et al. (2020).
Note, the BMRF was derived by OEHHA as follows:

Power(10, at dose Q1) = power(10, 0.50) = 3.16 IU/ml (mean antibody concentration at dose Q1);

10% decrease = 3.16 IU/ml × 0.90 = 2.846 IU/ml;

Log_{10}(2.846 IU/ml) = 0.454.

So, a 10% decrease from Q1 corresponds to a log_{10} value of 0.454, or a difference of 0.50 –

0.454 = 0.046 on the $\log_{10}$ scale.

Thus, the BMRF is an absolute deviation of 0.046.

Figure A10.4. BMD modeling of increased mean ALT concentrations in humans from Darrow et al. (2016)

Model run output for Figure A10.4: Hill Model for increased mean ALT levels in humans from Darrow et al. (2016).
Note, the BMRF was derived by OEHHA as follows:

A BMR of 1% would give a b of:

b = ln(1 + 0.01) = 0.00995. Thus, 0.00995 was used as the BMR of 1%.
Furthermore, the model did not converge with all quintiles, thus, quintile 5 was excluded.

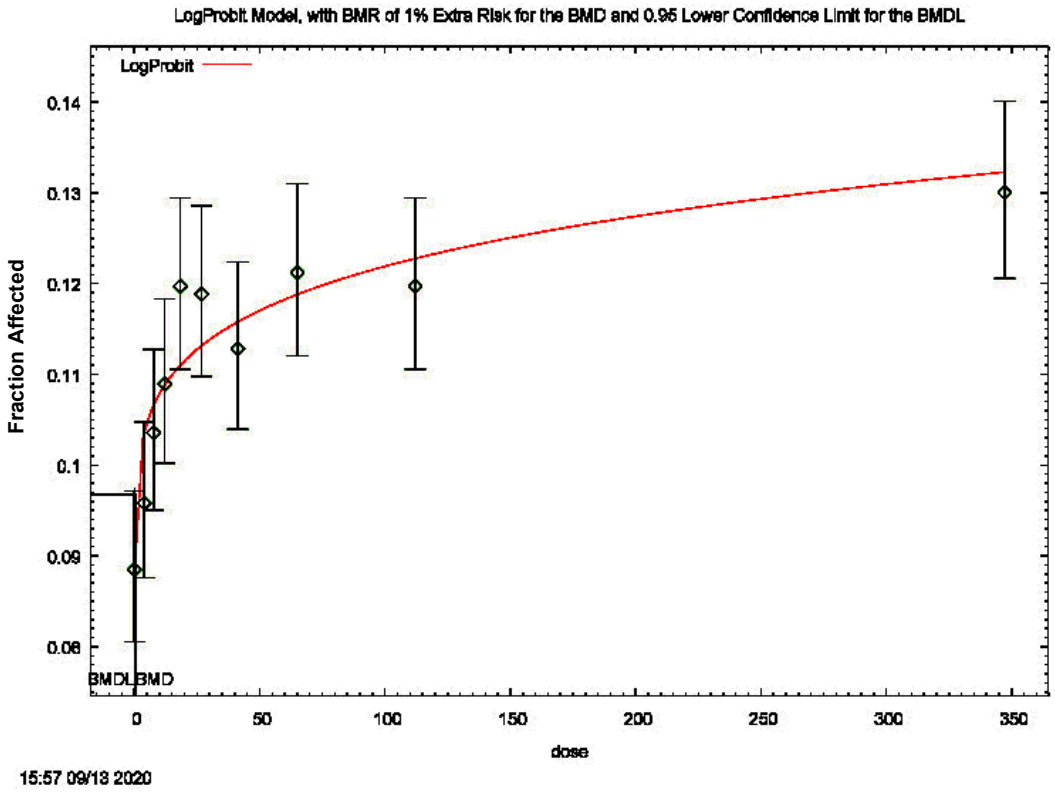
BMD modeling of increased ORs for high ALT in humans from Gallo et al. (2012)

Note: When all ten deciles are used, logprobit was the best fitting model (p=0.18; Figure A10.5A). Although p >0.10, this model resulted in a very steep dose-response curve at the lower doses (almost vertical) and an unusually low BMD (0.43 ng/ml), which did not correlate well with the observed data. Because of this, and because the fit was much improved with the logistic when the higher doses were removed, only deciles 1-5 were used in these BMD calculations (Figure A10.5B).

Figure A10.5A: BMD modeling of increased ORs for high ALT in humans from Gallo et al. (2012) (all ten deciles plotted)



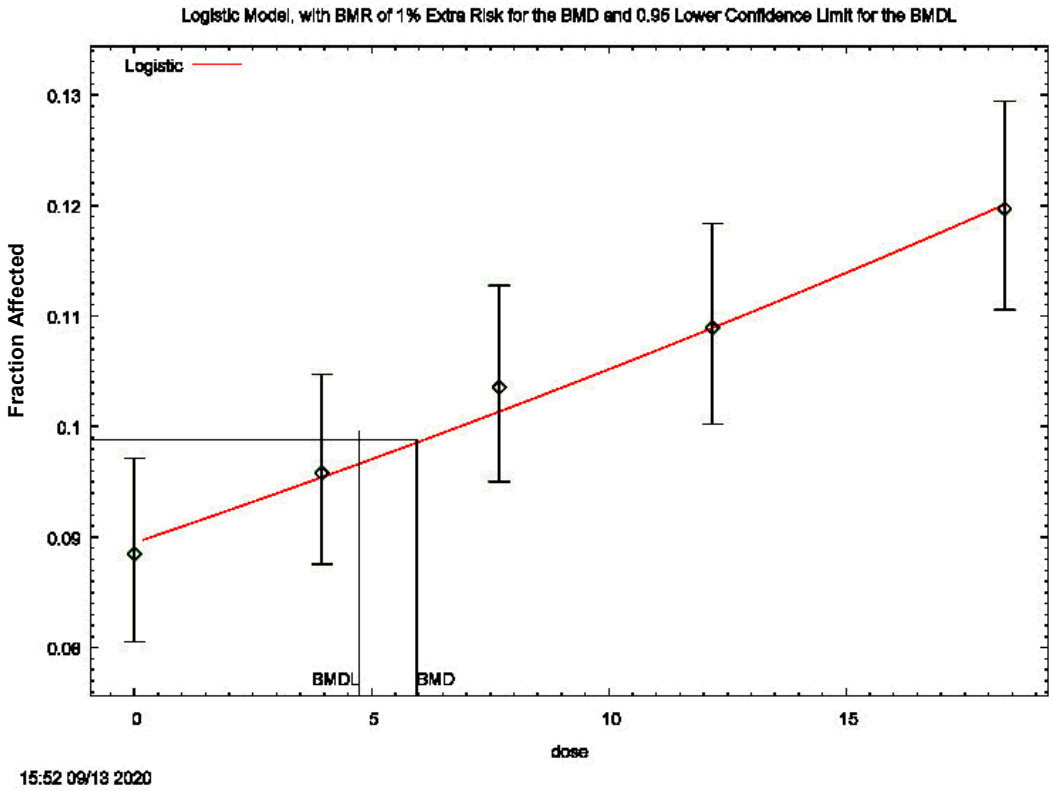


Figure A10.5B: BMD modeling of increased ORs for high ALT in humans from Gallo et al. (2012) (deciles 1-5 plotted)

Model run output for Figure A10.5B: Logistic Model for increased ORs for high ALT levels in humans from Gallo et al. (2012).

Figure A10.6. BMD modeling of increased mean serum total cholesterol in humans from Lin et al. (2019)

Model run output for Figure A10.6: Hill Model for increased mean serum total cholesterol levels in humans from Lin et al. (2019).

Note, the BMRF was derived by OEHHA as follows. The mean TC values in each quartile were not provided. However, the average TC in all subjects combined was provided. This overall average could be used, in combination with the mean differences, to estimate the mean TC in each quartile. These calculations are given in the "lipid reference level calculations" excel spreadsheet. Based on these calculations, the estimated mean TC in quartile 1 is 194.6. A 5% increase in this value is a mean difference of 194.6 × 5% = 9.73. Thus, 9.73 was used as the BMR of 5%.

Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2

Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A3 uses any fixed variance parameters that
were specified by the user

Model R: Yi = Mu + e(i)
Var{e(i)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	# Param's	AIC
A1	-3661.635617	5	7333.271234
A2	-3661.551213	8	7339.102426
A3	-3661.635617	5	7333.271234
fitted	-3661.635617	5	7333.271234
R	-3672.265777	2	7348.531554

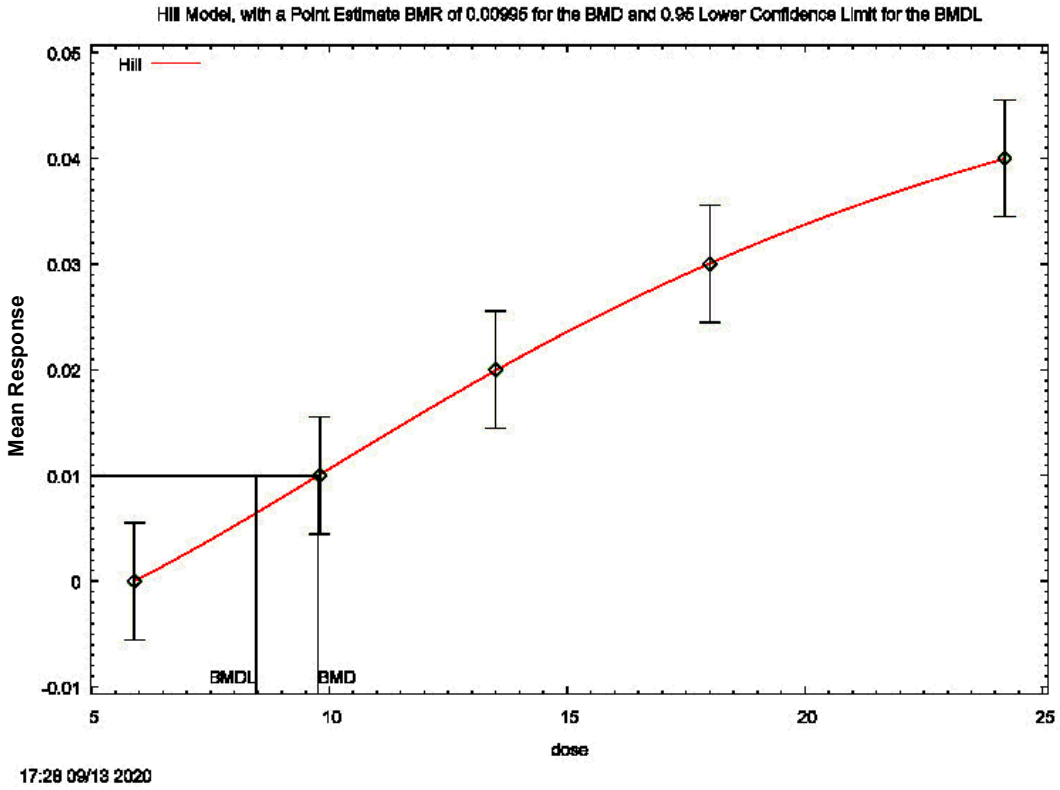
Explanation of Tests
Test 1: Do responses and/or variances differ among Dose levels?
(A2 vs. R)
Test 2: Are Variances Homogeneous? (A1 vs. A2)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does the Model for the Mean Fit? (A3 vs. fitted)
(Note: When rho=0 the results of Test 3 and Test 2 will be the same.)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	21.4291	6	0.001536
Test 2	0.168809	3	0.9825
Test 3	0.168809	3	0.9825
Test 4	9.09495e-013	0	NA

The p-value for Test 1 is less than .05. There appears to be a
difference between response and/or variances among the dose levels
It seems appropriate to model the data

The p-value for Test 2 is greater than .1. A homogeneous variance
model appears to be appropriate here



The p-value for Test 3 is greater than .1. The modeled variance appears
to be appropriate here

NA - Degrees of freedom for Test 4 are less than or equal to 0. The Chi-Square
test for fit is not valid

Benchmark Dose Computation
Specified effect = 9.73
Risk Type = Point estimate
Confidence level = 0.95

BMD = 5.51357
BMDL = 4.61048
BMDU = 7.05482

Figure A10.7. BMD modeling of increased mean serum total cholesterol in humans from Steenland et al. (2009)

Model run output for Figure A10.7: Hill Model for increased mean serum total cholesterol levels from Steenland et al. (2009).

Note, the BMRF was derived by OEHHA as follows. A 5% increase was within the range of the observed effects but close to the upper limit (the percent increase in the highest decile was 5.1%). Because of this, a BMR of 1% was used.
Percent change in TC = [exp(b) - 1] x 100%
or, exp(b) = percent change + 1
or, exp(b) = 0.01 + 1 = 1.01
or, b = ln(1.01) = 0.00995.
Thus, b = 0.00995 was used as the BMR of 1%.

Likelihoods of Interest

Model	Log(likelihood)	DF	AIC
A1	-25.30928	5	60.61856
A2	-22.04414	8	60.08828
A3	-23.09363	6	58.18726
R	-77.88171	2	159.7634
2	-43.5176	4	95.0352
3	-43.5176	4	95.0352
4	-23.42929	5	56.85859
5	-23.09363	6	58.18726

Additive constant for all log-likelihoods = -44.11. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.
Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)

Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)
Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)
Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	111.7	6	< 0.0001
Test 2	6.53	3	0.08848
Test 3	2.099	2	0.3501
Test 4	40.85	2	< 0.0001
Test 5a	40.85	2	< 0.0001
Test 5b	-1.421e-014	0	N/A
Test 6a	0.6713	1	0.4126
Test 6b	40.18	1	< 0.0001
Test 7a	1.048e-008	0	N/A
Test 7b	40.85	2	< 0.0001
Test 7c	0.6713	1	0.4126

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here.

The p-value for Test 4 is less than .1. Model 2 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

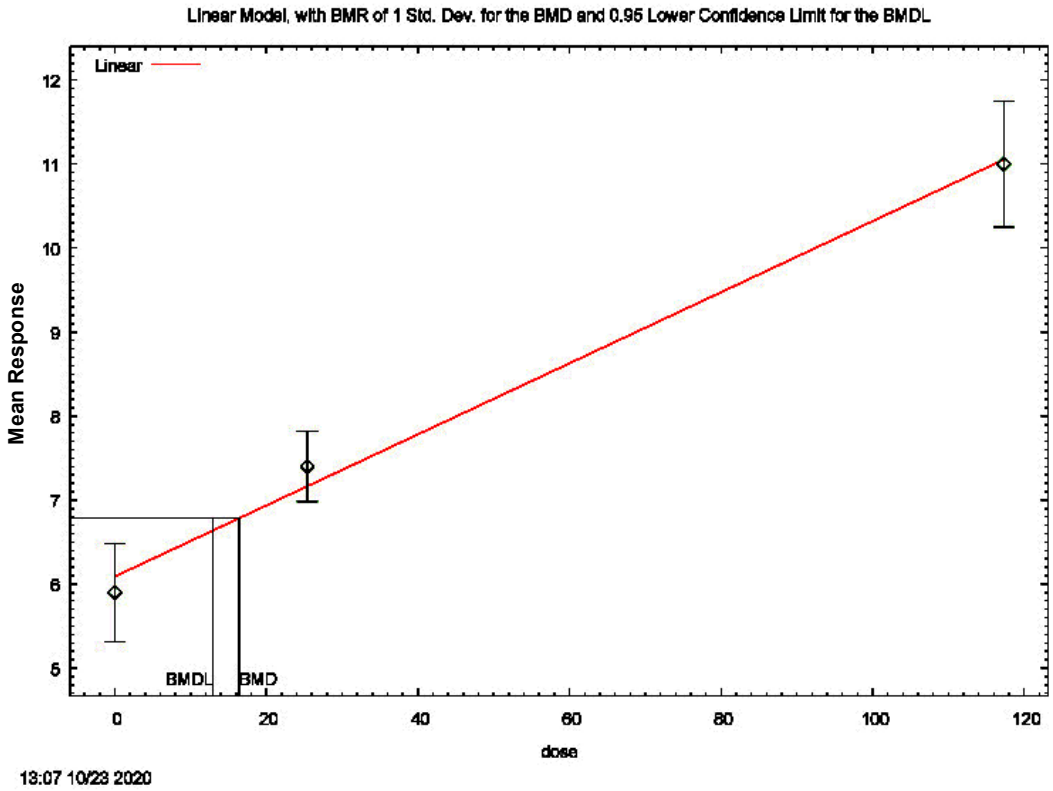
Degrees of freedom for Test 5b are less than or equal to 0. The Chi-Square test for fit is not valid.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

Degrees of freedom for Test 7a are less than or equal to 0.
The Chi-Square test for fit is not valid.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.



The p-value for Test 7c is greater than .05. Model 5 does not seem to fit the data better than Model 4.

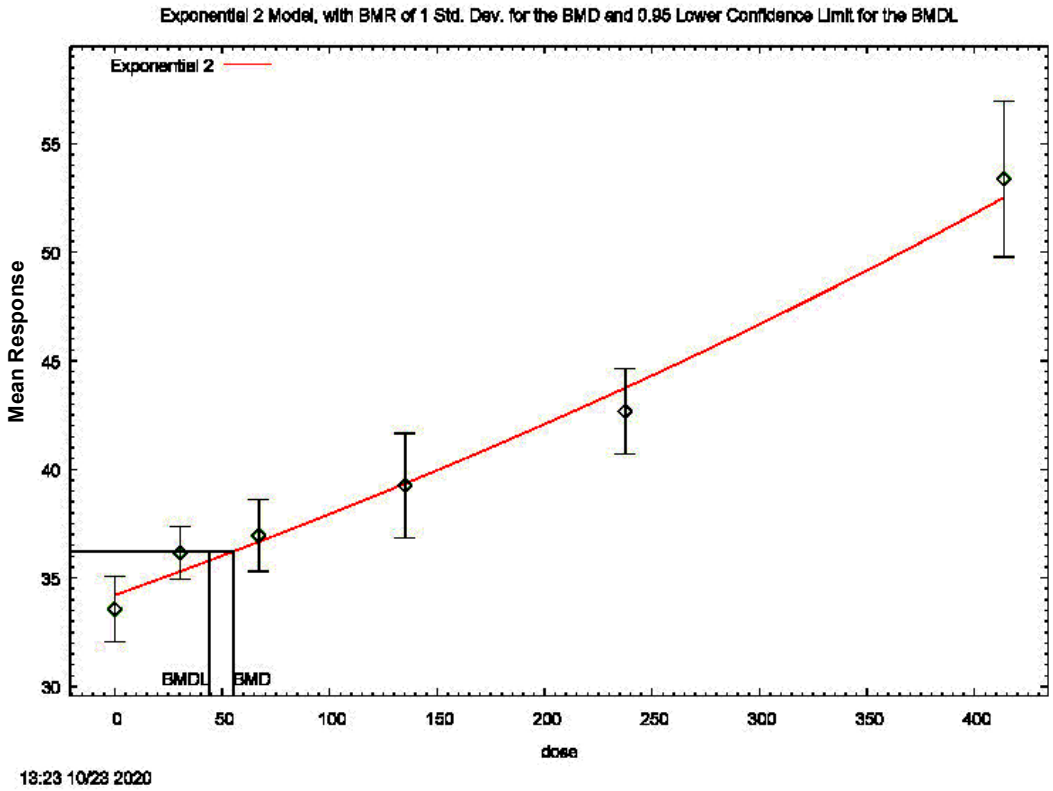
Test 1	33.5689	4	<.0001
Test 2	2.51578	2	0.2843
Test 3	2.51578	2	0.2843
Test 4	3.73386	1	0.05332

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels
It seems appropriate to model the data



The p-value for Test 2 is greater than .1. A homogeneous variance model appears to be appropriate here

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here

The p-value for Test 4 is less than .1. You may want to try a different model

	237.5	43.95	3.275	-1.234
	413.6	52.13	4.566	0.816

Other models for which likelihoods are calculated:
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)
Model R: Yij = Mu + e(i)
Var{e(ij)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	DF	AIC
A1	-89.95135	7	193.9027
A2	-83.54031	12	191.0806
A3	-84.99057	8	185.9811
R	-143.3548	2	290.7096
2	-87.11333	4	182.2267

Model	Log(likelihood)	DF	AIC
3	-87.11333	4	182.2267
4	-87.82322	5	185.6464
5	-87.68515	6	187.3703

Additive constant for all log-likelihoods = -54.22. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	119.6	10	< 0.0001
Test 2	12.82	5	0.0251
Test 3	2.901	4	0.5746
Test 4	4.246	4	0.3738
Test 5a	4.246	4	0.3738
Test 5b	2.842e-014	0	N/A
Test 6a	5.665	3	0.1291
Test 6b	-1.42	1	N/A
Test 7a	5.389	2	0.06757
Test 7b	-1.144	2	N/A
Test 7c	0.2762	1	0.5992

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here.

The p-value for Test 4 is greater than .1. Model 2 seems to adequately describe the data.

The p-value for Test 5a is greater than .1. Model 3 seems to adequately describe the data.

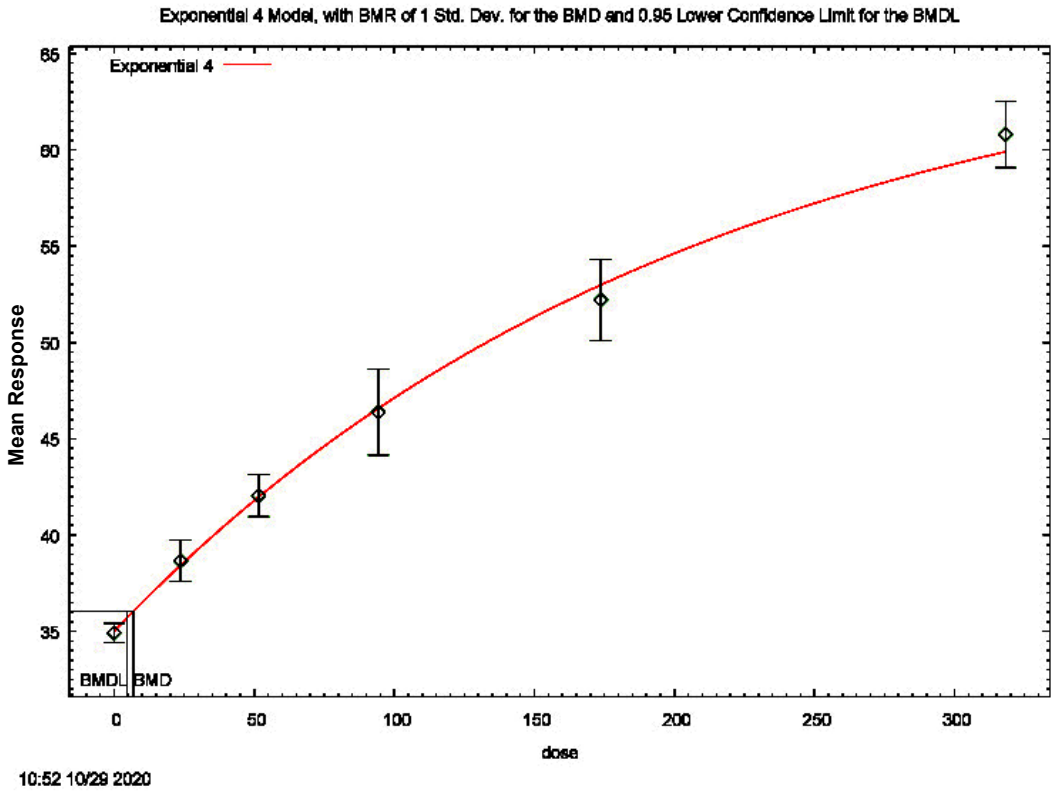
Degrees of freedom for Test 5b are less than or equal to 0. The Chi-Square test for fit is not valid.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is less than .1. Model 5 may not adequately describe the data; you may want to consider another model.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.



The p-value for Test 7c is greater than .05. Model 5 does not seem to fit the data better than Model 4.

	318.2	59.9	3.823	0.7436

Other models for which likelihoods are calculated:
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)
Model R: Yij = Mu + e(i)
Var{e(ij)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	DF	AIC
A1	-74.47572	7	162.9514
A2	-62.46333	12	148.9267
A3	-67.87277	8	151.7455
R	-161.2307	2	326.4615
2	-93.59988	4	195.1998

Model	Log(likelihood)	DF	AIC
3	-93.59988	4	195.1998
4	-68.62996	5	147.2599
5	-68.62996	5	147.2599

Additive constant for all log-likelihoods = -55.14. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	197.5	10	< 0.0001
Test 2	24.02	5	0.0002147
Test 3	10.82	4	0.02868
Test 4	51.45	4	< 0.0001
Test 5a	51.45	4	< 0.0001
Test 5b	-5.116e-013	0	N/A
Test 6a	1.514	3	0.679
Test 6b	49.94	1	< 0.0001
Test 7a	1.514	3	0.679
Test 7b	49.94	1	< 0.0001
Test 7c	-5.684e-013	0	N/A

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is less than .1. You may want to consider a different variance model.

The p-value for Test 4 is less than .1. Model 2 may not adequately

describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

Degrees of freedom for Test 5b are less than or equal to 0.
The Chi-Square test for fit is not valid.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is greater than .1. Model 5 seems to adequately describe the data.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.

Degrees of freedom for Test 7c are less than or equal to 0.
The Chi-Square test for fit is not valid.

	318.2	0.3547	0.1023	-0.7641

Other models for which likelihoods are calculated:
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)
Model R: Yij = Mu + e(i)
Var{e(ij)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	DF	AIC
A1	39.92491	7	-65.84982
A2	87.97322	12	-151.9464
A3	76.18026	8	-136.3605

Model	Log(likelihood)	DF	AIC
R	-19.81312	2	43.62624
2	26.96114	4	-45.92229
3	-19.81312	5	49.62624
4	73.99365	5	-137.9873
5	73.9962	6	-135.9924

Additive constant for all log-likelihoods = -55.14. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests

Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	D. F.	p-value
Test 1	215.6	10	< 0.0001
Test 2	96.1	5	< 0.0001
Test 3	23.59	4	< 0.0001
Test 4	98.44	4	< 0.0001
Test 5a	192	3	< 0.0001
Test 5b	-93.55	1	N/A
Test 6a	4.373	3	0.2239
Test 6b	94.07	1	< 0.0001
Test 7a	4.368	2	0.1126
Test 7b	187.6	1	< 0.0001
Test 7c	0.005103	1	0.943

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is less than .1. You may want to

consider a different variance model.

The p-value for Test 4 is less than .1. Model 2 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5b is less than .05. Model 3 appears to fit the data better than Model 2.

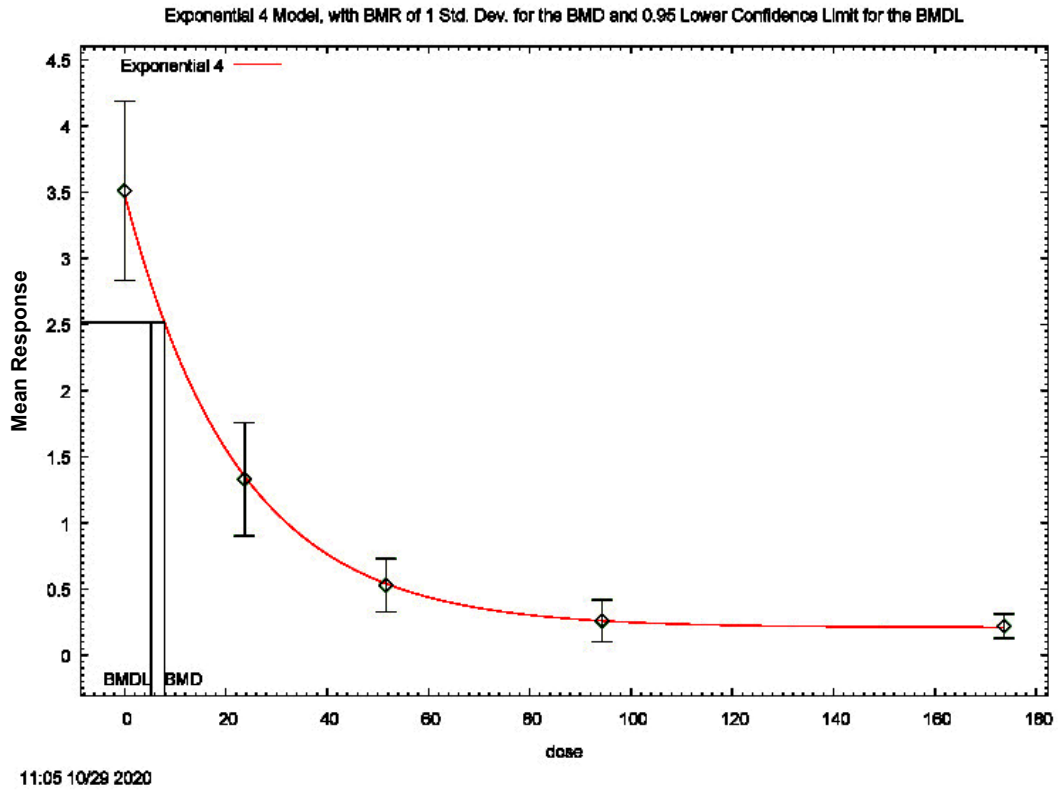
The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is greater than .1. Model 5 seems to adequately describe the data.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.

The p-value for Test 7c is greater than .05. Model 5 does not seem to fit the data better than Model 4.



Benchmark Dose Computations:
Specified Effect = 1.000000

	173.7	0.2116	0.1541	0.1728

Other models for which likelihoods are calculated:
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = exp(lalpha + log(mean(i)) * rho)
Model R: Yij = Mu + e(i)
Var{e(ij)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	DF	AIC
A1	9.347685	6	-6.69537
A2	31.52834	10	-43.05669
A3	30.74894	7	-47.49788
R	-39.43493	2	82.86987
2	17.68492	4	-27.36985
3	-39.43493	5	88.86987
4	30.5611	5	-51.1222
5	30.5611	5	-51.1222

Additive constant for all log-likelihoods = -45.95. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	D. F.	p-value
Test 1	141.9	8	< 0.0001
Test 2	44.36	4	< 0.0001
Test 3	1.559	3	0.6688
Test 4	26.13	3	< 0.0001
Test 5a	140.4	2	< 0.0001
Test 5b	-114.2	1	N/A
Test 6a	0.3757	2	0.8287
Test 6b	25.75	1	< 0.0001
Test 7a	0.3757	2	0.8287
Test 7b	140	0	N/A
Test 7c	-4.619e-013	0	N/A

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here.

The p-value for Test 4 is less than .1. Model 2 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

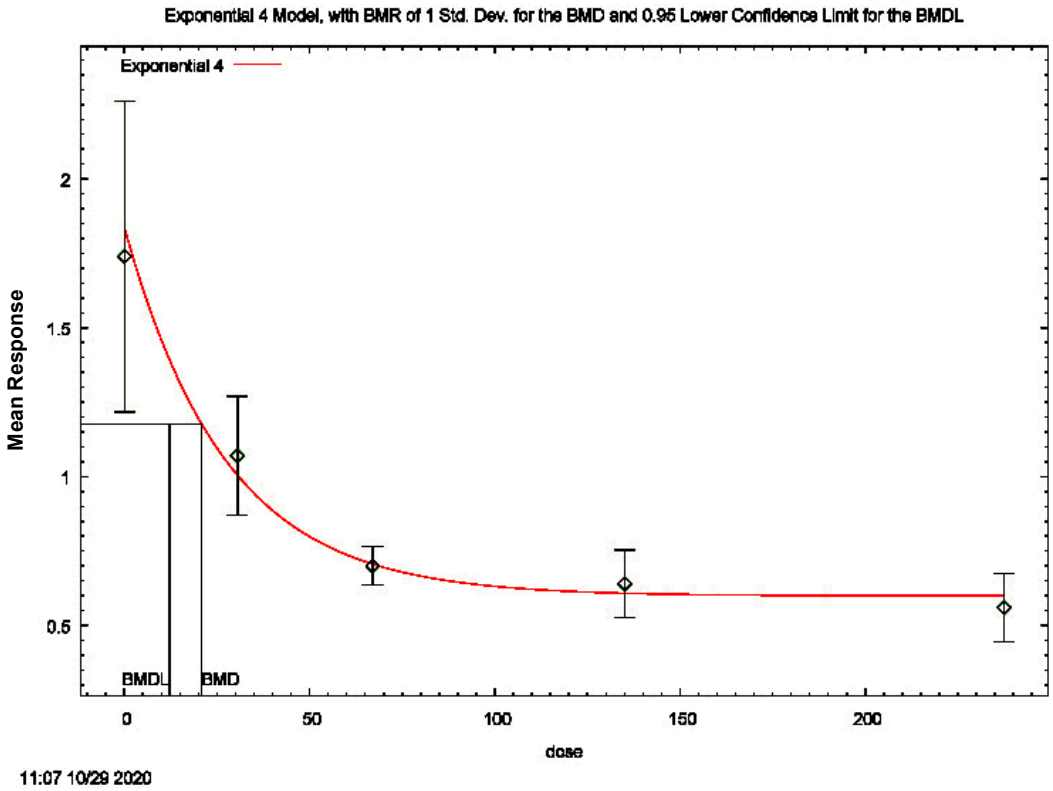
The p-value for Test 5b is less than .05. Model 3 appears to fit the data better than Model 2.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is greater than .1. Model 5 seems to adequately describe the data.

Degrees of freedom for Test 7b are less than or equal to 0. The Chi-Square test for fit is not valid.



Degrees of freedom for Test 7c are less than or equal to 0. The Chi-Square test for fit is not valid.

3	4.240573	5	1.518855
4	49.70844	5	-89.41688
5	50.15681	6	-88.31362

Additive constant for all log-likelihoods = -45.95. This constant added to the above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	D. F.	p-value
Test 1	100	8	< 0.0001
Test 2	52.76	4	< 0.0001
Test 3	6.851	3	0.07681
Test 4	38.84	3	< 0.0001
Test 5a	93.15	2	< 0.0001
Test 5b	-54.31	1	N/A
Test 6a	2.216	2	0.3302
Test 6b	36.62	1	< 0.0001
Test 7a	1.319	1	0.2507
Test 7b	91.83	1	< 0.0001
Test 7c	0.8967	1	0.3437

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is less than .1. You may want to consider a different variance model.

The p-value for Test 4 is less than .1. Model 2 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

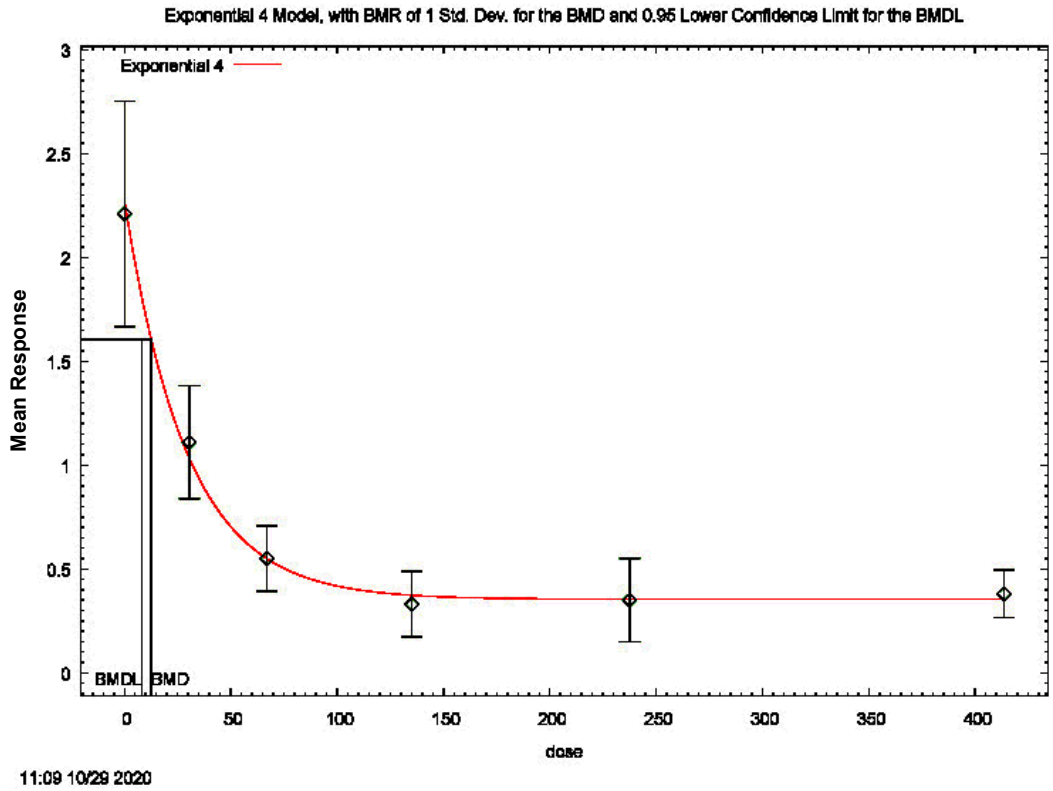
The p-value for Test 5b is less than .05. Model 3 appears to fit the data better than Model 2.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is greater than .1. Model 5 seems to adequately describe the data.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.



The p-value for Test 7c is greater than .05. Model 5 does not seem to fit the data better than Model 4.

4	-262.3839	5	534.7679
5	-262.3839	5	534.7679

Additive constant for all log-likelihoods = -45.95. This constant added to the

above values gives the log-likelihood including the term that does not depend on the model parameters.

Explanation of Tests
Test 1: Does response and/or variances differ among Dose levels? (A2 vs. R)
Test 2: Are Variances Homogeneous? (A2 vs. A1)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does Model 2 fit the data? (A3 vs. 2)

Test 5a: Does Model 3 fit the data? (A3 vs. 3)
Test 5b: Is Model 3 better than Model 2? (3 vs. 2)

Test 6a: Does Model 4 fit the data? (A3 vs. 4)
Test 6b: Is Model 4 better than Model 2? (4 vs. 2)

Test 7a: Does Model 5 fit the data? (A3 vs. 5)
Test 7b: Is Model 5 better than Model 3? (5 vs. 3)
Test 7c: Is Model 5 better than Model 4? (5 vs. 4)

Tests of Interest

Test	-2*log(Likelihood Ratio)	D. F.	p-value
Test 1	48.73	8	< 0.0001
Test 2	14.84	4	0.005055
Test 3	0.1596	3	0.9838
Test 4	13.13	3	0.004367
Test 5a	13.13	3	0.004367
Test 5b	-6.071e-011	0	N/A
Test 6a	0.5996	2	0.741
Test 6b	12.53	1	0.0004007
Test 7a	0.5996	2	0.741
Test 7b	12.53	1	0.0004007
Test 7c	0	0	N/A

The p-value for Test 1 is less than .05. There appears to be a difference between response and/or variances among the dose levels, it seems appropriate to model the data.

The p-value for Test 2 is less than .1. A non-homogeneous variance model appears to be appropriate.

The p-value for Test 3 is greater than .1. The modeled variance appears to be appropriate here.

The p-value for Test 4 is less than .1. Model 2 may not adequately describe the data; you may want to consider another model.

The p-value for Test 5a is less than .1. Model 3 may not adequately describe the data; you may want to consider another model.

Degrees of freedom for Test 5b are less than or equal to 0.

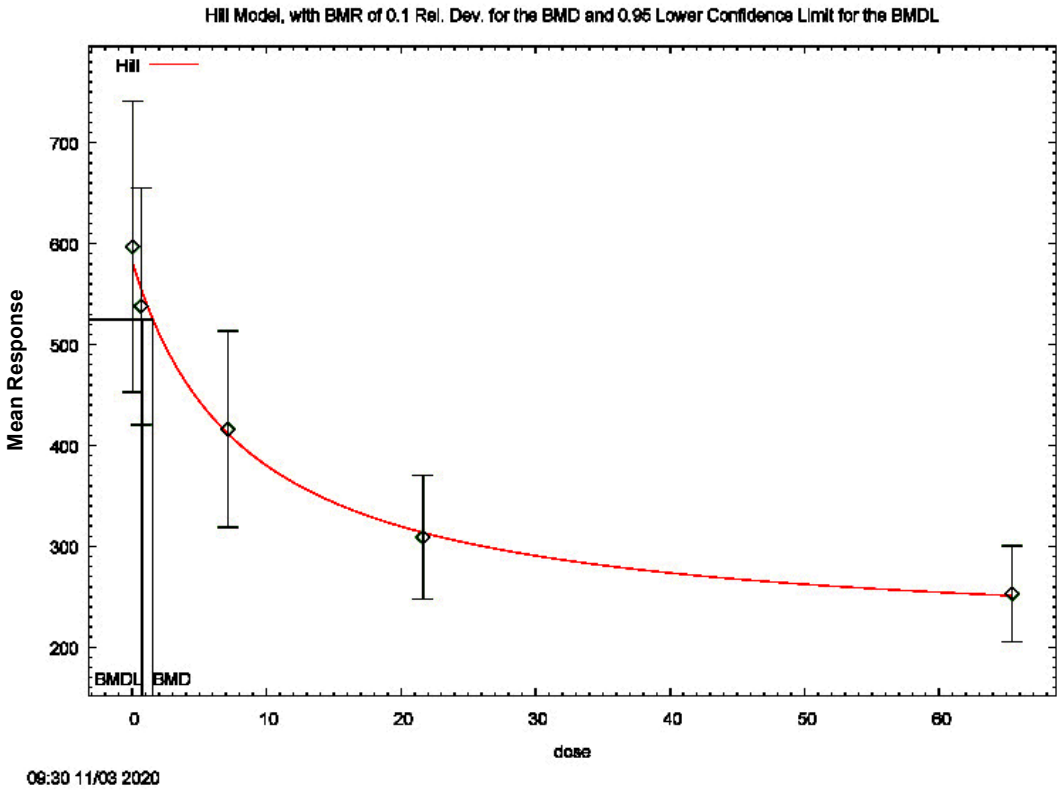
The Chi-Square test for fit is not valid.

The p-value for Test 6a is greater than .1. Model 4 seems to adequately describe the data.

The p-value for Test 6b is less than .05. Model 4 appears to fit the data better than Model 2.

The p-value for Test 7a is greater than .1. Model 5 seems to adequately describe the data.

The p-value for Test 7b is less than .05. Model 5 appears to fit the data better than Model 3.



Degrees of freedom for Test 7c are less than or equal to 0.
The Chi-Square test for fit is not valid.

BMDS Model Run
~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
The form of the response function is:
Y[dose] = intercept + v*dose^n/(k^n + dose^n)

Independent variable = Dose
Power parameter restricted to be greater than 1
The variance is to be modeled as Var(i) = exp(lalpha  + rho * ln(mean(i)))

Total number of dose groups = 5
Total number of records with missing values = 0
Maximum number of iterations = 500
Relative Function Convergence has been set to: 1e-008
Parameter Convergence has been set to: 1e-008
```

Default Initial Parameter Values
lalpha = 9.88224
rho = 0
intercept = 597
v = -344
n = 1.19729
k = 6.65559

Asymptotic Correlation Matrix of Parameter Estimates
(*** The model parameter(s) -n
have been estimated at a boundary point, or have been specified by the user,
and do not appear in the correlation matrix)

	lalpha	rho	intercept	v	k
lalpha	1	-1	0.34	-0.41	-0.12
rho	-1	1	-0.35	0.42	0.12
intercept	0.34	-0.35	1	-0.76	-0.54
v	-0.41	0.42	-0.76	1	-0.028
k	-0.12	0.12	-0.54	-0.028	1

Parameter Estimates

Variable	Estimate	Std. Err.	95.0% Wald Confidence Interval	
			Lower Conf. Limit	Upper Conf. Limit
lalpha	-5.75113	4.23737	-14.0562	2.55397
rho	2.54262	0.707137	1.15666	3.92858
intercept	582.785	43.8176	496.904	668.666
v	-374.609	50.0391	-472.684	-276.534
n	1	NA		
k	8.47933	4.00913	0.621581	16.3371

NA - Indicates that this parameter has hit a bound
implied by some inequality constraint and thus
has no standard error.

Table of Data and Estimated Values of Interest

Dose	N	Obs Mean	Est Mean	Obs Std Dev	Est Std Dev	Scaled Res.
0.048	10	597	581	202	184	0.28
0.674	10	538	555	164	174	-0.313
7.132	10	416	412	136	119	0.116
21.64	10	309	314	85.4	84.1	-0.175
65.43	10	253	251	66.4	63.4	0.092

Model Descriptions for likelihoods calculated
Model A1: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma^2
Model A2: Yij = Mu(i) + e(ij)
Var{e(ij)} = Sigma(i)^2
Model A3: Yij = Mu(i) + e(ij)
Var{e(ij)} = exp(lalpha + rho*ln(Mu(i)))

Model A3 uses any fixed variance parameters that
were specified by the user
Model R: Yi = Mu + e(i)
Var{e(i)} = Sigma^2

Likelihoods of Interest

Model	Log(likelihood)	# Param's	AIC
A1	-269.422105	6	550.844210
A2	-262.004309	10	544.008618
A3	-262.084125	7	538.168249
fitted	-262.335552	5	534.671105
R	-286.370083	2	576.740166

Explanation of Tests
Test 1: Do responses and/or variances differ among Dose levels?
(A2 vs. R)
Test 2: Are Variances Homogeneous? (A1 vs. A2)
Test 3: Are variances adequately modeled? (A2 vs. A3)
Test 4: Does the Model for the Mean Fit? (A3 vs. fitted)
(Note: When rho=0 the results of Test 3 and Test 2 will be the same.)

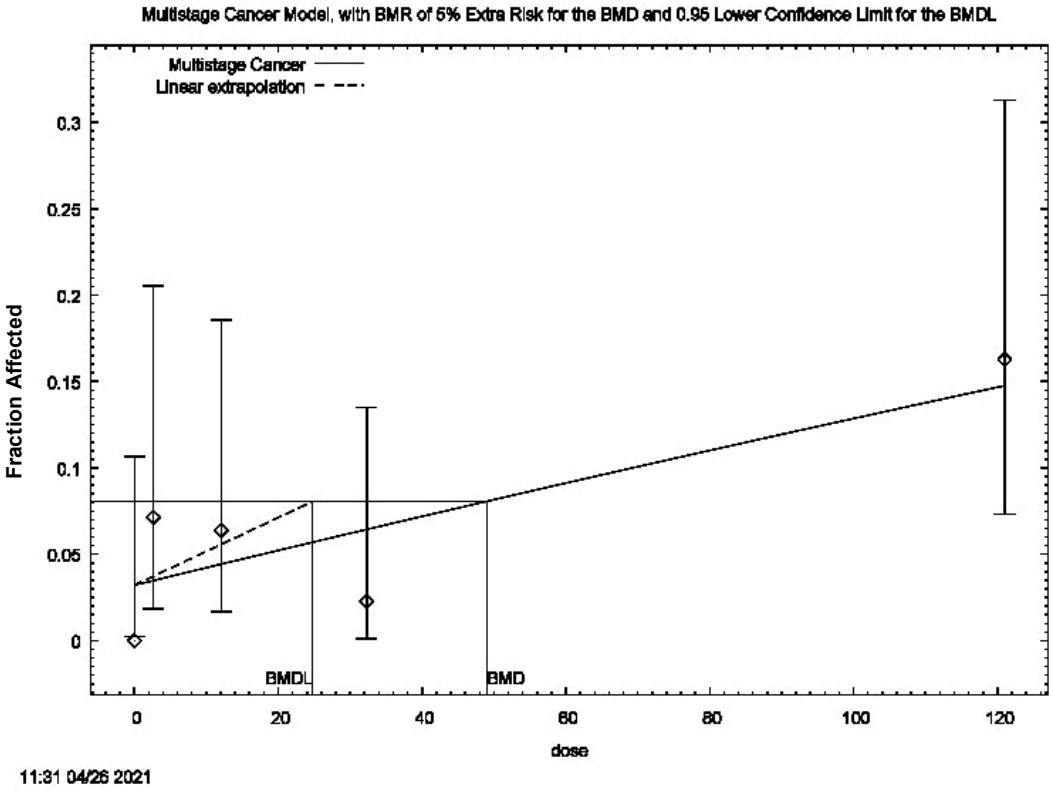
Tests of Interest

Test	-2*log(Likelihood Ratio)	Test df	p-value
Test 1	48.7315	8	<.0001
Test 2	14.8356	4	0.005055
Test 3	0.159631	3	0.9838
Test 4	0.502856	2	0.7777

The p-value for Test 1 is less than .05. There appears to be a
difference between response and/or variances among the dose levels
It seems appropriate to model the data

The p-value for Test 2 is less than .1. A non-homogeneous variance
model appears to be appropriate

The p-value for Test 3 is greater than .1. The modeled variance appears
to be appropriate here



The p-value for Test 4 is greater than .1. The model chosen seems
to adequately describe the data

Benchmark Dose Computation

APPENDIX 11. GENERALIZED LEAST SQUARES FOR TREND IN STATA

Stata output of ORs for high ALT from Gallo et al. (2012).

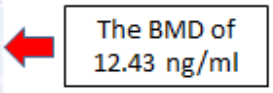
"No intercept model" used: lowest dose subtracted out
Poor model fit when all ten dose levels are used. Fit improved substantially when only the lowest five doses were used.

Figure A11.1. Dose-response graphs plotting all ten dose levels in comparison with plotting only the lowest nine, eight, seven, six or five doses.

Results:
The regression model between PFOA and lnOR using GLST in Stata

Generalized least- squares regression Number of obs = 4
Goodness-of-fit chi2(3) = 0.29 Model ch2(1) = 25.71
Prob > chi2 = 0.9621 Prob >chi2 = 0.0000

logrr	Coef.	Std. Err.	z	P>|z|	[95% Conf.	Interval]
dose0	.017	0.00354	5.07	0.000	.0110127	0.248891



This regression coefficient was then used to calculate the BMD01 and BMDL01 using the following equations:

$OR = \exp^{(dose \times slope)}$ (eq 1)
lnOR = dose x slope (eq 2)
dose = lnOR / slope (eq 3)
BMD01* = 0.1181 / 0.01795 = 6.58 ng/ml
BMDL01* = 0.1181 / 0.024889 = 4.74 ng/ml

*Since the lowest dose (5.85 ng/ml) was subtracted out (i.e. no intercept model), this dose was added back in:

BMD = 5.85 + 6.58 = 12.43 ng/ml
BMDL = 5.85 + 4.74 = 10.59 ng/ml

Decile	Dose (ng/ml)	Log10 dose	N	OR	CIL	CIU	Logrr	Percent with high ALT	Percent over baseline

APPENDIX 12. ALTERNATIVE METHODS FOR CALCULATING THE CANCER SLOPE FACTOR AND CANCER HEALTH-PROTECTIVE CONCENTRATION

Generalized least-squares for trend (glst): A potential disadvantage of the method described in the main PHG document to calculate the CSFs is that it assumes that the relative risk (RR) estimates for the different exposure categories are independent. However, they are not independent because for each study they rely on a common reference group. This lack of independence can lead to an underestimate of the variance of the dose-response slope derived from these data (Greenland and Longnecker, 1992). That is, it can lead to an artificially narrow CI around b. It could also lead to a less efficient estimator of b. The glst method is a way of correcting for this lack of independence. However, a potential weakness of the glst model is that it assumes a linear relationship between the exposure and the logarithm of the RR, a relationship that may or may not fit the data.

The effect of this lack of independence was evaluated by running dose-response analyses of the Shearer et al. (2021) and Vieira et al. (2013) data with and without the glst correction. The glst command in Stata/IC (version 15.1) was used to provide dose-response and variance estimates corrected for the lack of independence, and the variance-weighted least squares (vwls) command (also in Stata/IC) was used to provide uncorrected estimates of these variables. The vwls method is similar to the glst method in that it also assumes a linear-log relationship between exposure and RR, however it does not correct for lack of independence in the data. Printouts from these analyses are shown in Figure A12.1. As seen, the correction for lack of independence had only a small effect on the dose-response slopes (labeled "Coef." in the printouts) or their upper 95% CI. As such, these findings suggest that the lack of independence in the Shearer et al. (2021) and Vieira et al. (2013) results likely had only small effects on the CSF calculations.

Figure A12.1. Regression coefficients and their 95% CIs between the log of the RCC or kidney cancer ORs and serum PFOA concentrations using data from Shearer et al. (2021) and Vieira et al. (2013): adjusted (glst) and unadjusted (vwls) for OR dependence

As noted above, another difference between the glst model and the linear model used for the final CSF calculations is that the former assumes a linear relationship between dose and the log of the RR estimates. Plotting both the linear-linear model (used in Equation 1) and the linear-log model (used in the glst method) shows that both provide a reasonably good fit (both visually and based on R^2 values), but with the linear model being slightly better for both studies (Figure A12.2). This suggests that the linear-linear model was a good choice for the CSF calculations.

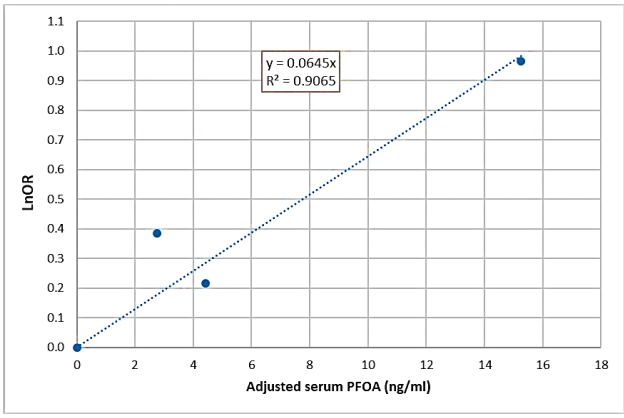

Figure A12.2. Plots, unweighted regression coefficients, and coefficients of determination (R^2) of RCC or kidney cancer ORs or natural log ORs (lnOR) and serum PFOA concentrations using data from Shearer et al. (2021) and Vieira et al. (2013)

Vieira et al. (2013):

OR (linear model, Equation 1)

LnOR (glst model)

Lifetime, cumulative, or peak exposure: Exposure assessment in the Shearer et al. (2021) study was based on a single serum measurement collected in adulthood, while exposure assessment in the Vieira et al. (2013) study was based on modeled estimates of a single year of exposure, also in adulthood. Because of the long half-life of PFOA in serum, these measurements are likely a good indication of several years of exposure. Regardless, the use of a single measurement at a single point in time or for a relatively short period of time raises concerns about the importance of even longer-term cumulative exposure, and concerns about whether important time windows of exposure (e.g., childhood exposures) might have been missed.

Currently, little information is available on the relative cancer risks from longer-term lower PFOA exposures (e.g., cumulative exposure) versus shorter-term higher PFOA exposures (e.g., peak exposure). In addition, information from human studies on the most important time window (e.g., latency period) or life stage of exposure are not currently available. Despite this, several factors suggest that the exposure measurements in the Shearer et al. (2021) and Vieira et al. (2013) studies are good metrics for assessing the true cancer risks of PFOA. The first factor is that in animal studies, cancer risks from PFOA were not increased when exposure occurred perinatally compared to when it occurred later in life (NTP, 2020). This suggests that the Shearer et al. (2021) and Vieira et al. (2013) studies did not underestimate cancer risks by not including earlier life exposures. The second factor is that the Barry et al. (2013) study of PFOA and kidney cancer examined various exposure lag periods and found that the model using unlagged exposures provided a better fit than the models using lag periods of 10 to 20 years. This finding suggests that the cancer latency of PFOA is not several decades long, and that important latency effects were not missed in either study.

The third factor is that RR estimates for PFOA and kidney cancer in the two population-based studies in the C8 area, Barry et al. (2013) and Vieira et al. (2013), were similar regardless of whether the exposure metric was cumulative exposure or an indicator of lifetime peak exposure. Table A.X.1 shows the RR estimates for kidney cancer in these two studies. As shown, the RR estimates in the higher exposure categories of the C8 studies were all near 2.0, regardless of whether the exposure metric was cumulative exposure over a number of years or an estimate of the lifetime peak. The fact that the RRs for cumulative exposure are not markedly higher suggests that the peak exposure metrics OEHHA used in its CSF calculations are a good way to assess the true cancer risks of PFOA.

Table A12.1. Relative risk estimates for modeled serum PFOA and kidney cancer in the C8 population-based studies

Barry et al. (2013)			**Vieira et al. (2013)**

* Tertile 3 excluding the upper 10th percentile

US EPA Benchmark Dose Software (BMDS): Categorical data from case-control studies cannot be used in the US EPA BMDS since these models are based on cancer risk, and the information needed to calculate risks is not available from the Shearer et al. (2021) or Vieira et al. (2013) publications. More specifically, although the number of RCC or kidney cancer cases in each exposure category is known, the exact number of people that generated these cases in each exposure category is not. These denominators could be estimated using the total number of participants in the underlying cohorts (e.g., the total number of people in the screening arm of the PLCO trial) and percentages of controls in each exposure category. However, entering

these estimates into the BMDS would lead to an artificially narrow 95% CI around the regression slope, and thus an artificially elevated BMDL.

One advantage of the BMDS is that the fit of a number of different dose-response models can be assessed (e.g., logistic, multi-stage, Weibull), allowing selection of the best fitting model. However, as discussed above, the linear model used in the above calculations provides a very good fit to the Shearer et al. (2021) and Vieira et al. (2013) data and it is unlikely that a different model will provide a fit that is substantially better.

APPENDIX 13. CANCER HEALTH-PROTECTIVE CONCENTRATIONS USING DIFFERENT VALUES FOR BASELINE RISK

PFAS reduction during biosolids drying correlates to initial moisture content and is accompanied by detection of PFAS in dryer condensate

Jessica Calteux, [a] Lynne Moss,[b] Rosely Ayala,[c] Aileen Baza,[c] Zhongzhe Liu,[c] Eric Redman,[d] Taryn McKnight,[d] Fabrizio Sabba, [be] Leon Downing[b] and Patrick McNamara *[ab]

Land application of biosolids has come under scrutiny for its potential to convey PFAS. Some water resource recovery facilities (WRRFs) have been forced to choose between implementing more extensive biosolids treatment technologies to achieve regulatory limits or altering their biosolids handling approach. Many novel biosolids treatments for PFAS removal include advanced thermal processes such as pyrolysis or gasification. Such processes require drying of biosolids as a preparatory step for treatment. However, little is known about the isolated impact of biosolids drying on the removal of PFAS from biosolids, or what fate PFAS may undergo during the drying process. The objective of this research was to elucidate how biosolids' PFAS profiles change due to drying, and to understand if PFAS can be transported with the gaseous vapor phase into liquid condensate. Biosolids were collected from five WRRFs and dried in a lab-scale oven. Additionally, biosolids from one of the WRRFs were dried in a system that captured and condensed vapor in a methanol impinger. Analysis of the PFAS profiles of the biosolids before and after drying indicated an average of 58% reduction in detectable PFAS across all sites, with the range being 43–74%. A positive correlation was established between the initial moisture content of the biosolids and reduction in detectable PFAS (R^2 = 0.61). The condensate contained 12–22% of the initial PFAS from the wet biosolids, indicating that PFAS can leave with the gas-phase vapor generated during drying. This research supports the conclusion that biosolids drying can reduce detectable concentrations of PFAS, and operational parameters could be adjusted to optimize dryers for this purpose. Treatment technologies could then be applied to the condensate to destroy the PFAS contained therein.

Water impact

Reduction of PFAS concentrations in biosolids may be necessary in some regions to meet land application regulations. While the implementation of novel treatment technologies may be prohibitive in terms of scale and energy costs, biosolids drying is a conventional technology that can reduce the concentration of PFAS in biosolids. After drying, some PFAS were detected in dryer condensate, indicating that treatment of condensate could disrupt PFAS cycles within WRRFs.

1.0 Introduction

Per- and polyfluoroalkyl substances (PFAS) are a recalcitrant group of chemicals that are ubiquitous throughout society and have been associated with several human health concerns, including decreased antibody response, decreased fetal growth, increased risk of kidney cancer, and neurotoxicity.[1–4] Due to their presence in consumer goods and industrial discharges, many PFAS end up in wastewater and biosolids.[5–7] Land application of biosolids has been scrutinized recently for its capacity to convey PFAS into the environment.[7,8] As a result, some states have restricted land application based on the PFAS concentration in biosolids, and other states have banned it entirely.[8,9] Now, water resource recovery facilities (WRRFs) must account for PFAS when designing their biosolids management plans.

Land application has long been regarded as one of the most cost effective biosolids handling methods, as well as a sustainable method for recovering nutrients.[10–12] Employing

land application to manage biosolids is also beneficial for reducing the amount of material sent to landfills.[10] Landfills emit volatile PFAS to the atmosphere and have potential to leach PFAS into nearby groundwater.[13,14] Moreover, sending biosolids to landfills may become costly or impracticable as space becomes limited and moisture content becomes a concern. Alternatively, incinerators, though potentially capable of defluorinating PFAS, may generate toxic gases like dioxin, furan, and fluorocarbons, including short-chain PFAS.[6,15,16] Furthermore, new incinerators are difficult to install if not part of an existing incinerator upgrade or expansion. Thermal processes have garnered recent interest as possible solids handling processes that could help mitigate PFAS in biosolids. Pyrolysis has been shown to reduce the detectable concentrations of PFAS in biochar, and gasification also likely reduces PFAS in the solid-phase.[17–20] Drawbacks to these emerging thermal processes include that they alter the inherent value of biosolids because biochar does not contain the same available carbon and nutrient content, and the long-term operational feasibility of these processes is still unknown.[21–23] Implementation of these thermal processes would require drying of the feed biosolids.[20,24,25]

Interestingly, drying may provide an avenue to help manage PFAS in biosolids. Previous research found that detectable PFAS concentrations were lower in biosolids after drying, in both a lab-scale oven and a full-scale dryer, and that reduction of detectable PFAS concentration was positively correlated to the initial moisture content of the biosolids sample.[26] Other research investigating the phenomenon of PFAS reduction during biosolids drying is limited, and comparison of data is complicated by varying analytical techniques. For example, other studies found PFAS concentrations increased during biosolids drying but analyzed fewer species.[27–29] The study which analyzed the most distinct PFAS species saw both increases and decreases to the PFAS profile of biosolids during drying across multiple sites.[30]

While multiple studies have reported decreases in detectable PFAS concentration, little information is available that elaborates on the mechanism by which this occurs. Only one study has captured and analyzed the vapor from the drying process, and in this full-scale study the mass of PFAS entering the regenerative thermal oxidizer (RTO) from a rotary biosolids dryer was orders of magnitude lower than the mass of PFAS removed from biosolids during drying.[31] More research is needed to determine the removal mechanism and phase distribution of PFAS during and after biosolids drying. Reductions in PFAS concentration have been observed at temperatures of 105 °C, which excludes mineralization as a removal mechanism; therefore, it is plausible that PFAS are being transferred to the vapor generated during drying.[63] Understanding the transport and fate of PFAS during biosolids drying will reveal avenues for appropriate management, including possible treatment, of PFAS after drying.

The objective of this research was to determine the reduction of detectable PFAS during biosolids drying across a range of moisture contents in biosolids and to establish if biosolids drying yielded PFAS in the gas-phase that could be detected in downstream condensate. It was hypothesized that higher moisture content would yield greater reductions in detectable PFAS concentration and that PFAS would be removed from biosolids during drying *via* aerosolization and appear in the captured condensate.[26,32,33] To test these hypotheses, triplicate samples of biosolids from five full-scale WRRFs were collected and dried in a lab-scale oven. The vapor from one set of drying experiments was captured with a methanol impinger to measure PFAS in condensate. This work sought to elucidate the feasibility of PFAS removal *via* transport with water during biosolids drying and determine the fraction of detectable PFAS reduction that could be explained by transfer to condensate.

2.0 Methods

2.1 Experimental setup

Biosolids samples were collected from five full-scale WRRFs with average flowrates ranging from 30 to 200 million gallons per day (MGD). Four of the five WRRFs employ secondary treatment systems with biological nutrient removal (BNR), while one facility (WRRF no. 1) utilizes secondary treatment for biochemical oxygen demand (BOD) removal only. All WRRFs use gravity thickening followed by anaerobic digestion and dewatering with centrifuges. The biosolids from these five WRRFs were dried in triplicate in a lab-scale oven overnight (24 hours) at 105 °C to determine the reduction of detectable PFAS achieved during biosolids drying. Biosolids from five different WRRFs were used for experiments to better understand how varied initial moisture contents impact PFAS removal. For these drying experiments, the wet and dry biosolids samples (before and after drying, respectively) were analyzed for PFAS as described below.

In addition to the oven-drying experiments, one set of biosoilds was dried in triplicate in a lab-scale heating system that allowed for vapor collection. The vapor collection system was customized by modifying a high-temperature conversion system (SI Fig. S1).[34] The customized system included a stainless-steel reactor vessel, a ceramic radiative heater, an inert gas purge system, and a gas collection system consisting of one impinger (20 mL of methanol, HPLC grade, >99.8%, Alfa Aesar™) in an ice bath. A pressure gauge and a thermocouple were used to monitor pressure and temperature inside of the reactor, respectively. The temperature of the system was raised at a rate of 8–15 °C min^{-1} to 105 °C, and the residence time of drying the biosolids in the reactor was 12 hours. To capture the system's off-gas, vapor from one drying experiment passed through PFAS-free tubing to the methanol impinger, where it was condensed (and henceforth referred to as condensate). The mass of the dried biosolids was determined gravimetrically, and the mass of the PFAS in the condensate was determined

KD1694

as a function of their concentration in the methanol impinger and the methanol + water volume; the volume of liquid in the impinger increased during the experiments from the water that transferred from the wet biosolids to the impinger during drying. The initial wet biosolids and the liquid from the impinger were stored in a freezer until shipment to Eurofins. The dry biosolids were stored at room temperature until shipment to Eurofins.

Negative controls were run to check for background PFAS contamination in this gas-phase collection system. Baked Ottawa sand (20–30 mesh, Spectrum™ Chemical) was loaded into the reactor, and 20 mL of methanol were loaded into the impinger. No detects were reported in the sand. The only species that was detected in the methanol negative controls was perfluoropropionic acid (PFPrA), at 1.4 μg L^{-1} in the methanol impinger. PFPrA was excluded from analysis for all gas-phase methanol samples because no samples had PFPrA concentrations greater than 10× the blank concentration. Pure methanol did not contain any reportable PFAS. The biosolids and liquid samples were put into containers provided by Eurofins for PFAS analysis. Samples were shipped in a cooler with ice packs to Eurofins for PFAS analysis.

2.2 PFAS analysis

The PFAS analysis employed in this experiment has been outlined previously.[26] A list of the sixty targeted PFAS analytes is included in the SI, section S1. Isotopically labeled analogs, referred to as extracted internal standards (EIS), were used for quantition where available. The list of EISs and their corresponding target analytes are listed in the SI Table S1. PFAS were analyzed with a SCIEX 5500+ triple quad LC/MS/MS system operated in multiple reaction monitoring (MRM) mode. Biosolids samples were manually homogenized in their collection containers before being subsampled (nominally 1 g for pre-drying and post-drying samples). The EISs of the native analytes were spiked into each subsample, then were sonicated with basic methanol for an hour. Water was added to the extracts to re-constitute them, and then they were cleaned up *via* solid-phase extraction (SPE) using a WAX SPE cartridge (Strata X-AW or equivalent) to retain the desired PFAS. Then, basic methanol was used to elute the IDAs and target analytes from the SPE cartridge and $^{13}C_2$-PFOA was added as the internal standard (ISTD) to fortify the extracts. A solution of 80 : 20 methanol/water was added to obtain a final extract volume of 10 mL. The same extraction procedure was used for pre-drying and post-drying biosolids samples.

To ensure the accuracy of the measurements of the 60 target analytes, initial and continual verification of accuracy and precision are achieved *via* laboratory control sample aliquots, laboratory control sample duplicates, laboratory method blanks, method detection limit (MDL) studies, MDL verification aliquots, and performance testing studies. The descriptions of these processes can be found in the corresponding laboratory standard operating procedures (SOPs). These procedures and performance test results are audited *via* 3rd party laboratory accreditation bodies for the relevant regulatory programs, including the National Environmental Laboratory Accreditation Program and the United States Department of Defense Environmental Laboratory Accreditation Program.

Additional measures of method performance monitored within each sample include EIS recovery, ISTD response, analyte retention times, analyte ion ratios, and analyte signal-to-noise ratios. The criteria for these sample-specific quality controls and identification elements are specified in the corresponding laboratory SOP. PFAS concentrations are reported on the basis of a sample's dry weight, which is determined after moisture has been removed at 105 °C and the sample has cooled to room temperature in a desiccator.

2.3 Statistical analysis

Concentrations of PFAS were normalized to μmol of F per kg of dry solids, where F represents the fluorine content of a given species of PFAS. Reported data were in units of μg PFAS per kg dried biosolids, so each measurement was divided by the molecular weight of the species and then multiplied by its F content per molecule. All data are available in the SI in units of μmol of F per kg of dry solids and also as the more commonly reported values of μg PFAS per kg of dry solids. For the condensate capture and mass balance experiment, the concentrations of PFAS in the biosolids and methanol were multiplied by the sample mass or volume, respectively. As such, the amount of total PFAS was normalized to moles of F in each targeted PFAS. Biosolids from source 5 were chosen by the anonymous utility partner for this phase of the experiment.

Effective statistical analysis required complete triplicate data, therefore, non-detects in the data were filled in with the reporting limits of the analytical method where triplicate data were incomplete. By contrast, if a species was not detected across any triplicates for either wet or dry biosolids, reporting limits were not used to fill in the data. Though this approach compensates for the potential trace presence of PFAS that evades detection, it slightly reduced the calculated percent removals of total PFAS compared to not using reporting limits (values of zero). Figure captions indicate when reporting limits are included in a given figure.

Additionally, significance was set to an alpha value of 0.05 or less for paired Student's *t*-tests. All statistical analyses were conducted in GraphPad Prism v10.4.2 (GraphPad Software, La Jolla, CA).

3.0 Results & discussion

3.1 Detectable PFAS removal during drying

Drying substantially reduced the presence of detectable PFAS in biosolids. In all five biosolids sample sets the total sum of detectable PFAS concentrations was significantly lower after drying (*p*-values of 0.0021, 0.0091, 0.0012, 0.0034, 0.0023, respectively) (Fig. 1). When categorized by speciation, nearly

KD1695

all classes of PFAS exhibited a measured concentration reduction during biosolids drying across all sites, including terminal species such as perfluorocarboxylic acids (PFCAs) and perfluorosulfonic acids (PFSAs). The average reduction in total detectable PFAS concentration across all samples was approximately 60% (57.6%), though reported reductions in concentration ranged from 42.3% to nearly 74.2% (Fig. 1). This range of percentages suggests that characteristic differences in biosolids samples impact PFAS concentration reduction during biosolids drying.

The presence of water affects the reduction in detectable PFAS during biosolids drying. The percent reduction was positively correlated to initial moisture content (Fig. 2). The R^2 value was 0.61 for a sample size of 18, which implies that 61% of variation in PFAS concentration reduction was explained by moisture content. The initial moisture contents of all samples were within a narrow range, from 72.4% (27.6% total solids) to 78.5% (21.5% total solids). This strong trendline justifies future research into a wider range of initial moisture (and total solids) contents. Also, while these data imply a mechanism of PFAS loss *via* transport with water, the exact removal mechanism cannot be determined from these data alone. The temperature of the lab-scale oven was slightly above the boiling point of water (105 °C). Previous research on the volatilization of pure chemical PFAS revealed that, at temperatures around 100 °C, thermogravimetrically analyzed weight loss of long-chain PFCAs such as PFOA, PFNA, and PFDA was less than 10%, and for PFSAs such as PFBS, PFHxS, and PFOS, weight loss was negligible.[36] The lack of removal

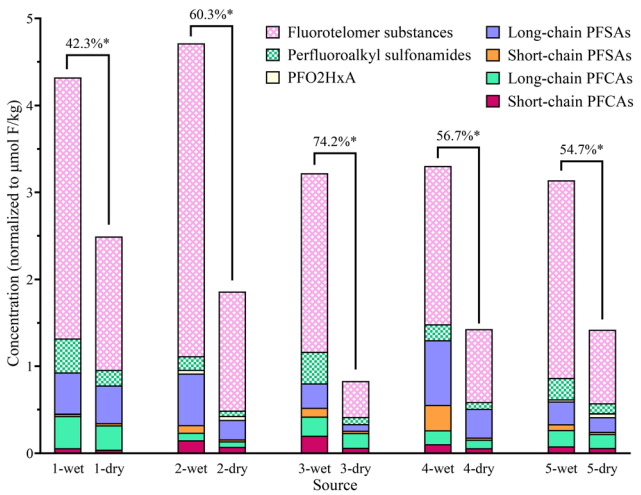

Fig. 1 Average concentration of categorized PFAS (normalized to µmol F kg^{-1}) in pre-drying ("wet") and post-drying ("dry") solids at five sites, labeled 1–5 (n = 3). Fluorotelomer substances include FTSes and FTCAs. Perfluoroalkyl sulfonamides include NMeFOSAA, NEtFOSAA, NMeFOSE, and NEtFOSE. According to the EPA, long-chain PFSAs have 6+ carbons, short-chain PFSAs have <6 carbons, long-chain PFCAs have 8+ carbons, and short-chain PFCAs have <8 carbons.[35] Reporting limits were substituted in for non-detects. Total PFAS percent removals were calculated for each triplicate and averaged (shown above each sample). Asterisk denotes statistical significance. Fig. 2 Initial moisture content of biosolids is positively correlated to concentration reduction of total detectable PFAS (n = 18). Reporting limits were substituted in for non-detects. Reprinted with permission. © The Water Research Foundation.

of pure chemical PFAS at 100 °C indicates that volatilization alone is not a substantial removal mechanism for PFAS at this temperature. The percent reductions of PFAS in these biosolids drying experiments indicate that a removal mechanism other than (or in addition to) volatilization occurred.[36]

The removal of both volatile and nonvolatile PFAS *via* attachment to aerosols has been demonstrated for aeration tanks.[32,33] By extension, the formation of aerosols during boiling may occur *via* the bubble microtome effect.[37] Due to the tendency of PFAS to partition to the air–water interface (AWI), both small air bubbles underwater (*e.g.*, boiling bubbles) and small water droplets in the air (*e.g.*, aerosols) may contain significant amounts of PFAS, as both have high surface area to volume ratios; the surface area of an aerosol is effectively composed of the AWI.[37,38] Therefore, drying biosolids may incite the boiling of the water within and around the biosolids, thus leading to the generation of PFAS-laden aerosols.[26] An increase in the moisture content of biosolids may result in greater formation of aerosols, thereby giving rise to the observed positive correlation between moisture content and percent reduction of total detectable PFAS shown in Fig. 2. This trend supports data from previous research, which found a similar positive correlation between these variables.[26]

3.2 Incomplete mass balance on PFAS removal to the lab-scale dryer condensate

A fraction of the PFAS entered the lab-scale dryer condensate, yet the PFAS mass balance was not complete. On average, 16% of total PFAS from the wet biosolids were detected in the condensate. Additionally, the biosolids' detectable PFAS mass was reduced by an average of 46%. The "unaccounted" fraction of PFAS (represented by the white bars in Fig. 3 and 4a–c) corresponds to the difference between the initial PFAS

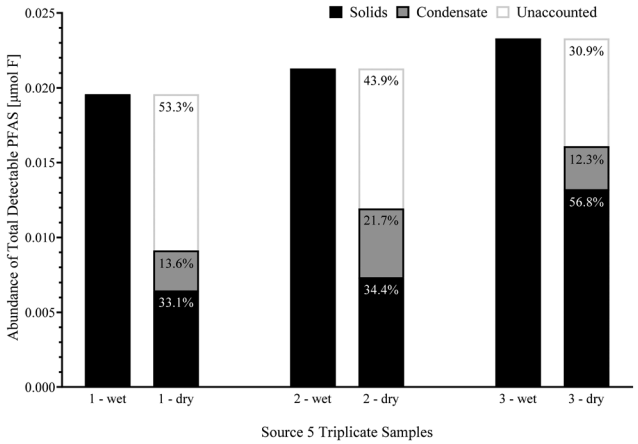

Fig. 3 Phase distribution of total detectable PFAS after drying (from source 5 triplicate samples). Abundance of PFAS was determined by normalizing reported concentrations to µmol F kg^{-1} solids or nmol F L^{-1} liquid, then multiplying that value by either the mass of solids or the volume of liquid in the impinger (Table S2). Only detected species were used for this figure (*i.e.*, reporting limits were not substituted in for non-detects). Reprinted with permission. © The Water Research Foundation.

mass in the wet biosolids and the combined mass detected in the dry solids and impinger methanol; the fate of this mass of unaccounted PFAS is unknown. On average, 43% of total PFAS as F remained unaccounted for across all triplicates, with a range from 31% to 53%.

Several reasons could contribute to explaining the unaccounted fraction. It is possible that PFAS were lost *via* sorption to part of the experimental apparatus since the entire surface area was not extracted for PFAS, *e.g.*, the tubing of the impinger system was not rinsed with methanol. If PFAS sorbed to the tubing, they did so by way of entering the gas-phase, which suggests that they should have been detected in the captured condensate but did not make it to the impinger. Additionally, a portion of unaccounted PFAS may stem from detectable PFAS transforming to undetectable PFAS, such as trifluoroacetic acid.[39] Approximately 10% weight loss of PFOA has been reported at temperatures of 100 °C, accompanied by the generation of volatile, fluorinated compounds.[36] OTM-50 was not employed in this research, and it is possible that non-polar volatile PFAS were generated as products of incomplete destruction but were not detected in the condensate.[40] Experimental data would be needed to validate this removal pathway. It is also possible there is an artifact arising from the heterogenous distribution of PFAS in biosolids samples, or that chemical extraction of PFAS from the dried solids samples was less efficient than extraction from wet solids samples.[41] Within the third triplicate specifically, the volume of methanol in the impinger was approximately eight mL less than the other triplicates by the end of the experiment. Although the reason for this difference in methanol volumes was not identified, it is possibly due to sample loss, thus reducing the mass of PFAS recovered in the condensate of the third triplicate in

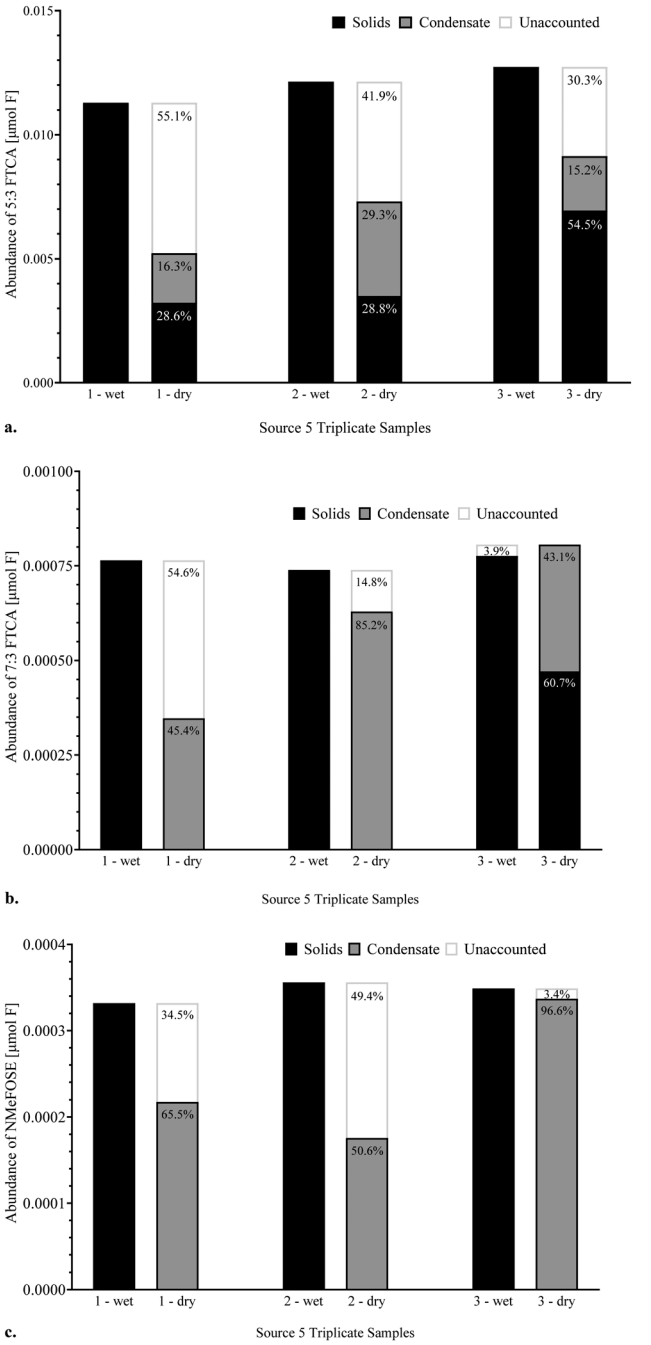

Fig. 4 a. Phase distribution of 5 : 3 FTCA after drying (from source 5 triplicate samples). b. Phase distribution of 7 : 3 FTCA after drying (from source 5 triplicate samples). c. Phase distribution of NMeFOSE after drying (from source 5 triplicate samples). Only detected species were used for this figure (*i.e.*, reporting limits were not substituted in for non-detects). Fig. 3 and 4a–c. Despite the unclosed F mass balance, these results demonstrate a proof-of-concept that PFAS can be captured in dryer condensate.

Precursor species, including fluorotelomer carboxylic acids (FTCAs), were removed from biosolids during drying and captured in the condensate. Three species were

KD1697

detected across all three triplicates of the captured condensate: 5:3 FTCA (Fig. 4a), 7:3 FTCA (Fig. 4b), and NMeFOSE (Fig. 4c); one species was detected only in one triplicate: NEtFOSE. More than three-quarters of the total PFAS in the condensate was attributable to 5:3 FTCA, across all triplicates. Though NMeFOSE and 7:3 FTCA comprised a smaller fraction of total PFAS across all phases than 5:3 FTCA, they exhibited substantial removal to the condensate.

Not only are PFAS leaving with the gas-phase and appearing in the condensate, but in the case of 7:3 FTCA and NMeFOSE, some PFAS may not be detected at all in the dried solids. None of the dried biosolids triplicates had detectable levels of NMeFOSE, and only one had 7:3 FTCA, despite all three condensate triplicates revealing detectable amounts of both, as shown in Fig. 4b and c. In the sample with the lowest condensate fraction of 7:3 FTCA and NMeFOSE, nearly half of the amount present in the pre-dried biosolids was captured in the condensate. Since the temperature of the oven was approximately 105 °C, it is possible that this removal mechanism was physical (*i.e.*, removal *via* attachment to aerosols) rather than a direct phase transition (*i.e.*, volatilization); the relatively low volatility and high water solubility of FTCAs is consistent with the tendency to partition to aerosols.[33]

3.3 Species specific concentration reduction rates

On average, the concentration of total detectable PFAS in the pre-drying biosolids decreased by 57.6% after drying. The reduction in concentration of precursor species, on average, accounted for over 80% of this observed concentration reduction of detectable PFAS. Specifically, 5:3 FTCA contributed 60% to the reduction in concentration of total PFAS, and the top three precursors (5:3 FTCA, 6:2 FTCA, and 7:3 FTCA) contributed more than 71% (Fig. 5). Of the terminal species, the average reduction in concentration of PFOS was the greatest, at more than 10% of the total PFAS-as-F (Fig. 5). All of the ten species that contributed to more than 1% of the concentration reduction of total detectable PFAS are shown in Fig. 5 below. These data demonstrate that the majority of detectable PFAS concentration reduction observed during drying is attributable to a limited number of species. It should be noted that the capacity for a species to contribute to the reduction in concentration of total detectable PFAS is heavily dependent on the initial concentration of the species. For example, 5:3 FTCA constituted the largest proportion of the PFAS profile for all biosolids samples across all sites. Therefore, reducing its concentration will contribute significantly to the reduction in concentration of total detectable PFAS.

3.4 Role of FTCAs and quantification methods

The analytical technique used for this experiment detected 60 distinct species of PFAS, including all 40 species

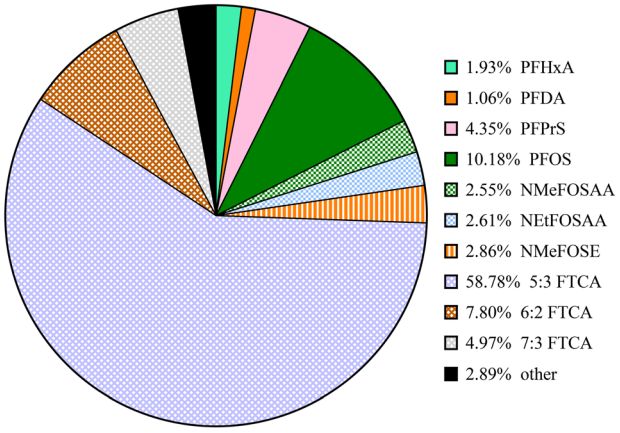

Fig. 5 Species that contributed at least 1% to the reduction in concentration of total detectable PFAS from biosolids. Reporting limits were substituted in for non-detects. Each species' contribution to the percent concentration reduction of total detectable PFAS from the biosolids was averaged for each site (n = 3), then the averages of each species across all sites were averaged (n = 5). Reprinted with permission. © The Water Research Foundation.

detected by EPA method 1633.[42] Five species that would have been excluded by method 1633 were detected in the experimental samples, making up, on average, 10.5% of the pre-dried biosolids' PFAS profiles and 1.6% of the post-dried biosolids' PFAS profiles. However, this experiment did not include detection of polyfluoroalkyl phosphoric acid diesters (diPAPs), which have been substantial PFAS species in other biosolids studies (54% and 56% of the total PFAS mass in biosolids, on average).[30,43]

Differing analytical techniques will detect different species of PFAS, which may influence concentration reduction calculations.[43] Some techniques exclude FTCAs in their analysis.[29] 5:3 FTCA was the most prevalent species of PFAS across all triplicates for all samples, including pre-dried solids, dried solids, and condensate. Had FTCAs not been detected in this set of experiments, the calculated average percent removal of total PFAS would have been 48% across all sites (instead of 58%). Furthermore, the exclusion of FTCAs from analysis dramatically reduces the detectable concentration of total PFAS to approximately 33% of the original values, as shown in comparing Fig. 6a and b. The detection (or lack of detection) of specific PFAS has a large influence on the results and conclusions drawn from an experiment.

Despite being the most prevalent PFAS species detected in biosolids from all sources, 5:3 FTCA is not a contaminant of direct industrial output; it is a metabolite from the transformation of other precursors, including 6:2 diPAP, 6:2 FTOH, and 6:2 FTSA, which may have extensive industrial applications.[44–50] 5:3 FTCA has been identified as the most highly concentrated PFAS present in landfill leachate.[46] Leachate being sent to the head of a WRRF may, therefore,

be a substantial source of 5 : 3 FTCA in wastewater treatment streams.

The FTCAs in land-applied biosolids may undergo transformation in food crops (*e.g.*, pumpkin and wheat) to terminal PFAS such as PFHxA, PFPrA, and PFOA.[51,52] Though FTCAs may not be regulated stringently, their presence is indicative of potential future contamination as they degrade and transform into perfluoroalkyl acid (PFAA) species.[51–55] This insight is especially crucial when paired with the condensate PFAS profile data that indicates 5 : 3 FTCA and 7 : 3 FTCA both left with the gas-phase during drying (Fig. 4a and b). The escape of these compounds, and their transformation potential, indicate that drying requires effective air pollution controls to reduce potential emission of not only these precursors, but their transformation products as well. Further research on the efficacy of current air pollution control technologies and possibly condensate treatment on PFAS-containing dryer emissions would be useful.[31]

3.5 PFAS treatment in condensate with PFAS from dryers

While drying could be a viable technology to reduce detectable PFAS levels in biosolids, treatment requirements for the resulting condensate from the drying process need to be further investigated. Condensate volumes from sludge dryers can vary significantly based on factors such as sludge type, dryer type, and operating conditions. Nonetheless, sludge dryers can produce substantial condensate volumes that may require further treatment and can be recycled to biological treatment portions of the plant.[56] In addition to conventional nutrients (*e.g.*, phosphorus and nitrogen), the condensate can also contain PFAS.[29] The mobilization of PFAS from the biosolids into the liquid phase (*i.e.*, condensate) represents an opportunity to disrupt the PFAS contamination cycle at WRRFs.[26]

To break this cycle, a separation step followed by destruction could be an efficient method to drastically reduce PFAS concentrations.[13] One possible separation technique is foam fractionation, where air bubbles are utilized to separate surface-active molecules (*i.e.*, PFAS). Through this process, PFAS are concentrated in a foamate solution that can be directed for subsequent destruction. This step offers a dual advantage as the PFAS concentrations in the foam can be enriched by a factor ranging from 100 to 100 000, and the volume requiring treatment is significantly smaller compared to not using foam fractionation.[57]

To date, various destruction techniques have been utilized to eliminate PFAS, each with its own distinct advantages and disadvantages, indicating a need for a customized approach for each WRRF.[58] Among other technologies, field installations of supercritical water oxidation (SCWO) and electrochemical oxidation (EO) have recently garnered significant attention. In SCWO, water is heated above its critical point to create a supercritical state where it exhibits properties of both a liquid and a gas. This high-temperature and high-pressure environment allows for the complete oxidation of organic contaminants, like PFAS, breaking them down into byproducts such as carbon dioxide, water, and mineral acids.[59] During EO, an electrical current is applied to the contaminated water or solution, causing oxidation reactions to occur at the electrode surfaces. These oxidation reactions break down the PFAS compounds into less harmful byproducts through electrochemical processes.[60] Combining foam fractionation with either SCWO or EO could offer a promising solution to prevent the re-mobilization of PFAS back into the biological treatment section of a WRRF after removal of the PFAS from the biosolids stream. The net life cycle cost of this flow diagram (drying with PFAS treatment of the condensate) may be advantageous when compared to PFAS destruction in the full biosolids stream.

3.6 Future perspectives

The current study has revealed that PFAS transport to dryer condensate during biosolids drying is feasible. Due to the heterogeneity of biosolids samples, it is necessary to analyze

KD1699

the PFAS profiles of dryer condensate from different biosolids samples to establish the reproducibility of these experiments. Additionally, a more robust experimental design is required to further elucidate PFAS fate, including their potential for transformation and removal during biosolids drying. Effective detection of precursor compounds, especially diPAPs, is key to developing a more comprehensive understanding of PFAS fate.[61] Future work should include the quantification of diPAPs in sample analysis and the extraction of PFAS from laboratory equipment with a methanol rinse. Augmenting targeted detection methods with analytical tools such as the total oxidizable precursor (TOP) Assay may also improve the understanding of PFAS fate.

4.0 Conclusions

This research confirms that concentrations of detectable PFAS in biosolids are reduced during drying. Furthermore, the majority of concentration reduction is attributable to a reduction in precursor species, particularly 5:3 FTCA. Therefore, reduction in concentration of PFAS in biosolids during drying may provide an avenue by which PFAS can be captured and destroyed, thus mitigating contamination cycles. However, should biosolids drying not be paired with some form of air pollution control and/or condensate treatment, dryer air emissions or condensate may contain precursors such as 5:3 FTCA, 7:3 FTCA, and NMeFOSE that can then transform into PFAAs.[62] While the vapor capture technique utilized herein revealed removal to condensate of some PFAS, more research is needed to more fully close the F mass balance from drying of biosolids, by either confirming transformation products or detecting previously undetectable PFAS. Measurements of PFAS concentration reduction are constrained by the chosen detection method.

This research aimed to help fill the gap in the literature on the effect of drying on biosolids' PFAS profiles, including concentration reduction percentages and phase distribution, and to correlate PFAS concentration reduction with initial biosolids moisture content. Moisture content of the initial biosolids sample correlated to greater reduction of total detectable PFAS concentration, indicating that aerosolization during biosolids drying is a potential avenue by which PFAS are being removed.[26,37] This process circumvents the requirement for high temperatures associated with volatilization and mineralization, and may be a substantial removal mechanism for PFAS in biosolids dryers. By developing a robust understanding of how PFAS concentrations are reduced during biosolids drying and where exactly they end up, full-scale facilities can be optimized to control and increase the removal of PFAS from biosolids during drying and to capture and treat the removed PFAS. Overall, drying could be used to increase the accessibility of biosolids land application.

Acknowledgments

This final report of the Aragonite Incineration System PFAS destruction performance test is made possible by the contributions and support of numerous individuals whose contribution is briefly described and acknowledged below.

Project Officers
Marc Mills, PhD, Office of Research and Development, U.S. Environmental Protection Agency
Erin Shields, PhD, Office of Research and Development, U.S. Environmental Protection Agency
William Roberson, Office of Research and Development, U.S. Environmental Protection Agency
Erica Thieleman, EA Engineering, Science, and Technology, Inc., PBC
Jason McNew, EA Engineering, Science, and Technology, Inc., PBC

Technical Review
Frank Barranco, PhD, EA Engineering, Science, and Technology, Inc., PBC

Project Sponsors
Paul Bratti, Senior Vice President, Project Services, Clean Harbors
Mike Crisenbery, Senior Vice President, Facility Compliance and Government Affairs, Clean Harbors
Stephen Zemba, PhD, Project Director, Sanborn Head with support from Department of Defense's Strategic Environmental Research and Development Program (SERDP)
U.S. Environmental Protection Agency, Office of Research and Development

External Technical Reviewers
Melvin Keener, PhD, Executive Director, Coalition for Responsible Waste Incineration
Jens Blotevogel, PhD, Commonwealth Scientific and Industrial Research Organisation

Abbreviations

°C	degree(s) Celsius
°F	degree(s) Fahrenheit
µg/m^3	microgram(s) per cubic meter
µg/sample	microgram(s) per sample
afterburner	afterburner chamber
AFFF	aqueous film-forming foam
ASTM	ASTM International
ATA	Additional Target Analyte
ATG	Alliance Technical Group
BT	breakthrough
CAS No.	Chemical Abstracts Service registry number
CF_4	tetrafluoromethane
C_2F_6	hexafluoroethane
CFR	Code of Federal Regulations
CHES	Clean Harbors Environmental Services
CO_2	carbon dioxide
DE	destruction efficiency
DI	deionized
DOD	U.S. Department of Defense
DQI	data quality indicator
DRE	destruction and removal efficiency
EA	EA Engineering, Science, and Technology, Inc., PBC
EPA	U.S. Environmental Protection Agency
EPA ORD	U.S. EPA Office of Research and Development
Eurofins	Eurofins Environment Testing
FRC	Fluorinated Replacement Chemical
FSMB	field sample media blank
FTIR	Fourier transform infrared
HDPE	high-density polyethylene
HWI	hazardous waste incinerator
lb/hr	pound(s) per hour
LC/MS/MS	liquid chromatography/tandem mass spectrometry
LCS	laboratory control sample
LCSD	laboratory control sample duplicate
MDC	minimum detectable concentration
MDL	method detection limit
Method 0010	EPA SW-846 Method 0010
MeOH	methanol
mL	milliliter(s)

MS	matrix spike
MSD	matrix spike duplicate
Na_2CO_3	sodium carbonate
ng/dscm	nanogram(s) per dry standard cubic meter
ng/g	nanogram(s) per gram
ng/L	nanogram(s) per liter
ng/m^3	nanogram(s) per cubic meter
ng/sample	nanogram(s) per sample
NH_4OH	ammonium hydroxide
No.	number
O_2	oxygen
OTM-45	EPA Other Test Method 45
OTM-50	EPA Other Test Method 50
PFAS	per- and polyfluoroalkyl substances
PID	product of incomplete destruction
POHC	principal organic hazardous constituent
ppb	part(s) per billion
ppbv	part(s) per billion by volume
QA	quality assurance
QC	quality control
RPD	relative percent difference
SOP	Standard Operating Procedure
Spectrum	Spectrum Environmental Solutions, Inc.
SSI	Superior Spiking Industries
STPB	sampling train proof blank
TMT-15	15 percent aqueous solution of trimercapto-s-triazine trisodium salt
UMO	used motor oil
VFC	volatile fluorinated compound
XAD-2	Tradename for hydrophobic copolymer of styrene-divinylbenzene resin

Given the length and complexity of the definitions for the PFAS abbreviations, this report deviates from generally accepted rules of abbreviation handling for PFAS abbreviations only. To make the descriptions within the text of this report less cumbersome, PFAS target analytes and PFAS classes are not defined at first use in the text and the abbreviations only are used. The table below provides the group, abbreviation, and full name of the PFAS target analytes referenced in this report.

The remainder of the abbreviations used in the report are compiled in the Abbreviations list on page xi and are defined at first use in the body of the report.

PFAS Target Analyte Abbreviations

Class	Abbreviation	Compound
Perfluorinated Carboxylic Acids (PFCAs)	PFBA	perfluorobutanoic acid
PFCAs	PFPeA	perfluoropentanoic acid
PFCAs	PFHxA	perfluorohexanoic acid
PFCAs	PFHpA	perfluoroheptanoic acid
PFCAs	PFOA	perfluorooctanoic acid
PFCAs	PFNA	perfluorononanoic acid
PFCAs	PFDA	perfluorodecanoic acid
PFCAs	PFUnA	perfluoroundecanoic acid
PFCAs	PFDoA	perfluorododecanoic acid
PFCAs	PFTriA	perfluorotridecanoic acid
PFCAs	PFTeA	perfluorotetradecanoic acid
PFCAs	PFHxDA	perfluorohexadecanoic acid
PFCAs	PFODA	perfluorooctadecanoic acid
Perfluorinated Sulfonic Acids (PFSAs)	PFBS	perfluorobutanesulfonic acid
PFSAs	PFPeS	perfluoropentanesulfonic acid
PFSAs	PFHxS	perfluorohexanesulfonic acid
PFSAs	PFHpS	perfluoroheptanesulfonic acid
PFSAs	PFOS	perfluorooctanesulfonic acid
PFSAs	PFNS	perfluorononanesulfonic acid
PFSAs	PFDS	perfluorodecanesulfonic acid
PFSAs	PFDoS	perfluorododecanesulfonic acid
Perfluorinated Sulfonamides (FOSAs)	FOSA	perfluorooctanesulfonamide

Class	Abbreviation	Compound
FOSAs	NMeFOSA	N-methyl-perfluorooctane sulfonamide
FOSAs	NEtFOSA	N-ethylperfluoro-1-octanesulfonamide
Perfluorinated Sulfonamidoacetic Acids (FOSAAs)	NMeFOSAA	N-methylperfluorooctanesulfonamidoacetic acid
FOSAAs	NEtFOSAA	N-ethylperfluorooctanesulfonamidoacetic acid
Perfluorinated Sulfonamide Ethanols (FOSEs)	N-MeFOSE	2-(N-methylperfluoro-1-octanesulfonamido) ethanol
FOSEs	N-EtFOSE	2-(N-ethylperfluoro-1-octanesulfonamido) ethanol
Fluorotelomer Sulfonates (FTSs)	4:2 FTS	1H, 1H, 1H, 2H, 2H-perfluorohexanesulfonic acid
FTSs	6:2 FTS	1H, 1H, 1H, 2H, 2H-perfluorooctanesulfonic acid
FTSs	8:2 FTS	1H, 1H, 1H, 2H, 2H-perfluorodecanesulfonic acid
FTSs	10:2 FTS	1H, 1H, 1H, 2H, 2H-perfluoroundecanesulfonic acid
Fluorinated Replacement Chemicals (FRCs)	DONA	4,8-dioxa-3H-perfluorononanoic acid
FRCs	HFPO-DA	hexafluoropropylene oxide dimer acid
FRCs	9Cl-PF3ONS	9-chlorohexadecafluoro-3-oxanonane-1-sulfonic acid
FRCs	11Cl-PF3OUdS	11-chloroeicosafluoro-3-oxaundecane-1-sulfonic acid
Additional Target Analytes (ATAs)	PFECA F	perfluoro-3-methoxypropanoic acid
ATAs	PFECA A	perfluoro-4-methoxybutanoic acid
ATAs	PFECA B	nonafluoro-3,6-dioxaheptanoic acid
ATAs	PES	perfluoro (2-ethoxyethane) sulfonic acid
ATAs	3:3 FTCA	3-perfluoropropylpropanoic acid
ATAs	5:3 FTCA	5:3 fluorotelomer carboxylic acid
ATAs	7:3 FTCA	7:3 fluorotelomer carboxylic acid
ATAs	8:2 FTUCA	8:2 fluorotelomer unsaturated acid
ATAs	10:2 FTCA	10:2 fluorotelomer carboxylic acid
ATAs	8:2 FTCA	8:2 fluorotelomer carboxylic acid
ATAs	6:2 FTCA	6:2 fluorotelomer carboxylic acid
ATAs	PFECHS	perfluoro(perfluoroethyl)cyclohexanesulfonic acid
ATAs	6:2 FTUCA	6:2 fluorotelomer unsaturated acid

Executive Summary

Per- and polyfluoroalkyl substances (PFAS) are a large group of synthetic chemicals. The wide use of both polymeric and non-polymeric PFAS in manufactured products is based on their unique heat resistance, chemical resistance, and surface-active properties, which are associated with the multiple carbon-fluorine bonds and various functional groups characteristic of these chemicals. Unfortunately, the stability that results from the multiple carbon-fluorine bonds and contributes to the utility of PFAS also makes these chemicals difficult to degrade naturally. This, combined with the broad use of PFAS, has led to significant persistence of some of these chemicals in the environment. This persistence, combined with emerging evidence of human and ecological toxicity associated with certain PFAS, have raised concerns regarding the potential risk of these "forever chemicals" to human health and the environment.

Thes concerns have led to a comprehensive search for technologies and methods that can effectively destroy PFAS, either when co-mingled with environmental media or in more concentrated forms in industrial wastes. Given the wide range of individual PFAS and their inherent chemical stability, Resource Conservation and Recovery Act (RCRA)-permitted hazardous waste incineration, which operate at conditions to destroy other persistent organic compounds, may be a candidate technology for ensuring complete, non-selective destruction of PFAS.

Full-scale experience with incineration of PFAS in commercial hazardous waste incinerators has been limited to date. Two previous comprehensive test programs were conducted in 2021 and 2022 at a RCRA-permitted hazardous waste incinerator in Utah, which is owned and operated by Clean Harbors Environmental Services (CHES). The CHES test programs demonstrated high (>99.9999 percent) destruction and removal efficiency (DRE) for PFAS present in aqueous film-forming foam (AFFF) concentrate and dynamically spiked into the incinerator for DRE demonstration. PFAS effectively destroyed in these tests included legacy materials (no longer manufactured due to health and environmental concerns) and replacement PFAS, including GenX. The uncertainty about products of incomplete destruction (PIDs), even after demonstration of high PFAS DREs, led to additional testing at the same unit in November 2024.

The November 2024 testing incorporated most components of the 2021 and 2022 test campaigns, including sampling of liquid waste feed streams, input chemicals and utilities, process residuals, and exhaust emissions for PFAS target analytes, to support an overall PFAS mass balance. This test program included feeding AFFF concentrate and dynamic spiking of nine PFAS compounds for DRE determination. For each test condition, triplicate runs were conducted under normal incinerator operating conditions with mixed solid and liquid waste feeds used to maintain a temperature in the rotary kiln between 950 and 1196 °C and over 1100 °C in the afterburner. As during the two previous test programs, EPA's Other Test Method-45 (OTM-45) was used to sample exhaust emissions for 49 semi-volatile, polar PFAS target analytes. Other Test Method-50 (OTM-50), released by EPA in January 2024, was used in this test for sampling exhaust emissions for 30 volatile fluorinated compounds (VFCs), which could include potential PFAS PIDs such as tetrafluoromethane (CF_4) and hexafluoroethane (C_2F_6). EPA's SW-846 Method 0010 (Method 0010) was used for sampling exhaust emissions for semi-volatile, non-polar PFAS. In addition, exhaust emissions were sampled and analyzed by Fourier transform infrared (FTIR) spectroscopy using ASTM method D6348, as an alternate means of quantifying CF_4 and C_2F_6.

Nine semi-volatile PFAS, for which EPA has established human health toxicity assessments, were spiked as to determine the DRE and destruction efficiency (DE). C_2F_6 was also spiked to enable determination of DRE for this difficult-to-destroy VFC.

OTM-45 results were similar to those from the two previous tests for semi-volatile polar PFAS with most of OTM-45's target list not detected or near the detection limit. Some PFAS were also found as contaminates in the blanks, such as hexafluoropropylene oxide dimer acid. Method 0010 results indicated no semi-volatile non-polar PFAS were identified in the exhaust emissions. OTM-50 sample analysis was conducted by both Eurofins and EPA. Concentrations of all 30 VFCs in the samples analyzed by Eurofins were below detection level for these analytes in all nine runs. EPA analytical results indicated low level detections for six OTM-50 VFC analytes near the detection limit. For two of these compounds, concentrations in the blanks were in the same range as the concentrations in the actual samples.

For the nine spiked PFAS, calculated DREs ranged from 99.95 percent to 99.9999 percent. Based on the results of OTM-50 and FTIR sampling and analysis, DRE for C_2F_6 ranged from 99.99 percent to 99.9999 percent depending on the detection limits of the analytical method.

DREs relate the amount of a compound in the stack emissions to the mass fed into the system without regard of the amount of the destruction of the compound but the removal from the emissions. DE calculations were performed to determine total PFAS destruction by the entire treatment system. DE was based, to the extent practicable, on the comprehensive overall PFAS mass balance, using total mass of PFAS entering the process in all streams and the total mass of PFAS leaving the system in process residuals and exhaust emissions. For the nine spiked PFAS, calculated DEs ranged from 99.97 percent to 99.9999 percent.

An EPA dispersion model, AERSCREEN, was used to predict ground-level ambient air concentrations for twelve PFAS measured in exhaust emissions. All modeled values were between two and eight orders of magnitude below levels outlined for the regulated PFAS concentrations in several state ambient air quality regulations and guidelines.

The results of the November 2024 PFAS destruction testing demonstrated for the third time the Aragonite RCRA-permitted hazardous waste incineration facility can produce DREs as high as 99.9999 percent for a variety of PFAS. The testing also demonstrated that incineration of PFAS-containing wastes can achieve low to non-detectable concentration of VFCs, below 1.00 parts per billion by volume, that could be considered PFAS PIDs in exhaust emissions. DRE values from 99.99 to 99.9999 percent were demonstrated for C_2F_6, supporting the potential use of C_2F_6 as an indicator for PFAS destruction. Implementation of this approach may help to reduce the complexity and cost of future tests at this and similar facilities by relying primarily on verification that C_2F_6 can be destroyed at high efficiencies, but more data is needed.

This is the most comprehensive PFAS incineration test to date and provides valuable data about PFAS incineration but is not intended to be a general recommendation of incineration for the treatment of PFAS. There are some uncertainties and limitations to the data. The results here may only apply to the incinerator that was tested and not all hazardous waste incinerators. Each incinerator may need to be tested to determine its performance. As the methods improve, greater certainty will occur and target lists may grow, making future results even more comprehensive. Here, the method to identify semi-volatile fluorinated compounds in the emissions, modified Method 0010, is still under development and

no PIDs were observed. This is promising, but as the method is improved greater sensitivity may help detect fluorinated compounds in the emissions. The presence of polar volatile fluorinated compounds was not investigated, since there is no standardized method for polar volatile fluorinated compounds, such as trifluoroacetic acid, and may be an area for future development. The results from the OTM-45 trains had HFPO-DA in the trains and in the proof blank, likely from contamination. This may show that great cleaning or other modifications may be needed to OTM-45 to reduce contamination.

1 Introduction

1.1 Background

Widespread detection of per- and polyfluoroalkyl substances (PFAS) in environmental media, along with mounting evidence of their harmful effects on human health and ecosystems, is driving the need to identify effective PFAS remediation and destruction technologies (U.S. Environmental Protection Agency [EPA] 2024a). Due to the strength of multiple carbon-fluorine chemical bonds in these compounds, many PFAS are difficult to completely degrade. There are insufficient data on the performance of commercially available destruction technologies with capacities to treat large amounts of PFAS-contaminated wastes. Evaluation of PFAS destruction technologies is difficult due to the wide array of different physical and chemical properties of the large number of chemicals classified as PFAS. Recent development of new methods to sample and measure PFAS and potential products of incomplete destruction (PIDs) makes more comprehensive evaluations of various remediation and destruction technologies possible.

Incineration is an established destruction technology for a wide range of materials, including difficult-to-destroy hazardous organic compounds. The high temperatures and residence times in hazardous waste incinerators (HWIs) may provide adequate conditions to break the carbon-fluorine bonds, and other bonds, in PFAS (Blotevogel 2023). Many wastes currently being processed at commercial Resource Conservation and Recovery Act-permitted HWIs contain PFAS, sometimes at significant concentrations, as in the case of aqueous film-forming foam (AFFF) concentrate wastes.

PFAS destruction studies on the scale described in this report and the reports from two previous Clean Harbors Environmental Services (CHES) tests have been conducted at only a few other HWI facilities. Therefore, publicly available data on large-scale testing of PFAS destruction in HWIs are very limited.

1.2 Test Program Overview

CHES has previously conducted two full-scale performance tests of PFAS destruction at its HWI in Aragonite, Utah (Crisenbery et al. 2024). The test programs were conducted in 2021 and 2022, and both successfully demonstrated greater than 99.9999 percent destruction and removal efficiency (DRE) for a target list of semi-volatile, polar PFAS. At the time those test programs were conducted, there was no sampling and analytical method for assessing the identities and concentrations of volatile fluorinated compounds (VFCs) that may be produced as PIDs. In January 2024, EPA released Other Test Method 50 (OTM-50) for the sampling and analysis of selected VFCs. This method was used in this study to characterize whether PFAS PIDs are present in thermal treatment exhaust emissions.

This report summarizes the third PFAS destruction study conducted at CHES. The third test was conducted from November 12 to 14, 2024 in collaboration with the U.S. EPA Office of Research and Development (EPA ORD) and U.S. Department of Defense (DOD) Strategic Environmental Research and Development Program (SERDP). The test team consisted of contributors from CHES; EPA ORD; DOD; Focus Environmental, Inc.; EA Engineering, Science, and Technology, Inc., PBC (EA); Alliance Technical Group (ATG); Eurofins Environment Testing (Eurofins); Spectrum Environmental Solutions, Inc. (Spectrum); Superior Spiking Industries (SSI); Sanborn Head & Associates; and Teri Bales (an independent data validator). The test team developed the test plan, executed the field testing,

conducted the laboratory analysis, performed data validation, and worked together to prepare this project report.

The report was reviewed internally by EPA scientists and externally by independent technical reviewers. The two independent reviewers are knowledgeable in the incineration field and in PFAS incineration and provided feedback on the technical merit and structure of the report. Their reviews were implemented into this final version.

1.3 Test Objectives

The key study objectives for the sampling and analysis campaign were:

- Determine the efficacy of an HWI for the treatment of PFAS as indicated by DRE and destruction efficiency (DE) results
- Perform a PFAS mass balance around the entire incineration system
- Characterize PIDs that are observed in exhaust emissions
- Investigate the incinerator's performance by determining the DRE of hexafluoroethane (C_2F_6) and correlating the DRE of C_2F_6 to the presence of PIDs and PFAS in the exhaust emissions

1.4 Technical Approach

A detailed work plan was developed before conducting the tests to facilitate systematic execution of the field activities, including collecting data on process operations, process sampling and analysis, exhaust emissions sampling and analysis, Fourier transform infrared (FTIR) monitoring, PFAS spiking, C_2F_6 spiking, and quality control (QC) testing. The testing program was conducted under three conditions, with triplicate runs performed for each, resulting in a total of nine runs over three days. The incineration system was operated with typical waste feeds and at normal process operating conditions during each run. During Runs 1A, 2A, and 3A, AFFF was fed to the rotary kiln at rates similar to those used during normal operations, and the rotary kiln was spiked with nine selected PFAS spiking compounds. Runs 1B, 2B, and 3B served as baseline runs, during which no AFFF was fed and no PFAS spiking was conducted. During Runs 1C, 2C, and 3C, C_2F_6 spiking was conducted. No AFFF was fed and no PFAS spiking was conducted during Runs 1C, 2C, or 3C. The waste feed, spiking materials, and exhaust emissions sampling methods used during each run are presented in Table 1-1.

The following conventions are used in this document for reporting analytical results and performing mass balance calculation:

- The term "method detection limit" (MDL) is a laboratory reporting convention which defines the lowest level for detection for which false positive results are assumed to be absent with a 99.9% confidence. MDLs are used in this report to define performance and perform all emission, DRE, DE, and mass balance calculations. Analytical values reported as non-detect are below the MDL.
- The term "reporting limit" is a laboratory reporting convention which defines the floor of the quantifiable range of the analytical method. The given certainty of the measured concentrations

is applicable above this limit. The reporting limits for the methods are not used in this report to calculate performance or perform any calculations.

- The term "PFAS" is used in this report to discuss the targeted PFAS measured by the employed methods. The lack of standards and methods to measure all PFAS, or those not on targeted lists limits these evaluations to the PFAS in the methods used.

To achieve the objectives, a targeted PFAS mass balance was assessed by sampling and analyzing the waste feeds into the incinerator, chemicals fed to the emission control system, process water inputs to the incinerator and emission control system, residuals out of the incinerator and the emission control system, and exhaust emissions. The sampling and analysis of process streams included incinerator liquid waste feed streams, treatment chemicals, process water, and solid and liquid process residual streams. The samples from these process locations were analyzed for 40 PFAS target analytes using EPA Method 1633 (liquid chromatography/tandem mass spectrometry [LC/MS/MS] with isotope dilution) (EPA 2024b). The exhaust emissions were characterized using EPA's Other Test Method 45 (OTM-45) (EPA 2021) for 49 PFAS target analytes and OTM-50 (EPA 2025a) for 30 target VFC analytes. Semi-volatile nonpolar fluorinated compounds were sampled using Method 0010 (EPA 1986) and analyzed using EPA's SW-846 Method 8270C (EPA 1996). Tetrafluoromethane (CF_4) and C_2F_6 were monitored using FTIR by ASTM D-6348-12 (ASTM 2020). The solid and liquid process residuals were sampled and analyzed using EPA Method 1633.

To evaluate the efficacy of this HWI for destroying PFAS, AFFF was fed into the rotary kiln along with nine semi-volatile polar PFAS that have EPA published human health toxicity assessments (EPA 2024c, 2025b, 2025c) that were spiked as principal organic hazardous constituents (POHCs) for the purpose of measuring DRE and DE.

To attempt to help evaluate the performance of the HWI, C_2F_6 was also spiked into the rotary kiln to determine DRE for a difficult-to-destroy VFC. Since nontargeted analyses are not quantifiable due to lack of standards and calibrations, every PFAS could not be evaluated. The injection of C_2F_6 as an indicator compound provides data for a hard to destroy PFAS that can provide insight into the performance of the system with an easily measured compound. This study provides more data to determine if the destruction of C_2F_6 corelates with high destruction of known PFAS and the absences of PIDs. Further research is necessary to determine if the indicator gas may be used to aid in the evaluation incinerators' destruction of PFAS in the future.

Table 1-1. Feed Conditions and PFAS Emissions Sampling and Monitoring Methods

Run No.	Normal Waste Feed Materials	AFFF Feed Materials	PFAS Spiking Feed Materials	C_2F_6 Spiking Feed Materials	OTM-45 Emissions Sampling	Method 0010 Emissions Sampling	OTM-50 Emissions Sampling	ASTM D-6348-12 Emissions Monitoring

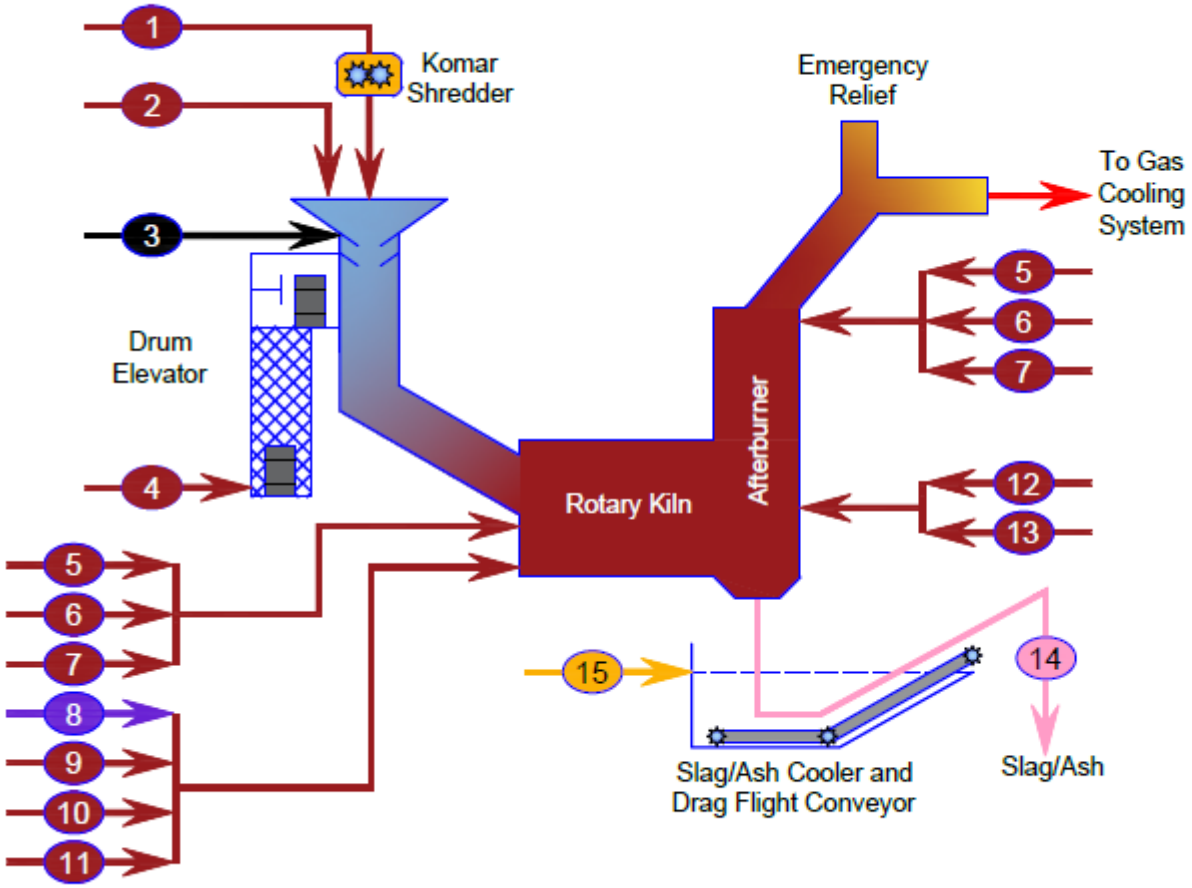
2 Incineration Facility Description

2.1 Overview

CHES is a provider of hazardous waste treatment and disposal services in North America and operates ten HWIs at five locations. In the past, as shown in compliance test reports, these units have consistently demonstrated compliance with high DREs through test-burn studies using Class 1 POHCs.

The CHES Aragonite Incineration facility is located in northern Utah at 11600 North Aptus Road, Grantsville, Utah. The facility processes approximately 60,000 tons of hazardous waste each year. The incinerator has a thermal input limit of approximately 156 million Btu/hr (British thermal units per hour) and consists of a slagging rotary kiln with a vertical afterburner chamber (afterburner). The emission control system consists of a spray dryer, powdered activated carbon injection system, baghouse, saturator, packed bed scrubber, induced draft fan, and stack.



A process flow diagram of the waste feed systems, rotary kiln, and afterburner is presented on Figure 2-1. This figure also shows sampling points for waste feed, PFAS spiking compound, slag/ash, and process water. A process flow diagram of the emission control system showing sampling points for chemical reagents, process water, process residuals, and exhaust emissions is presented on Figure 2-2.

2.2 Waste Feed Systems

The solid waste feed system is capable of feeding bulk solids (including soil), solids that are shredded and fed by a Komar shredder, and containerized solids. The Komar shredder is used for size reduction of bulk and drummed solids, liquids and sludges, lab packs, and other containerized wastes. Bulk solids and output from the Komar shredder are fed to the rotary kiln through a solids waste feed chute in the front wall. Containerized waste is raised by the waste feed elevator and discharged into the solid waste feed chute. Because all the solid wastes are heterogeneous, obtaining representative samples was not possible and solid waste feed samples were not collected. Therefore, any PFAS that may have been in the solid materials are not included in either the PFAS material balance or DRE calculations, potentially biasing the DRE estimates low.

Liquids or sludges may be stored and fed from tanks, tanker trailers, drums, or totes. Waste blend liquids and used motor oil (UMO) are fed to the rotary kiln through lances located inside the burner can. Direct burn liquids from drums and totes, sludge, and direct burn liquids from a tanker are fed to the rotary kiln through individual lances in the front wall. For Runs 1A, 2A, and 3A, the direct burn liquids from a tanker consisted of a commercial AFFF product. This stream was not used during the other runs (Runs 1B, 1C, 2B, 2C, 3B, and 3C).

Waste blend liquids and UMO are fed to the north afterburner and south afterburner wall lances located inside their respective burner cans. Aqueous liquids are fed to the afterburner through lances in both the north and south walls and corrosive waste is fed to the afterburner through a lance in the south wall.

Figure 2-1. Combustion Systems Process Stream Sampling Points

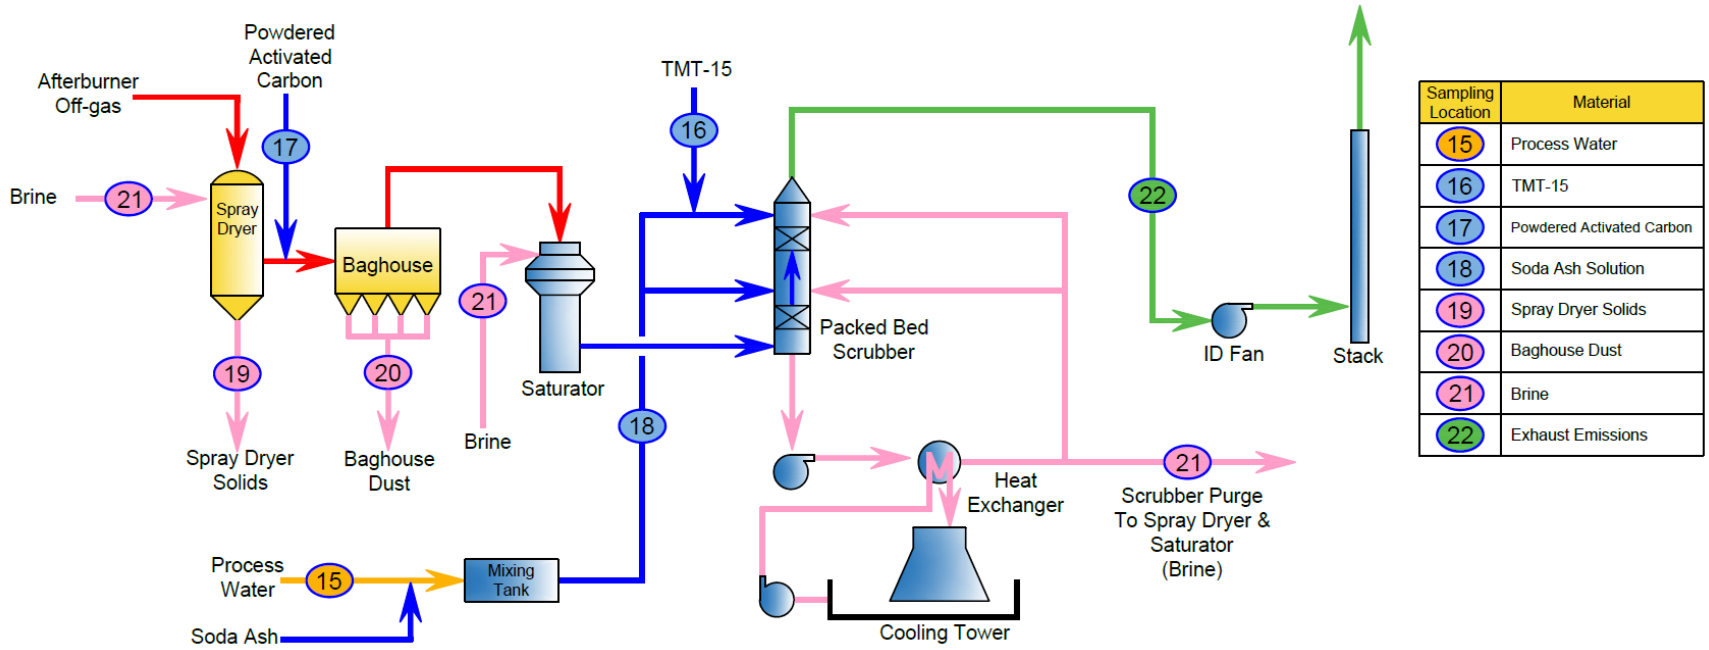

Figure 2-2. Emission Control System Process Stream Sampling Points

2.3 Combustion Systems

The thermal treatment process includes a high-temperature slagging rotary kiln incinerator with an afterburner. Combustion air is delivered to the front wall of the rotary kiln by a forced draft fan. Combustion air is also delivered to the burners on the north and south walls of the afterburner by two forced draft fans, one for each burner. The oxygen (O_2) concentration in the combustion gas at the afterburner exit ranges from approximately 9 to 11 percent. During the testing, the exit gas temperature of the rotary kiln ranged from 2,006 to 2,233 degrees Fahrenheit (°F) (1,097 to 1,223 degrees Celsius [°C]) and the exit gas temperature of the afterburner ranged from 2,048 to 2,096°F (1,120 to 1,147°C). Non-combustible solid material residence time in the rotary kilns was estimated by CHES personnel to be approximately 60 minutes.

Slag/ash is discharged from the rotary kiln into a water-filled slag cooler, where it is cooled and moisturized before being removed by a drag flight conveyor and deposited into a roll-off container. Process water is added to the slag cooler to cool the slag/ash.

2.4 Emission Control System

The emission control system consists of spray dryer, powdered activated carbon injection system, baghouse, Na_2CO_3 solution supply system, saturator, packed bed scrubber, decommissioned electrostatic precipitator, induced draft fan, and stack. Exhaust emissions samples were collected from the outlet duct of the packed bed scrubber because this location is more accessible and safer than collecting samples from sampling ports on the stack platform.

The purpose of the spray dryer is to cool the gas before entering the baghouse. The emission control system is a zero-blowdown process and the purge water (brine) from the packed bed scrubber is evaporated in the spray dryer. Some solids collect on the walls of the spray dryer and in the duct that connects the spray dryer to the baghouse. Solids that slough off the spray dryer walls, and dust collected in the outlet duct, are collectively defined as “spray dryer solids” and are discharged through an airlock into a roll-off bin.

Powdered activated carbon is injected upstream of the baghouse for control of polychlorinated dibenzo-p-dioxins, polychlorinated dibenzofurans, and mercury. The baghouse also removes particulate matter from the flue gas. “Baghouse dust” is discharged from the baghouse through airlocks and is conveyed by screw conveyors to a roll-off container.

The baghouse is followed by a saturator. A brine solution is sprayed into the gas to cool and precondition it in the saturator before the gas enters the packed scrubber.

The gas then flows to the packed scrubber where a Na_2CO_3 solution is used to react with and neutralize acid gases including hydrogen chloride, chlorine, sulfur dioxide, and hydrogen fluoride. Na_2CO_3 is stored as a dry powder in a silo and metered into a mixing tank where it is mixed with process water to form a Na_2CO_3 solution. The flow rate of the Na_2CO_3 solution into the packed scrubber is controlled by pH measurements of the scrubber recirculation water. In the packed scrubber, acid gases are absorbed by the recirculating water stream and are neutralized by reaction with the Na_2CO_3. Since this reaction produces sodium chloride, sodium sulfite, and sodium fluoride salts, some of the water (brine) must be purged from the packed scrubber to control the concentration of total dissolved solids in the scrubber

water. Part of this brine is sent to the saturator and the rest of it is sent to the spray dryer. The packed scrubber discharge water is routed through a heat exchanger to lower its temperature before it is recycled into the packed scrubber.

TMT-15 is also injected into the packed scrubber recirculating water for additional mercury control. TMT-15 reacts with mercury and other heavy metals to form a stable, virtually insoluble complex of heavy metal and TMT-15 that is easy to separate from the water.

The gas leaving the packed scrubber goes through a decommissioned electrostatic precipitator, which is no longer needed to meet emission standards. The electrostatic precipitator shell is in place, but its internal parts have been removed. The gas then flows through an induced draft fan and is discharged through the stack.

3 Process Parameter Data Collection

3.1 Continuous Process Monitoring

During runs, CHES plant personnel were responsible for operating the incineration process. Personnel confirmed the system was operated within permitted operating limits and maintained operating parameters within typical operating ranges. This was to ensure that the PFAS destruction testing process conditions were representative of normal operations.

Key process parameters were monitored and their values recorded electronically at 1-minute intervals on the CHES distributed control system. The project team reduced the 1-minute data records to calculate the minimum, average, and maximum rates from the start time to the end time of each run. The standard deviation of the data within a run was also calculated. The types of parameters that were monitored and recorded include solid waste feed rates to the rotary kiln; liquid waste feed rates to the rotary kiln; liquid waste feed rates to the afterburner; chemical reagent feed rates to the emission control system; temperatures; liquid flow rates to the scrubber system; differential pressures; broken bag indicators; pH of the recycle water going into the packed scrubber; total fluorine and total chlorine waste feed rates; exhaust emissions concentrations of sulfur dioxide, nitric oxide, nitrogen dioxide, carbon dioxide (CO_2), carbon monoxide, O_2, total hydrocarbons, and exhaust emissions flow rates. Detailed records of process parameters are presented in Appendix B for each day of testing. Summaries of waste feed rates to the rotary kiln and the afterburner are presented in Table 3-1 and Table 3-2, respectively. A summary of key process parameters that may affect the DRE of PFAS is presented in Table 3-3.

Table 3-1. Waste Feed Rates to Rotary Kiln

Date	Run No.	Komar Feed Drop to Rotary Kiln (lb/hr)	Containerized Solids Feed Drop to Rotary Kiln (lb/hr)	Bulk Solids Bin Weight to Rotary Kiln (lb/hr)	Waste Blend Liquid Flow to Rotary Kiln (lb/hr)	UMO Flow to Rotary Kiln (lb/hr)	Drum Direct Burn Educt 1 to Rotary Kiln (lb/hr)	Tote and Drum Direct Burn Educt 2 to Rotary Kiln (lb/hr)	Tanker Direct Burn Flow to Rotary Kiln (lb/hr)

3.2 Parameters Derived by Mass Balance Calculations

Three process parameters that were not continuously monitored but were calculated by mass balance or mass and energy balance calculations include (1) Na_2CO_3 solution flow rate, (2) process water flow rate, and (3) brine flow rate. The Na_2CO_3 solution flow rate and process water flow rate are used in the overall plant PFAS mass balance, DRE, and DE calculations. The brine flow rate is an internal process stream that does not affect the overall plant PFAS mass balance, DRE, or DE calculations. Descriptions of the methods used to perform these calculations are presented below.

The Na_2CO_3 solution flow rate was computed using mass balance calculations. Na_2CO_3 is stored as a dry powder in a silo, and the Na_2CO_3 level in the silo is monitored continuously. The mass flow rate of Na_2CO_3 powder was calculated at 1-minute intervals based on the depth of the Na_2CO_3 powder in the silo, the diameter of the silo, and the bulk density of the dry Na_2CO_3. The Na_2CO_3 powder is mixed with process water to feed Na_2CO_3 to the scrubber as a solution; this solution was sampled and analyzed to determine its PFAS content. The flow rate of the Na_2CO_3 solution was calculated based on the mass flow rate of Na_2CO_3 powder and the concentration of Na_2CO_3 in solution. CHES provided the Na_2CO_3 solution density measurements. A chart showing the correlation between Na_2CO_3 solution density and Na_2CO_3 concentration was then used to calculate the flow rate of the process water used to create the solution. An example of these calculations is presented in Appendix B, Table B-3.

The flow rate of process water to the system is not monitored. Process water is introduced into the system to make Na_2CO_3 solution, and the flow rate of process water for this purpose was calculated as described above. Process water is also introduced into the system in the slag/ash cooler. The flow rate of this stream was determined using mass and energy balance calculations based on the flow rate of the slag/ash, the temperature of the slag/ash as it exits the rotary kiln (assumed to be the same as the off-gas temperature), the temperature of the slag/ash exiting the slag/ash cooler, and the residual moisture in the slag/ash. These calculations are presented in Appendix B, Table B-4.

The flow rate of brine is also not monitored, but the flow rate of this stream does not affect any DRE, DE, or mass balance calculations since it is an internal process stream. However, it may be useful in interpreting the PFAS mass balance between the spray dryer solids, baghouse dust, and scrubber blowdown streams. It can be calculated by a mass and energy balance around the entire plant. These calculations were performed as part of the 2022 PFAS test program (Crisenbery et al. 2024), and the brine flow rate from those calculations — 128 gallons per minute — was applied to this study.

3.3 Process Residual Measurements

Solid process residual streams include slag/ash, spray dryer solids, and baghouse dust. Each bin is weighed empty when it is put into service and weighed again when it is full and taken out of service. Therefore, it is not possible to get a weight of material in each bin at the beginning and end of each run. For these three streams, the average fill rate for a bin was calculated from the time it was put in service before a run started until it was taken out of service after a run ended. Detailed calculations of residual stream flow rates are presented in Appendix C. A summary of residual stream flow rates is presented in Table 3-4.

Table 3-4. Residual Stream Flow Rates

Run No.	Date	Slag/Ash (lb/hr)	Spray Dryer Solids (lb/hr)	Baghouse Dust (lb/hr)	Total (lb/hr)
Run 1A	11/13/2024	5,302	118	1,107	6,526
Run 1B-1	11/12/2024	2,155	118	977	3,249

Run 3C	11/14/2024	5,974	118	1,073	7,165

4 Process Stream Sampling and Analysis

4.1 Overview

The Test Plan is based on a comprehensive approach to sampling process streams that includes as many process inputs and outputs as practical. The purpose of collecting and analyzing the process samples is to develop as complete a PFAS mass balance as possible to help evaluate PFAS destruction. This approach results in identifying potential sources of PFAS in process streams entering the process, and PFAS sinks for process streams leaving the process. Process sampling includes liquid waste feed streams, treatment chemicals, process water, and process residues. Containerized, shredded, and bulk solids waste feed streams were not sampled. Due to their complexity and heterogeneity, it was not practical to sample and perform PFAS analyses on the solid waste feed materials. Therefore, PFAS that may be contained in the solid waste feed streams were not included in the mass balance, DRE, or DE calculations.

4.2 Scope of Sample Collection

During the test program, representative process stream samples were only collected during Runs 1A, 2A, and 3A. No process stream samples were collected during Runs 1B, 1C, 2B, 2C, 3B, or 3C. The types of process streams that were sampled and analyzed include liquid waste feed streams, treatment chemicals, utilities, and process residues. The types of streams within each of these categories are listed below.

All liquid waste feed streams were sampled and analyzed, including the following:

Liquids waste feed streams:

- Waste blend liquids (fed to rotary kiln, north afterburner, south afterburner)
- UMO (fed to rotary kiln, north afterburner, south afterburner)
- Drum direct burn educt (fed to rotary kiln)
- Tote direct burn educt (fed to rotary kiln)
- Tanker direct burn (AFFF fed to rotary kiln)
- Aqueous liquid (fed to north afterburner, south afterburner)
- Corrosive waste (fed to south afterburner)

For liquid waste streams that are fed to the system in more than one location, samples were collected at one location, analyzed, and the analytical results applied to multiple streams.

Treatment chemicals:

- Powdered activated carbon

- Na_2CO_3 solution
- TMT-15

Utilities:

- Process water

Process residues:

- Slag/ash
- Spray dryer solids
- Baghouse dust

Schematic diagrams of the combustion and emission control processes showing sampling location for each process stream were previously presented on Figure 2-1 and Figure 2-2, respectively.

4.3 General Process Sampling Approach

Given the ubiquity of PFAS in the environment, particular care was taken with all sampling activities to avoid inadvertent PFAS contamination of samples. Process sampling activities were conducted following best practices as avoiding use of the following materials in proximity to sampling activities:

- Teflon® or low-density polyethylene containing materials
- Water-proofed materials
- Water-proof markers
- Water-proof clothing and footwear
- Fire-retardant clothing
- Coated Tyvek®
- Personal care products and synthetic sunscreens
- Food and drink containers

In addition to observing general best practices during sample collection activities, individuals collecting samples for PFAS analysis wore new, powder-free nitrile gloves at all times and placed all samples in high density polyethylene (HDPE) sample jars. All hand-held sampling equipment was disposable and was used at only one sampling location and for only one sampling event.

4.4 Sampling Responsibilities

CHES personnel were responsible for collecting all process samples under the direction of EA. EA personnel were responsible for overall coordination of process sampling activities, compositing grab samples provided by CHES plant personnel, on-site storage of process samples, and delivery of process samples packaged for shipment with completed chain-of-custody forms to the Eurofins courier.

The EA SOP used for obtaining process samples was provided in an approved Work Plan as an attachment to the EPA quality assurance project plan (QAPP). Process sampling logs showing the time of collection of each grab sample are presented in Appendix D. Grab samples were collected for each sample type, and the grab samples were then combined into a composite sample for each run. The composite samples were homogenized, sealed, and stored in a secure area of the CHES on-site laboratory to minimize the potential for cross-contamination. At the end of the test program, the process samples were packaged and preserved in coolers, along with Request for Analysis/Chain-of-Custody forms and transferred to the Eurofins courier.

4.5 Sample Transport and Analysis

The Eurofins courier delivered the project's properly preserved process samples under chain of custody to the Eurofins laboratory in West Sacramento, California. The Eurofins West Sacramento laboratory was responsible for the analyses of all process samples and reporting final analytical results. Samples were analyzed by LC/MS/MS by EPA Method 1633. The process sample analytical data reports were prepared to comply with DOD Data Validation Guidelines Module 6. This reporting process provides the necessary quality assurance (QA)/QC results and supporting documentation enabling independent data validation and quality assessment of the analytical results.

For liquid waste feed streams, a duplicate and a matrix spike (MS)/matrix spike duplicate (MSD) analysis were performed on one sample of each waste type. For process residual streams, MS/MSD analyses were performed on one sample of each residual type. For every extraction batch (less than or equal to 20 samples), method blank and MS analyses were performed. Isotope dilution internal standards were spiked into the samples to assess extraction efficiencies, and internal standards were spiked into final extracts to assess instrument drift. The LC/MS/MS instrument was calibrated using a minimum of five concentration levels. All assays were bracketed by passing continuing calibration verification evaluations. A maximum of ten samples were assayed between continuing calibration verifications. All laboratory QC procedures and results are documented in the Eurofins Analytical Report in Appendix J-1.

4.6 Analytical Results

Select summary tables representing process sample analytical results for Run 1A and containing data for target analytes of EPA Method 1633 are presented in Tables 4-1 through 4-5. A complete set of tables for Runs 1A, 2A, and 3A are included in Appendix A-1, Table A-1-14, Table A-1-15, and Table A-1-16, respectively. These tables include the analytical results, MDL, data qualifier flags applied by the laboratory, and the data qualified flags applied by the data validator. Complete process sample analytical results are presented in Eurofins Analytical Report, which is included as Appendix J-1.

Spray dryer solids consisted of materials with a range of particle sizes. These samples were sieved in the laboratory into three size fractions as part of their preparation for analysis: less than 250 micrometers, 250 micrometers to 2 millimeters, and greater than 2 millimeters. Each size fraction was weighed and analyzed separately. The concentration values reported for Spray dryer solids are the mass weighted average concentrations of the three size fractions. Concentration data for the individual size fractions are presented in Appendix A-1, Table A-1-16.

Analytical results for process stream samples were generally consistent between runs in terms of the types of PFAS and order of magnitude concentrations observed for all but two waste streams. The waste blend liquid stream was determined after the analyses were conducted to be a two-phase liquid with a dark-brown top phase and a dark-green bottom phase. Analytical results for this stream were significantly different between Runs 1A, 1B, and 1C. It appears that the samples that were analyzed came from different phases for Runs 1A and 1B, and that the sample analyzed for Run 1C may have been a mixture of materials from the two phases. The variability of the analytical results for this stream would have had a very minor effect on the overall PFAS mass balance because the PFAS in this stream made up less than 0.0033% of the total PFAS fed to the system.

The analytical results for the Run 1A process water had detectable concentrations for 11 PFAS, with PFOS (58 nanograms per liter [ng/L]) and 6:2 FTS (27 ng/L) having the two highest concentrations. These results were unexpected and likely due to an unidentified external source of contamination. The analytical results for Run 2A and Run 3A for process water were all non-detect, except for 6:2 FTS, which was detected at concentrations of 2.49 ng/L and 1.42 ng/L respectively.

4.7 Quality Assurance/Quality Control Results

Throughout the project, various measures were implemented to ensure the overall quality and usability of the collected data. The field investigation activities included collection of additional QC samples (e.g., duplicates, MS/MSD, etc.). Duplicate samples were submitted, and field and laboratory QC requirements were completed. A detailed discussion of the process sampling and analytical QA/QC results is presented in Section 8.0.

5 PFAS Spiking

5.1 PFAS Spiking Objective

The incinerator PFAS spiking was coordinated and executed by EA. One of the overall testing objectives was to be able to demonstrate up to 99.9999 percent DRE for select target analytes. To demonstrate DRE performance at this level, the mass of any PFAS target analyte in the waste feed was planned to be at least 1,000,000 times the mass that can be detected in the exhaust emissions at the analytical MDL. Since the native mass of the PFAS target analytes in the waste feed materials prior to the test was unknown, spiking to fortify their concentration levels was used to ensure that sufficient masses of target analytes were fed during the test for selected compounds to achieve the DRE performance demonstration objective.

5.2 PFAS Spiking Target Analytes

Nine PFAS were selected to be spiked into the rotary kiln to facilitate determining DRE and DE values. These chemicals were selected from the compounds that the EPA had published human health toxicity assessments (EPA 2025c). Three of the perfluoroalkyl acids were not readily available in the acid (H^+) form required for the test program. Therefore, their potassium (K^+) salt forms were purchased for spiking in place of the acid (H^+) forms.

The liquid chromatography methodology (LC/MS/MS) used for the analysis of the individual PFAS compounds quantifies the anionic form (A^-) of the PFAS target analyte. Therefore, the initial form of the spiked PFAS compound, whether acid or the potassium salt, does not affect the analytical quantification of the target analytes. The PFAS spiking compounds include:

- PFHxA CAS No. 307-24-4 $C_6HF_{11}O_2$ MW 314.05
- PFOA CAS No. 335-67-1 $C_8HF_{15}O_2$ MW 414.07

5.3 Calculation of PFAS Spiking Rates

The required spiking mass feed rates were calculated using the estimated exhaust emissions flow rate, the OTM-45 sample volume, and the MDL for each specific analyte in the exhaust emissions. The calculated feed amounts for all nine PFAS were adjusted to account for the purity of the purchased chemicals. For PFBS, PFHxS, and PFOS, which were supplied as potassium salts, the PFAS spiking compound amounts were further adjusted to reflect the molecular weights of the salt forms, ensuring the calculations were based on equivalent molar quantities of the PFAS target analytes. These adjustments were necessary to support consistent interpretation of DRE results across analytes with varying physical and chemical properties. The spiking rate calculations for each of the nine PFAS are provided in Attachment 1 of Appendix E.

5.4 PFAS Spiking Material Preparation

Reagent grade PFAS spiking compounds were purchased from the following vendors:

- Matrix Scientific (Columbia, SC)
- Smolecule (San Antonio, TX)
- Indofine Chemical Company (Hillsborough Township, NJ)

Safety data sheets and Certificate of Analysis for the PFAS spiking compounds are presented in Appendix E, Attachment 5 and 6 respectively.

The PFAS spiking compound mass amounts were precisely weighed to two decimal places (plus or minus 5 milligrams) using a calibrated analytical scale. The weights were recorded, and the weighed portions were placed in labeled PFAS-free HDPE containers and sealed. Each of the sealed containers held the measured mass of an individual PFAS. The containers were then bundled into groups of the nine spiking compounds, each in their own HDPE container. Multiple containers were used for some compounds, as needed. The individual bundles were then packaged in PFAS-free, disposable cardboard boxes, sealed, and labeled with sequential identification numbers by EA personnel. The sequential identification number and corresponding spiking material weights were recorded on the PFAS Spiking Bundle Tracking Spreadsheet. Each box was labeled with a sequential identification number matching its assigned bundle. Photographs of the spike material packaging system are shown in Appendix E, Attachment 2.

5.5 PFAS Spiking Execution

PFAS spiking was conducted during Run 1A, 2A, and 3A. PFAS spiking was not conducted during Runs 1B, 1C, 2B, 2C, 3B, or 3C. During each day when PFAS spiking was conducted, the required number of spiking material boxes were removed from storage and staged at the rotary kiln feed chute. The first container of PFAS spiking compounds was fed into the rotary kiln at least 60 minutes before any process stream sampling or exhaust emissions sampling began. This lead time allowed the PFAS concentration in the rotary kiln slag/ash to reach equilibrium, as the residence time of the solids in the rotary kiln was approximately 1 hour. The residence time estimate was based on historical observations by CHES of the

elapsed time between the start of material feeding and its appearance in the slag/ash discharge during a cold startup.

The CHES operator performed the spiking by placing the individual boxes sequentially into the rotary kiln feed chute (as shown on Appendix E, Figure E-1) at 15-minute intervals. Once initiated, spiking continued without interruption through the preconditioning period and until the run sampling was completed (Run 1A, 2A, or 3A).

The CHES operator recorded the identification number printed on each box and the time each box was dropped was documented on the PFAS Spiking Bundle Feed Log, as well as at the conclusion of each run. The recorded times from the PFAS Spiking Bundle Feed Log Sheet were transferred to the PFAS Spiking Bundle Tracking Spreadsheet (Appendix E, Attachment 3). The total mass of PFAS spiking compound added during the run was calculated accordingly and is presented in the tables in Appendix E, Attachment 4.

Table 5-1 presents the total amount of each PFAS spiking compound in the form that it was spiked during each run. Table 5-1 also presents the total amount of each target analyte in the acid form, which includes adjusting the form spiked for chemical purity. For the three compounds that were spiked as potassium salts, molecular weights were used to calculate the mass of the acid form for that chemical. The mass of the PFAS acid form was used in all mass and energy balance, DRE, and DE calculations.

Table 5-1. PFAS Spiking Compound Amounts During Sampling Runs

Bottle Number	Analyte	Purity (%)	MW of K Salt Form	MW of Acid Form	Run 1A Weight in Form Spiked[(a)] (g)	Run 2A Weight in Form Spiked[(a)] (g)	Run 3A Weight in Form Spiked[(a)] (g)	Run 1A Weight of Acid Form[(b,c)] (g)	Run 2A Weight of Acid Form[(b,c)] (g)	Run 3A Weight of Acid Form[(b,c)] (g)
1	PFOA	96	NA	414.07	172.32	140.01	183.09	165.43	134.41	175.77

g = gram(s)
K = potassium
MW = molecular weight
NA = not applicable

6 C_2F_6 Spiking

6.1 Overview

The C_2F_6 spiking services were provided by SSI. A complete description of the C_2F_6 spiking procedures and results is presented in Appendix F. This section describes the process for and results of spiking C_2F_6 into the rotary kiln during Runs 1C, 2C, and 3C. C_2F_6 has been proposed as a potential indicator compound POHC for conducting DRE testing for a wide range of PFAS. The purpose for spiking C_2F_6 is to evaluate the performance of the incinerator by determining the DRE for a stable compound. The evaluation of C_2F_6 as a potential indicator compound will be performed by correlating the DRE values achieved for C_2F_6 with the DREs of other PFAS and the presence of PIDs in the exhaust emissions.

The C_2F_6 spiking rate required to achieve a target DRE value is based on the exhaust emissions flow rate and the analytical detection limit of C_2F_6 in the exhaust emissions. For planning purposes, the maximum exhaust emissions flow rate that had been measured during previous testing in 2021 and 2022 (Crisenbery et al. 2024) was used in the C_2F_6 spiking calculations. The exhaust emissions flow rate from Run 8 of the June 2021 test program is 38,565 dry standard cubic feet per minute.

Both OTM-50 sampling and analysis as well as FTIR monitoring were used to assess C_2F_6 emission concentrations. Prior to conducting the PFAS test program, the estimated analytical detection limit for C_2F_6 analyzed by OTM-50 was estimated by Eurofins to be 0.031 parts per billion (ppb) (0.175 micrograms per cubic meter [µg/m^3]). The MDC was determined by Method #3, determination of analytical algorithm errors per ASTM D6348-12 Section A2.3. The MDC for C_2F_6 analyzed by FTIR was estimated by Spectrum to be in the range of 10 to 25 ppb (56 to 141 µg/m^3). Therefore, the lower MDL value from the OTM-50 analysis was used to perform C_2F_6 spiking calculations. Spiking C_2F_6 at a feed rate (12.43 lb/hr) was deemed sufficient to achieve a concentration in the exhaust emissions of 15 parts per million by volume if there was no C_2F_6 destruction during thermal treatment. This spiking rate was estimated to allow demonstration of a C_2F_6 DRE value of 99.99979 percent at the Eurofins OTM-50 estimated pre-test MDL. After the first run, spiking C_2F_6 at a rate of 12.43 lb/hr, the plan for the remaining testing, Runs 2C and 3C, was changed to increase the feed rate to 45 lb/hr. This allowed for a higher DRE to be calculated and for a greater possibility of detectable measurement of C_2F_6 in exhaust emissions.

6.2 Spiking Equipment

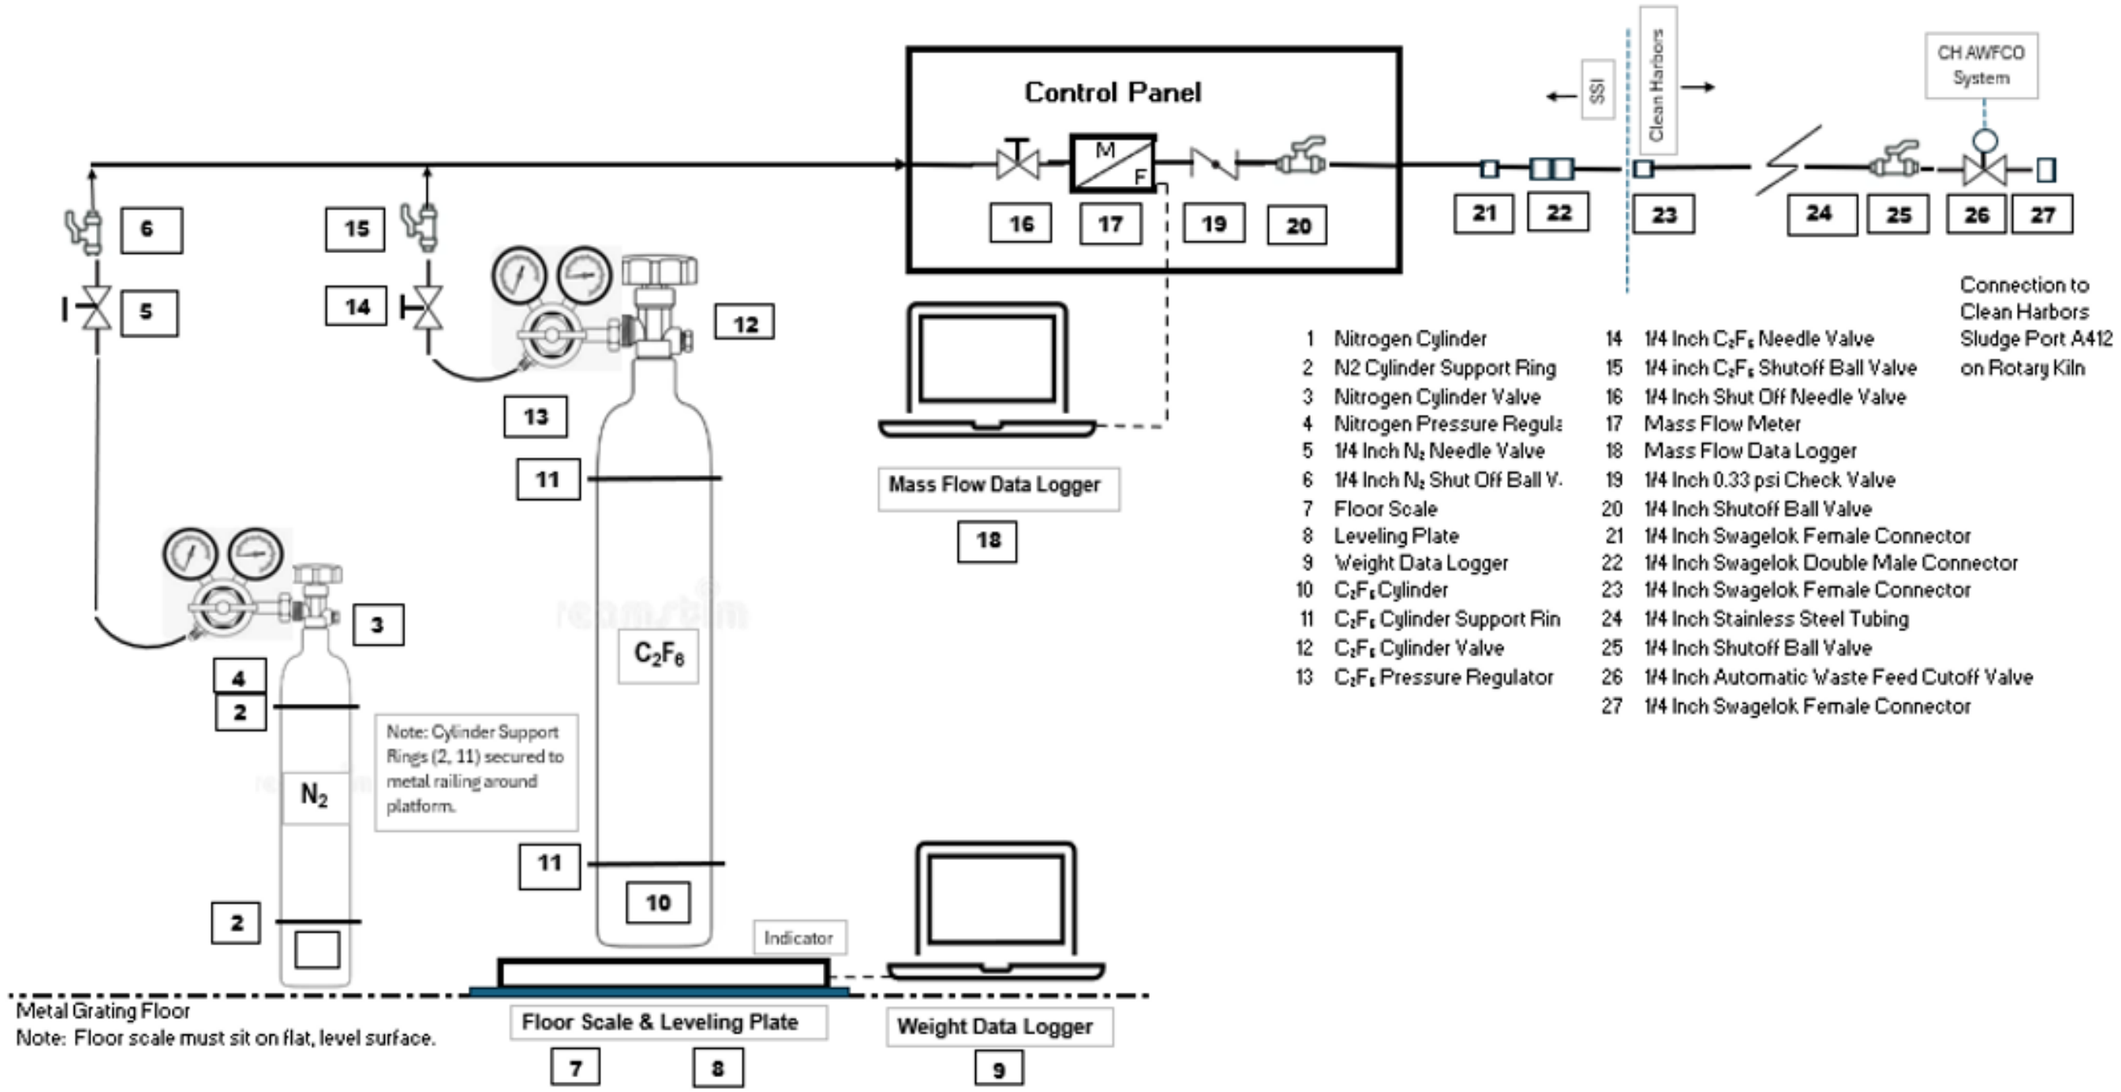
The spiking system was comprised of a cylinder of C_2F_6 gas placed on a calibrated weigh scale, pressure gauges, pressure regulators, a weight data logger, a mass flow meter, a mass flow rate data logger, and a set of control and shutoff valves. A schematic of this setup is displayed on Figure 6-1. Nitrogen gas was used to purge the lines before each run.

Prior to the test, CHES ran a ¼-inch stainless steel tube from the sludge port on the rotary kiln to the spiking equipment. The spiking equipment was set up on a working platform on the north side of the afterburner. The stainless steel tubing was provided with a ¼-inch female Swagelok connector and a ¼-inch ball valve type shutoff. SSI set up their equipment and connected it to the tubing provided by CHES.

6.3 Spiking Procedures

The C_2F_6 spiking gas was injected through the sludge port on the rotary kiln. This port fires below the burner. The project team purposely chose to inject the C_2F_6 gas through this port to avoid feeding it through a burner flame. This feed location exposes the spiked gas material to conservatively lower temperature conditions than if the gas were fed through a burner port. No other waste materials were fed at this location during the spiking process to avoid the occurrence of back pressure in the lines.

Before each run, the spiking system was primed with the C_2F_6 gas and the flow rate was set and stabilized at the target flow rate. The target C_2F_6 feed rate was then maintained for the duration of the run. During the run, weigh scale recordings of the cylinder weight loss were manually recorded at 5-minute time intervals. Records were kept both electronically and manually as shown in Appendix F.



Two independent spiking rate measurement methods were used:

- The Weight Loss versus Time Method
- The Mass Flow Meter Method

For the Weight Loss versus Time Method, the spiking material was released out of the cylinder into the feed line. Consequently, the mass remaining in the cylinder and on the weight scale decreases. The rate at which the mass changes with time defines the spiking material injection rate. A computer-based data logger was used to record the cylinder weight at 1-minute time intervals. The instantaneous and cumulative average spiking rates were subsequently calculated from these data. This method provided a continuous record of the spiking rate. The accuracy of the scale system was demonstrated both pre-test and post-test by placing a weight standard on the scale. The calibration certified check weights are traceable to the National Institute of Standards and Technology.

Weight measurements were also manually recorded on a paper log sheet at 5-minute time intervals. The 5-minute average feed rate and the cumulative feed rate are also recorded on the log. This record provided a backup spiking record if the data logger failed during a run.

The mass flow meter provided a continuous flow rate measurement. The data from the mass flow meter were used during the runs to adjust the flow rate of the spiked gas. These data were not used in the mass balance calculations. The data from the mass flow meter were recorded on a data logger at 1-minute intervals. SSI could not recover the data from the disk at the end of the test program. However, the inability to recover data had no effect on meeting the test objectives because the data from the Weight Loss versus Time method were utilized in all C_2F_6 spiking rate calculations.

6.4 Spiking Results

The planned and measured amounts of gas spiked to the rotary kiln during each run are summarized in Table 6-1. The C_2F_6 feed rate was slightly below the actual gas flow rate because the purity of C_2F_6 in the gas was 99.9 percent. Detailed spiking results are presented in Appendix F. Log sheets are provided that document the start and stop time for each run. A summary of spiking results recorded on the Weight Loss versus Time data logger is presented in Appendix F, Attachment A-1, Table A-2. This data was used for all mass balance and DRE calculations. The measured spiking accuracy values ranged from 98.02 to 99.84 percent. Detailed spiking data are presented in Appendix F, Attachment A-1, Table A-3.

Spiking results that were recorded manually are presented in Appendix F, Attachment A-2 in Tables A-4, A-5, and A-6 for Runs 1C, 2C, and 3 C, respectively. Spiking results are graphed in Appendix F, Attachment A-2 on Figures A-1, A-2, and A-3 for Runs 1C, 2C, and 3C, respectively. Field log sheets for these data are presented in Appendix F, Attachment A-3 on Figures A-4, A-5, and A-6 for Runs 1C, 2C, and 3C, respectively.

Table 6-1. C_2F_6 Spiking Results Summary

Run No.	Gas Feed Rate[(a)] (lb/hr)	Target Gas Feed Rate (lb/hr)	Gas Feed Rate Accuracy[(b)] (%)	C_2F_6 Feed Rate[(c)] (lb/hr)
Run 1C	12.41	12.43	99.84	12.40

% = percent

6.5 Quality Assurance/Quality Control Procedures

QA checks included spiking material composition documentation and test equipment calibrations, performance of leak checks, and redundancy of system measurements of the C_2F_6 spiking rate. The QA checks included the following elements:

- The composition of the C_2F_6 spiking gas was analyzed by the industrial gas supplier (Linde) prior to the test. A certificate of analysis for C_2F_6 spiking material is provided in Appendix F, Attachment A-4, Figure A-7.

- The General Electronic platform scale was calibrated prior to the test by Carlton Scale in Knoxville, Tennessee, using certified check weights. The calibration range is 0 to 400 pounds. Carlton Scale performed a post-test calibration check when the scales were returned after the completion of the test. The post-test calibration was performed on January 14, 2025; however, the Carlton Scale representative confirmed that the scale had not been used since it was returned following the field test on November 20, 2024. Certificates of calibration for the pre-

test and post-test calibrations are included in Appendix F, Attachment A-4, Figure A-8, and Figure A-9.

- The Emerson mass flow meter was calibrated by Coastal Flow Liquid Measurement, Inc. in Houston, Texas, before the test. The calibration range is set for 0 to 20 lb/hr. A certificate of calibration is included in Appendix F, Attachment A-4, Figure A-10.

- SSI performed leak checks on the spiking system and all valves prior to use during the test program. Upon completion of successful leak checks, the system was purged for 2 minutes with nitrogen gas before each run.

- Redundant electronic and manual C_2F_6 flow rate recording systems were used. These systems are described in Section 3.0. (*FTIR Experimental Parameters*) of Appendix G.

Based on the above procedures, it was determined that the data presented for this spiking program is sufficiently accurate and representative and suitable for its intended use to demonstrate the DRE of C_2F_6.

7 FTIR Monitoring

7.1 Overview

The FTIR monitoring was conducted by Spectrum. Long-path extractive FTIR spectroscopy by Method ASTM D6348-12 was used to continuously profile incinerator exhaust emissions for PIDs. This testing methodology was chosen for its ability to speciate and quantify PFAS analytes present within the relatively complex mixture of gases present in the incinerator exhaust on a continuous, (near) real-time basis. The complete FTIR Monitoring Report is presented in Appendix G.

The Spectrum FTIR WaveRunIR™ system was pre-configured and optimized to detect and accurately quantify C_2F_6 and CF_4 at sensitivities below single-digit ppbv in near real-time (4- to 5-minute spectral signal averaging periods). The hardware/software configurations needed to achieve these requirements are described in detail within Section 3 (*FTIR Experimental Parameters*) of Appendix G, while the analytical figures-of-merit achieved in the field, per ASTM D6348-12 definitions, are rigorously presented in Section 5 (*FTIR Data Quality Assurance/Quality Control [QA/QC]*) of Appendix G.

Analytical parameters-directly pertinent to the exhaust emissions test results, including those related to FTIR system detection limits, also known as MDCs, are included in Appendix G. Sample measurement accuracies as derived from certified analyte gas spiking recovery percentages (percent recoveries) within the representative gas sample matrices, are also included in Appendix G. Table 7-1 summarizes the field detection capabilities demonstrated for the FTIR hardware/software assembly deployed on this project.

Table 7-2 summarizes the field recovery (i.e., sampling system + analytical measurement accuracies) capabilities demonstrated for the FTIR hardware/software assembly deployed on this project. An acceptable criterion, per ASTM D6348-12, is nominally plus or minus 30 percent (i.e., 70 to 130 percent recovery).

The summary of FTIR field test results, listed for each run, is shown in Table 7-3. The graphical real-time series data plots are presented in Section 4 (*FTIR Stack Emission Test Results*) of Appendix G. The values in Table 7-3 represent average concentration amounts and pertinent minimum/maximum values. In this case, zero values are expressed more appropriately as the measurement system's MDC.

Table 7-1. FTIR Empirically Determined Field Detection Limits for C_2F_6 and CF_4

Species	Quant Region NEA_{RMS} (abs units)	$A_{refpeak}$ (abs units)	Instrumental detection limit (ppbv)	Analytical Method MDC[(a)] (ppbv)
C_2F_6	1.46×10^{-5}	0.0034	0.22	0.62
CF_4	8.07×10^{-5}	0.0245	0.17	0.60

Notes:
(a) This minimum detectable concentration (MDC) evaluation of dataset 1B corresponds to the MDC #3 determination of analytical algorithm errors per ASTM D6348-12 Section A2.3.
NEA_{RMS} = root mean square value of the noise equivalent absorbance
$A_{refpeak}$ = absorbance of the reference peak

8 Exhaust Emissions Sampling

8.1 Overview

The exhaust emissions sampling was conducted by ATG. The ATG Source Testing Report is presented in H. Samples were collected from a vertical duct on the discharge side of the packed scrubber. During Runs 1A, 2A, and 3A, the exhaust emissions sampling was conducted using the following methods:

- OTM-45
  Semi-volatile polar PFAS (49 target analytes)

- Method 0010
  Semi-volatile non-polar compounds (106 non-PFAS target analytes, plus a characterization of unknowns)

- OTM-50
  Volatile nonpolar PFAS (30 target analytes) plus characterization of unknowns

During Runs 1B, 1C, 2B, 2C, 3B, and 3C, the exhaust emissions sampling was conducted using OTM-50.

8.2 Stack Sampling Methods — EPA Methods 1, 2, 3A, and 4

Each run also included the use of EPA Method 1 (Sample and Velocity Traverses for Stationary Sources), EPA Method 2 (Determination of Exhaust Emissions Velocity and Volumetric Flow Rate), EPA Method 3A (Determination of Oxygen and Carbon Dioxide Concentrations), and EPA Method 4 (Determination of Moisture Content in Exhaust Emissions). Descriptions of EPA Methods 1, 2, 3A, and 4 are presented below.

8.2.1 EPA Method 1 — Sample and Velocity Traverses for Stationary Sources

EPA Method 1 was used to assure that representative measurements of volumetric flow rates were obtained by dividing the cross-section of the stack into perpendicular transects and then locating a traverse sampling location point at intervals along each transect. Acceptable sample location points were located at least two stack equivalent diameters downstream from a flow disturbance and one-half equivalent diameter upstream from a flow disturbance. Acceptable cyclonic flow conditions were confirmed prior to testing using EPA Method 1, Section 11.4.

8.2.2 EPA Method 2 — Determination of Exhaust Emissions Velocity and Volumetric Flow Rate

EPA Method 2 was used to measure the exhaust emissions velocity with an S-type pitot tube connected to a differential pressure measurement device, and to measure the exhaust emissions temperature using a calibrated thermocouple connected to a thermocouple readout indicator. Type-S pitot tubes conforming to the geometric specifications in the test method were used, along with an inclined manometer. The measurements were made at the traverse points specified by EPA Method 1. The molecular weight of the gas stream was determined from independent measurements of O_2, CO_2, and moisture content. The exhaust emissions volumetric flow rate was calculated at the measurement plane using the average square root of the velocity head, the area of the stack at the measurement plane, the

average temperature, the stack static pressure, the molecular weight of the gas stream, and the moisture content.

8.2.3 EPA Method 3A — Determination of Oxygen and Carbon Dioxide Concentrations

EPA Method 3A is an instrumental method used to measure the concentration of O_2 and CO_2 in the exhaust emissions, and nitrogen was then calculated by difference. Data was collected online with a continuous emissions monitoring system and reported in 1-minute averages. The sampling system consisted of a stainless-steel probe, Teflon sample line, gas conditioning system, and gas analyzer. The gas conditioning system was a non-contact condenser used to remove moisture from the exhaust emissions. A portable non-contact condenser was placed in the system directly after the probe. The performance requirements of the method were met to validate data.

8.2.4 EPA Method 4 — Determination of Moisture Content in Exhaust Emissions

EPA Method 4 is a manual, non-isokinetic method used to measure the moisture content of gas streams. Gas was sampled at a constant sampling rate through a probe and impinger train. Moisture was removed using a series of pre-weighed impingers containing methodology-specific liquids and silica gel immersed in an ice water bath. The impingers were weighed after each run to determine the percent moisture. Independent Method 4 samples were collected in conjunction with each sampling train (OTM-45, OTM-50, Method 0010).

8.3 EPA OTM-45 Sampling and Analysis

The OTM-45 sampling train was operated to collect samples during Runs 1A, 2A, and 3A. PFAS spiking was being conducted and AFFF was being fed during these runs. The process data and stack testing data during these runs were used to calculate exhaust emissions rates and to perform a PFAS mass balance for the entire incineration system. The data were also used to calculate DRE and DE for EPA Method 1633 target analytes.

8.3.1 OTM-45 Sampling Method Description

EPA OTM-45 uses an extractive isokinetic sampling method to collect semi-volatile polar PFAS in the exhaust emissions. Semi-volatile polar PFAS are defined as compounds with boiling points greater than 100°C. Gaseous and particulate pollutants were withdrawn from the emission source at an isokinetic sampling rate and collected in a multicomponent sampling train.

The principal components of the train included a high-efficiency, quartz-fiber filter to collect organic-laden particulate, an XAD-2 sorbent trap, a set of chilled impingers, and a breakthrough (BT) XAD-2 sorbent trap located after the impingers and before the last impinger containing silica gel desiccant. XAD-2 is the tradename for hydrophobic copolymers of styrene-divinylbenzene resin. The purpose of the BT XAD-2 sorbent trap is to collect PFAS that pass through the other components of the sampling train. Specific components of the exhaust emissions sampling train included:

- Glass nozzle
- Heated, glass-lined probe
- Heated quartz filter in filter holder with a silicon O-ring seal

- Ice water cooled condenser
- XAD-2 sorbent trap with cooling jacket
- Short-stem knockout impinger in ice water bath
- Three impingers with 100 milliliters (mL) deionized (DI) water in an ice water bath
- BT XAD-2 sorbent
- Trap with cooling jacket
- Impinger containing 200 g of silica gel desiccant
- Ground glass connections for impingers
- O-rings to seal connections for all ball joints
- Vacuum sampling pump
- Calibrated dry gas meter to measure the collected sample volume

A schematic of the OTM-45 sampling train as implemented by ATG is shown on Figure 8-1.

After a sampling run was completed, the probe was removed from the sample train and the open outlet was capped. The filter inlet, the filter-holder outlet, and inlet to the XAD-2 sorbent trap were capped with certified PFAS free aluminum foil (foil). The XAD-2 sorbent trap was separated from the condensate knockout trap and the openings were capped with foil or parafilm. The impingers and both XAD-2 sorbent traps were weighed to determine moisture. The particulate filter was removed from the filter holder, folded or rolled with the particulate on the inside, and placed in an HDPE sample container. Any residual particulate matter on the glass nozzle, probe liner, or front half of the filter holder was recovered by brushing and rinsing these sample train components three times with a 95 percent methanol (MeOH)/5 percent ammonium hydroxide (NH_4OH) solution and collecting the rinse solution into an HDPE bottle. The XAD-2 sorbent traps were capped, and all recovered samples were immediately placed in coolers and kept on ice. The back-half of the filter holder, coil condenser and connecting glassware were rinsed three times with 95 percent MeOH/5 percent NH_4OH solution and collecting the rinse solution into an HDPE bottle. The condensate and impinger water were combined in a 1-liter HDPE bottle.

The ATG SOP for the PFAS OTM-45 exhaust emissions sampling includes detailed protocols for the following procedures:

- Stack sampling equipment and glassware cleaning procedures (in laboratory prior to field deployment)
- Laboratory preparation of sampling media (i.e., XAD-2 sorbent traps, particulate filters, MeOH/5 percent NH_4OH impinger solution, and DI water)

- Prevention of cross-contamination from equipment that previously may have been used to sample PFAS or sources (i.e., isolation of sampling equipment, use of new storage coolers, new containers, proper selection of consumables, etc.)

- Avoiding materials of construction that may contain fluoropolymers (i.e., Viton O-rings, Teflon filter frits, or other fluoropolymers items)

- Packaging procedures to ensure the cleanliness of equipment was maintained during shipping and transport to the field.

8.3.2 OTM-45 Sample Analysis & Results

At the end of the field testing program, the OTM-45 samples were packaged and preserved in coolers. Request for Analysis/Chain of Custody forms were placed in the cooler and the cooler was transferred to the Eurofins courier. The Eurofins courier delivered the OTM-45 samples under strict chain of custody to the Eurofins laboratory in Knoxville, Tennessee. The Eurofins Knoxville laboratory was responsible for analyses of all OTM-45 samples and for reporting final analytical results. Samples were analyzed by LC/MS/MS. The analytical results for this project, including the laboratory QC procedures, are provided in the Eurofins Analytical Report in Appendix J-2.

Detailed OTM-45 analytical results are presented in tables in Appendix A-1. These tables include the analytical results, MDL, data qualifier flags applied by the laboratory, and data qualifier flags applied by the data validator. A summary of emission concentrations for Runs 1A, 2A, and 3A is presented in Table 8-1.

8.3.3 OTM-45 QA/QC Samples

OTM-45 field sampling and analysis data quality was assessed using a variety of QA/QC procedures, including collection and analysis of the following types of field QA/QC samples:

- Sampling train proof blank (STPB)

- Glassware proof blank

- Field sample media blanks (FSMB)

The following types of laboratory QA samples were also analyzed:

- Laboratory media checks

- Laboratory method blanks

- Laboratory control samples (LCSs)

- Laboratory control sample duplicates (LCSDs)

Summaries of OTM-45 field sample QA/QC data and OTM-45 laboratory sample QA/QC data are presented in Section 9. Section 9 also provides a detailed discussion of the purpose of each type of QA/QC sample, along with the corresponding analytical results and related sample data.

8.3.4 Results Summary

Nineteen PFAS were detected in one or more exhaust emissions samples; concentrations were all non-detect for the remaining 30 compounds. Exhaust emissions concentrations were calculated for 147 data points (49 compounds times three runs). Figure 8-2 presents a frequency distribution of measured stack emission concentrations. Approximately 69 percent of targeted PFAS results were non-detect and approximately 96 percent had concentrations less than 10 nanograms per cubic meter (ng/m^3) for individual analytes.

One compound, HFPO-DA, had a stack emission concentration ranging from 107 to 2,223 nanograms per dry standard cubic meter (ng/dscm). However, the total contamination in the sampling train proof blank was 31.52 nanograms. Therefore, it is plausible that this analyte is contamination from an external source and not derived from the incinerator off-gas.

HFPO-DA emission results from HWI have historically been inconsistent. Another HWI study also reported HFPO-DA in emissions under different equipment design and process operating conditions (Hofman et al. 2025). However, two previous test programs in June of 2021 and February of 2022 at the CHES Aragonite incinerator produced HFPO-DA exhaust emissions concentrations of <0.23 ng/dscm at 7 percent O_2 and <7.21 ng/dscm, respectively (Crisenbery et al. 2024). Recent tests conducted by Veolia North America at an HWI in Port Arthur Texas also reported non-detect levels of HFPO-DA in stack emissions (Veolia 2025). The inconsistency in measured HFPO-DA emissions suggests that the presence or absence of HFPO-DA in emissions can be system dependent and/or the result of background contamination from sampling or analysis activities. The historical data lends credence to the conclusion that the emissions measured during the most recent CHES test were derived from an external source of contamination.

Appendix K, HFPO-DA Data Analysis, describes the analytical results and data evaluation procedures that are used to come to this conclusion. In addition to the test results described above, there are several other lines of evidence to support this conclusion:

- HFPO-DA is thermally unstable and decarboxylates at 194°F (Ryan 2019)
- Pilot scale tests in the EPA Rainbow Furnace indicate that HFPO-DA is destroyed at >99.99 percent efficiency at 1,382°F, the lowest temperature that was tested. (Weber, 2025). The operating temperatures in both the rotary kiln and afterburner during the Clean Harbors tests were in excess of 2,000°F.
- Chemical kinetic models indicate that HFPO-DA is much less thermally stable than PFOA and that other shorter chain PFCAs decompose at roughly the same temperature as PFOA (Blotevogel et al. 2023).
- If the HFPO-DA were not destroyed in the incinerator, other thermally stable compounds would also have been expected in the exhaust emissions at similar or higher concentrations. The other eight spiked PFAS compounds (with one exception for PFBA on Run 1A) had exhaust emissions concentrations of <5 ng/dscm 7 percent O_2 as shown in Table 8-1.
- HFPO-DA was not detected in any emission control system process residual stream (spray dryer solids, baghouse dust, or brine).

- HPFO-DA is highly soluble in water (739 grams per liter) (EPA 2022). If it were present in the process gas entering the emission control system, it would be efficiently removed in the packed scrubber. No HFPO-DA was detected in the packed scrubber brine.

Appendix K presents a detailed discussion of the steps that were taken to investigate the magnitude of the HFPO-DA emissions. Several approaches were taken to attempt to identify potential sources of HFPO-DA contamination:

- Analysis of OTM-45 sample data and QA data
- Analysis of rinses from graduated glass cylinders used in OTM-45 sample preparation
- OTM-45 sample extracts confirmation analysis by a second laboratory
- Post test analysis of samples of the wet scrubber packing materials
- Post test analysis of wipe samples collected on scrubber internal walls
- Post test analysis of new baghouse bag materials
- Post test analysis of OTM-45 sampling train O-rings and filter holders

Discussions of the results of each of these analyses are presented in Appendix K.

10.0-15.0 ng/dscm	2	1.4	97.3
15.0-25.0 ng/dscm	1	0.7	98.0
>25.0 ng/dscm	3	2.0	100.0
Total	147	100.0	

Figure 8-2. Summary of Other Test Method (OTM) 45 Exhaust Emissions Emission Concentrations

8.4 EPA OTM-50 Sampling and Analysis

OTM-50 samples were collected under all three test conditions. During Runs 1A, 2A, and 3A, OTM-50 sample results were available to identify and quantify PIDs produced when significant amounts of PFAS and precursor compounds were being fed to the incinerator, including the nine spiked PFAS and AFFF.

Runs 1B, 2B, and 3B were conducted with normal waste feed conditions, with no PFAS spiking or AFFF waste feed. These B-labeled runs afforded baseline C_2F_6 emission rates to be subtracted from measured C_2F_6 exhaust emissions during Runs 1C, 2C, and 3C when C_2F_6 was being spiked into the unit. This baseline adjustment is necessary to determine the inherent emission rates for C_2F_6 from the spiked C_2F_6.

Runs 1C, 2C, and 3C were conducted with normal waste feed conditions, plus C_2F_6 spiking to provide data to determine DRE for C_2F_6.

8.4.1 OTM-50 Sampling Method Description

EPA OTM-50 uses an extractive non-isokinetic sampling train to collect volatile PFAS exhaust emissions. A gas sample is withdrawn from the emission source, passed through a series of four chilled midget impingers to condense moisture and remove acid gases, and then collected in two evacuated ceramic-coated (Silonite™) canisters, each equipped with a critical orifice. After sample collection, any condensate collected in the impingers is discarded. One canister was analyzed by Eurofins and the second canister was analyzed by EPA ORD. The specific components of the sampling train included:

- Inert coated stainless steel or glass-lined heated probe
- Hot box and particulate matter filter
- Ice water bath with three impingers with 15 mL DI water and one empty impinger
- Critical orifices (two)
- Ceramic-coated (Silonite™) canisters (two)
- Bypass vacuum pump

A schematic of the OTM-50 sampling train with two canisters is shown in Figure 8-3.

The two canister samples for each run are normally collected simultaneously during approximately a 1-hour sampling period. The initial plan was to use flow controllers for the Eurofins canisters and critical orifices for the EPA canisters. However, during Run 1B, the Eurofins canister did not collect a significant amount of sample while the EPA canister received sufficient exhaust emissions for the sampling run. Therefore, this run was labeled Run 1B-1 and the EPA canister was retained but the Eurofins canister was voided. A second Eurofins canister was then fitted with a critical orifice to collect the canister sample for analysis by Eurofins. The run was repeated and labeled Run 1B-2. Because the two canisters were not collected concurrently, they are not considered duplicates. Critical orifices were used to collect all other OTM-50 samples.

8.4.2 OTM-50 Sample Analysis and Results

At the end of the field test program, the Eurofins canisters from all runs were transferred to the Eurofins courier, along with Request for Analysis/Chain-of-Custody forms. The Eurofins courier delivered OTM-50 under strict chain of custody to the Eurofins laboratory in Knoxville, Tennessee. The Eurofins Knoxville laboratory was responsible for analyses of these OTM-50 sample canisters and reporting final analytical results. Samples were analyzed by gas chromatography/mass spectroscopy by the OTM-50 canister method. All analytical results and laboratory QC procedures are documented in the Eurofins Analytical Report in Appendix J-3. The Eurofins sample canisters were diluted at the dilution factors shown in Appendix J-3 prior to analysis.

The second canister from each run was retained by EPA personnel and shipped by FedEx to the EPA laboratory in Research Triangle Park, North Carolina, for analysis.

A comparison of emission concentrations of the Eurofins and EPA analytical data sets for Runs 1A, 1B, and 1C are presented in Table 8-2. A comparison of emission concentrations based on the Eurofins and EPA analytical data sets for Runs 2A, 2B, and 2C is presented in Table 8-3. A comparison of emission concentrations based on the Eurofins and EPA analytical data sets for Runs 3A, 3B, and 3C is presented in Table 8-4.

Eurofins results for all analytes were below the MDL for both the pre-test and post-test blank samples. EPA results for all but two analytes were below the MDL for both the pre-test and post-test blank samples. Chlorodifluoromethane and trichlorofluoromethane were reported at concentrations slightly above the detection limit. The pre-test and post-test blank data are presented in Section 9.

Detailed OTM-50 sample analytical results from the Eurofins laboratory are summarized in Appendix A-2, Tables A-2-5. The results of the Eurofins analyses are non-detect for all thirty target analytes for all nine runs. Eurofins' OTM-50 unknowns analysis did not identify any other fluorinated compounds. These tables include MDLs reported on both an undiluted and diluted sample basis. Table A-2-6 presents the analytical results, MDLs, data qualifier flags applied by the laboratory, data qualifier flags applied by the data validator, and the exhaust emissions rates.

Detailed OTM-50 sample analytical results from the EPA laboratory are summarized in Appendix A-2 and Table A-2-7. Table A-2-8 presents the analytical results, the MDLs, and stack emission rates. No data qualifier flags were applied by the EPA laboratory and the data were not independently validated. EPA analyses produced MDLs that were slightly lower than the MDLs reported by Eurofins for all but three target compounds. As shown in Tables 8-2 through 8-4, EPA analyses detected six compounds in one or more runs above the detection limit but below the reporting limit. Two of the compounds, chlorodifluoromethane (R-22) and trichlorofluoromethane (R-11), are common refrigerants in the atmosphere, were in the pre-test and post-test blanks at similar concentrations as the actual samples and were likely in the gas used to pressurize the canisters. The EPA's OTM-50 unknowns analysis did not identify any other fluorinated compounds.

CF_4, which has high thermal stability, was not detected in two of the EPA samples but was detected in the other seven EPA samples at low concentrations ranging from 1.64 to 6.31 µg/m^3. The highest CF_4 concentrations (3.35 to 6.31 µg/m^3) were measured during Runs 1A, 2A and 3A when PFAS were being spiked and AFFF was being fed. The second highest concentrations (1.64 to 3.83 µg/m^3) were measured during Runs 1C, 2C and 3C when C_2F_6 was being spiked. The lowest concentrations (<0.93 to 3.70 µg/m^3)

were measured during Runs 1B, 2B and 3B when no AFFF was being fed, no PFAS was being spiked, and no C_2F_6 was being spiked.

8.4.3 OTM-50 QA/QC Samples

OTM-50 field sampling and analysis data quality was assessed by collecting both pre-test and post-test blank samples. The pre-test blank is collected with a laboratory cleaned set of glassware, filter housing, and probe. The post-test blank is collected with a set of glassware, filter housing and probe that has been used during the project and field cleaned. These results are presented in Section 9. Concentrations of all analytes were below the MDL except for chlorodifluoromethane and trichlorofluoromethane in the EPA pre-test sample.

Eurofins also reported results for laboratory method blanks which are presented in Section 9. The concentrations of all analytes in the method blank were below the MDL.

8.4.4 Results Summary

Eurofins analytical results of the 30 target analytes from all nine runs were non-detect. Values for the non-detect results are reported using the MDL. MDL values reported by EPA are, on average, about four times lower than those reported by Eurofins. EPA reported hits near the detection limits and below the reporting limits for several compounds. Several of the compounds are common refrigerants that may have been in the compressed air cylinders used to pressurize the canisters, as they were also in blanks. The presence of CF_4 near the detection limit provides some evidence of the production of a PID from the high concentrations of PFAS added to the kiln. The analysis of unknowns did not detect any fluorinated compounds.

8.5 Method 0010 Sampling and Analysis

A Method 0010 (EPA 1986) sampling train was used to collect semi-volatile non-polar compounds which could potentially have been produced as PIDs.

8.5.1 Method 0010 Sampling Method Description

Method 0010 uses an extractive isokinetic sampling train to collect semi-volatile non-polar compounds in the exhaust emissions. Semi-volatile compounds are defined as those with boiling points greater than 100°C. Gaseous and particulate compounds are withdrawn from the emission source at an isokinetic sampling rate and collected in a multicomponent sampling train.

The principal components of the train included a high-efficiency, quartz-fiber particulate filter to collect organic-laden particulate, an XAD-2 sorbent trap, and a set of chilled impingers charged with 100 mL of DI water. Specific components of the exhaust emissions sampling train include:

- Glass nozzle
- Heated, glass-lined probe
- Temperature sensor
- Pitot tube
- Manometer
- Heated quartz filter in filter holder with silicon O-ring seal
- Ice water cooled condenser
- XAD-2 sorbent trap, with cooling jacket
- Short-stem knockout impinger in ice water bath
- Three impingers with 100 mL DI water in an ice water bath
- Impinger containing 200 g of silica gel desiccant
- Ground glass connections for impingers
- O-rings to seal connections for all ball joints
- Vacuum sampling pump
- Calibrated dry gas meter to measure the collected sample volume

A schematic of the Method 0010 sampling train is shown on Figure 8-4.

After a sampling run was completed, the probe was removed from the sample train and the open outlet was capped. The filter inlet, the filter-holder outlet, and inlet to the XAD-2 sorbent trap were capped

with aluminum foil. The XAD-2 sorbent trap was separated from the condensate knockout trap and the openings were capped with aluminum foil. The impingers and XAD-2 sorbent trap were weighed to determine moisture. The particulate filter was removed from the filter holder, folded or rolled with the particulate on the inside, and placed in a glass petri dish. Any residual particulate matter on the glass nozzle, probe liner, or front half of the filter holder was recovered by brushing and rinsing these sample train components three times with acetone, followed by brushing and rinsing three times with methylene chloride. The rinse solutions were combined into an amber glass bottle. The back-half of the filter holder, coil condenser and connecting glassware were rinsed three times with acetone and three times with methylene chloride. The rinses were combined and placed in an amber glass bottle. The condensate and impinger water were combined in a 1-liter amber glass bottle. All impingers and connecting glassware prior to the silica gel impinger are rinsed three times with ultra filtered DI water and added to the same bottle. The impingers and glassware are rinsed three times with acetone and three times with methylene chloride and the rinses were placed in a separate amber glass bottle. The silica gel impinger was reweighed to determine moisture. All recovered samples were immediately placed in coolers and kept cold on ice.

The ATG SOP for the SW-846 Method 0010 exhaust emissions sampling includes detailed protocols for the following procedures:

- Stack sampling equipment and glassware and ancillary tools cleaning procedures (in laboratory prior to field deployment)
- Prevention of cross-contamination from equipment that previously may have been used to sample other sources (i.e., isolation of sampling equipment, field cleaning of sampling equipment, use of new coolers and consumables, proper selection of consumables, etc.)
- Avoiding, to the extent possible, materials of construction that may contain fluoropolymers (i.e., Viton O-rings, Teflon filter frits, or other fluoropolymers items)
- Packaging procedures to ensure the cleanliness of equipment was maintained during shipping and transport to the field.

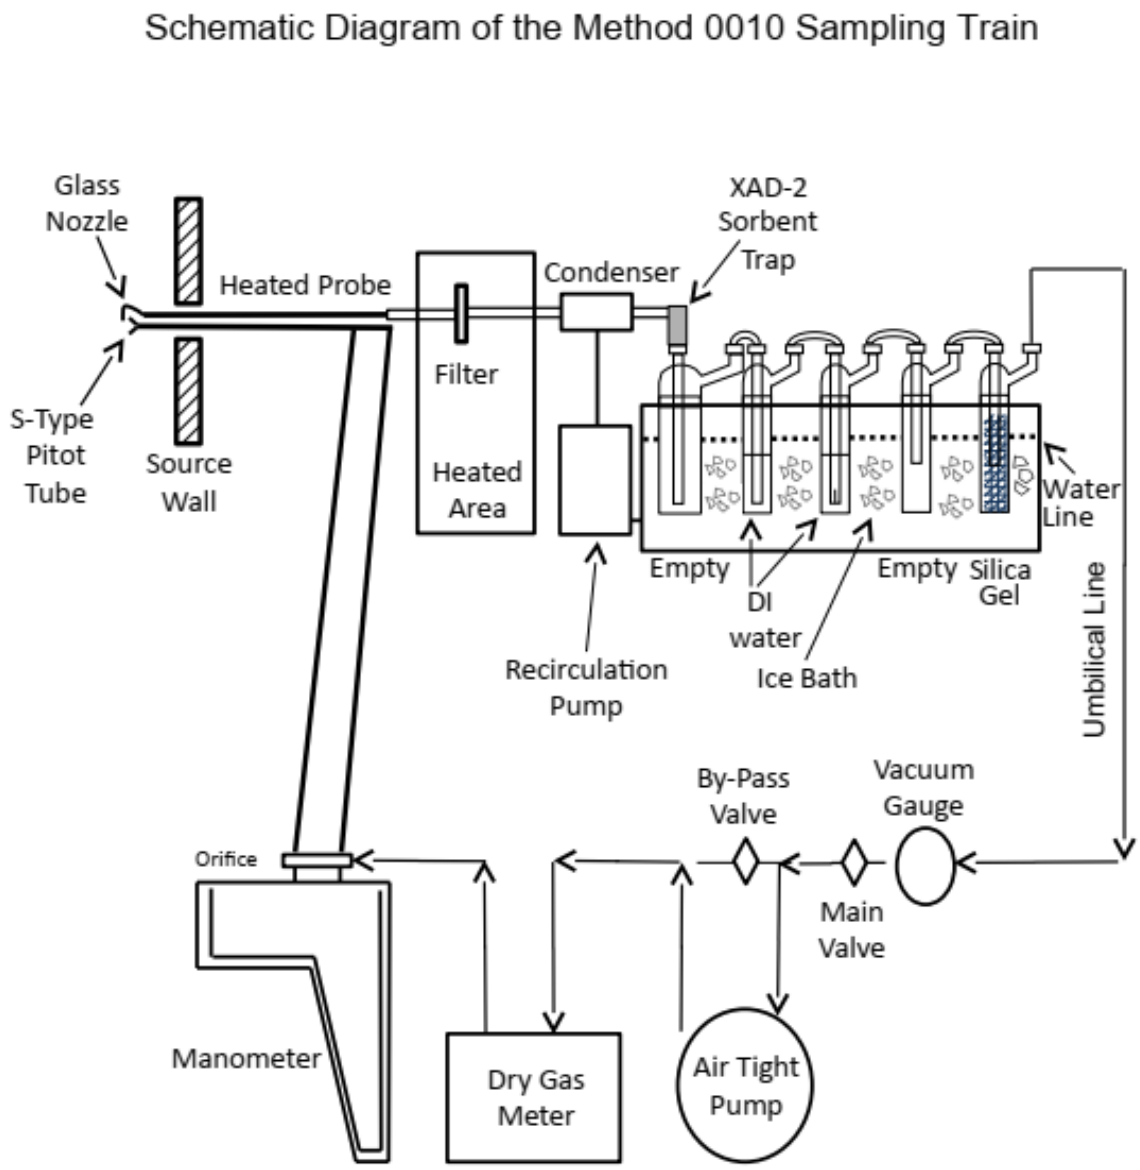

Figure 8-4. SW-846 Method 0010 Sampling Train

8.5.2 Method 0010 Sample Analysis and Results

At the end of the test program, the Method 0010 samples were packaged and preserved in coolers. Request for Analysis/Chain-of-Custody forms were placed in the cooler and the cooler was transferred to the Eurofins courier. The Eurofins courier delivered Method 0010 samples under strict chain of custody to the Eurofins laboratory in Knoxville, Tennessee. The Eurofins Knoxville laboratory was responsible for the analyses of all Method 0010 samples and reporting final analytical results. Samples were analyzed by gas chromatography/mass spectroscopy by EPA Method 8270C.

All analytical results and laboratory QC procedures and results are documented in the Eurofins Analytical Report in Appendix J-4. Reduced data for the semi-volatile compounds are included in Appendix A-3, Table A-3-1 through Table A-3-4. The 8270 analysis only measured N-Nitrosodimethylamine above the reporting limit. Of the handful of compounds detected above the detection limit, phenol was the only compound observed in all three runs. No fluorinated unknown compounds were observed.

8.5.3 Method 0010 QA/QC Samples

Method field sampling and analysis data quality was assessed using a variety of QA/QC procedures, including collection and analysis of the following types of field QA/QC samples:

- Proof blank train
- Reagent blanks (filter, XAD-2 sorbent trap, methylene chloride, acetone, DI water)

The analytical results for the proof blank train are discussed in Section 9.2.2.2.3.

The following types of laboratory QA samples were also analyzed:

- Laboratory media checks
- Laboratory method blanks
- LCSs (not summarized)
- LCSDs (not summarized)

Analytical results for all analytes in laboratory media checks and method blanks were non-detect. All Method 0010 QA data are summarized in the Eurofins analytical reports in Appendix J-4.

8.5.4 Results Summary

No fluorinated PIDs were identified by the Method 0010 analysis.

9 Data Quality and Usability

9.1 Overview

This section of the report is an evaluation at the conclusion of data collection activities, which uses the results from data validation with context of the overall project decisions and objectives. Using both quantitative and qualitative methods, the assessment determines whether project execution and the resulting data have met project QA objectives. Both sampling and analytical activities are considered to assess whether the collected data are of the right type, quality, and quantity to meet project objectives.

Data quality indicators (DQIs) (representativeness, comparability, precision, accuracy, completeness) are important components in assessing data usability. These DQIs are evaluated in the subsequent sections. The results of the evaluation demonstrate that the data presented in this report are of high quality overall. A small subset of data was qualified to indicate uncertainty due to analytical quality issues, as described below. The Data Validation Reports in Appendix L present explanations for all qualified data in greater detail. QA/QC measures for each sampling and analytical method are discussed separately in the following sections, with dedicated subsections addressing process and exhaust emission samples for each DQI.

9.2 Sampling Data Quality Review

This section presents an evaluation of sampling data quality as part of the overall data usability assessment. This evaluation incorporates results from field QA/QC procedures, considering both process and stack sampling activities.

9.2.1 Bias

Bias is a measure of confidence in a measurement. The smaller the difference between the measurement of a parameter and its true or expected value, the more accurate the measurement and the less bias present. The more precise or reproducible the result, the more reliable the result.

9.2.1.1 Process Samples

Accuracy of field sampling for process samples was evaluated through the analysis of one equipment blank associated with spray dryer solids and disposable funnels for liquid process samples for Runs 1A, 2A, and 3A.

As shown in Table 9-1, five PFAS were detected in the equipment blank made by rinsing the sampling equipment (sieve) with 134.2 mL of DI water: HFPO-DA (1.9 ng/L), PFOS (2.16 ng/L), PFHxA (0.931 ng/L), PFOA (0.786 ng/L), and PFBA (1.77 ng/L). Among these, only PFOS was detected in the spray dryer solids sample, at a concentration of 0.35 ng/g. Assuming that the entire PFOS mass from the equipment blank transferred to the 4,594 g spray dryer solids sample, the contribution would equate to a negligible fraction relative to the measured value. None of the other PFAS detected in the blank were observed in the spray dryer solids sample. As such, the data indicated no significant impact from equipment blank contamination, and the field sample results for process samples are considered accurate and reliable. While not shown here in detail, similar results were observed for equipment blanks from Runs 2A and 3A, supporting consistent and reliable sampling performance across all events.

For liquid process samples, disposable funnels were used, with a new funnel dedicated to each individual sample to prevent cross-contamination. One funnel was selected and rinsed as a representative equipment blank to assess potential background PFAS contributions. Two PFAS—PFNA (3.01 ng/L) and PFUnA (0.814 ng/L)—were detected in the funnel rinse blank (Table 9-2). PFNA was subsequently detected in waste blend liquid, aqueous liquid, tote (educt station #2), and corrosive waste, while PFUnA was detected in tote (educt station #2) and corrosive waste.

Table 9-1. EPA 1633 Sampling Equipment (Sieve) Blank QA/QC Data Summary

9.2.1.2 Exhaust Emission Samples

Exhaust emissions samples were collected and analyzed to evaluate the presence of PFAS in emissions and assess potential sampling-related contamination.

9.2.1.2.1 OTM-45

Multiple QC blanks were included in accordance with OTM-45 protocols to verify the accuracy and integrity of the field sampling procedures during Runs 1A, 2A, and 3A. Accuracy of field sampling for exhaust emissions samples was evaluated through the collection and analysis of multiple QC blanks, including STPBs, Glassware Proof Blanks, and FSMBs, during Runs 1A, 2A, and 3A. These blanks were used to assess potential contamination from sampling equipment, glassware, reagents, and field procedures, in accordance with OTM-45 method protocols.

9.2.1.2.1.1 Sample Train Proof Blank

The definition of a STPB from OTM-45 Section 3.32 is as follows:

> "Sampling Train Proof Blank. The complete field assembly and recovery of a clean OTM-45 sampling train without actual sampling, including bringing the train to sampling location, heating, and leak checks. The STFB is conducted using clean glassware that has not been previously used for exhaust emissions sampling as part of the current field test. The purpose of the STPB is to determine if method analytes or other interferences are introduced into the sample from the clean, unused sample train glassware, train assembly, preparation, and recovery, including the field environment."

As shown in Table 9-3, 10 compounds were detected in the STPB. PFHpA, PFOA, PFBS, and HFPO-DA were the only PFAS with concentrations measured over the reporting limit, as presented in the Eurofins analytical report in Appendix J-2. Details of the impacted samples and the full range of PFAS concentration ratios—calculated as detected levels in the samples divided by the corresponding detected STPB values—is provided in Table 9-4.

9.2.1.2.1.2 Glassware Proof Blank

A glassware proof blank consists of a solvent rinse of a set of sampling train glassware prior to its use in the field. All analytes in the glassware proof blank were non-detect.

9.2.1.2.1.3 Field Sample Media Blanks

The FSMB includes the sampling media (i.e., particulate filter, XAD-2 sorbent trap and reagents (95 percent MeOH/5 percent NH_4OH rinsing solvents and DI water) associated with the field sample collection and recovery. These samples are treated as actual samples in all respects, including shipment to the sampling site, exposure to sampling site conditions, sample storage, and processing by all of the same analytical procedures. The purpose of the FSMB is to determine if target analytes or other interferences are introduced into the sample media from shipping, storage, and the field environment and procedures. As shown in Table 9-3, for the filter media and 95 percent MeOH/5 percent NH_4OH media blanks, all analytes are reported as non-detect. There were three target compounds (PFDoA [0.281 ng/sample], PFBS [2.010 ng/sample], and PFOS [0.555 ng/sample]) reported in the XAD-2 sorbent trap. One target analyte (HFPO-DA) was reported at 0.842 ng/sample for the DI water.

PFDoA concentrations in Runs 1A and 3A were approximately twice those observed in the blanks, while the levels in Run 2A were about six times higher than the sum of the fractions in the FSMB. PFBS concentrations were up to three times higher for Runs 1A, 2A, and 3A than the sum of the fractions in the FSMB. PFOS levels were generally comparable to the blanks, ranging from 30 to 90 percent higher than the sum of the fractions in the FSMB.

9.2.1.2.1.4 Stack Sampling QA/QC

A number of stack sampling QA/QC procedures were used, and are described in Appendices B, C, D and E of the ATG Test Report in Appendix F. These procedures were applicable to measuring exhaust emissions flow rates for OTM-45, OTM-50, and Method 0010. They include performing leak and temperature checks as required by the sampling method, using certified calibration gases for O_2 and CO_2

continuous emissions monitors, verifying CEM system response times, and performing bias/drift determinations.

9.2.1.2.2 OTM-50

Accuracy of OTM-50 field sampling was assessed through background determinations, system purging, and field and laboratory sample integrity checks conducted in accordance with the method. Accuracy was measured by analyzing pre-test and post-test blanks. As shown in Table 9-5, chlorodifluoromethane and trichlorofluoromethane were both detected in the EPA pre-test blank at concentrations similar to those observed in actual samples. Results from analysis of all target analytes were not detected in the Eurofins pre-test and post-test blanks or the method blank.

9.2.1.2.3 Method 0010

Multiple QC blanks were included in accordance with Method 0010 protocols to verify the accuracy and integrity of the field sampling procedures during Runs 1A, 2A, and 3A. Accuracy of field sampling for exhaust emissions samples was evaluated through the collection and analysis of multiple QC blanks, including proof blanks and reagent blanks. These blanks were used to assess potential contamination from sampling equipment, glassware, reagents, and field procedures in accordance with Method 0010 protocols.

9.2.1.2.3.1 Proof Blank

A Method 0010 proof blank was collected by the complete field assembly and recovery of a clean Method 0010 sampling train without actual sampling, including bringing the train to sampling location, heating, and leak checks. The proof blank was conducted using clean glassware that had not been previously used for exhaust emissions sampling as part of the current field test. The purpose of the STPB is to determine if method analytes or other interferences are introduced into the sample from the clean, unused sample train glassware, train assembly, preparation, and recovery, including the field environment. Proof blank samples included the filter, front half solvent rinse, XAD-2 sorbent trap, back half solvent rinse, and impinger solvent rinse. Three detections were recorded on the blank train: di-n-butyl phthalate at 3.59 micrograms per sample (µg/sample) in the filter and front half solvent rinse, acetophenone at 10.8 µg/sample in the XAD-2 sorbent trap and solvent rinse, and phenol at 3.71 µg/sample in the XAD-2 sorbent trap and solvent rinse. All other analytes in blank train sample fractions were non-detect.

9.2.1.2.3.2 Reagent Blanks

Reagent blanks were analyzed for the filter, methylene chloride, acetone, DI water, and XAD-2 sorbent trap. Analytical results for all target analytes for all reagent blank samples were non-detect.

9.2.2 Precision

Precision is the degree of agreement among repeated measurements of the same characteristic on the same sample or on separate samples collected as close as possible in time and place. Field sampling precision is measured with the field duplicate relative percent differences (RPDs), and laboratory precision is measured with RPDs for laboratory duplicates, such as MS and MSD pairs.

9.2.2.1 Process Samples

Field duplicate process samples were collected for Runs 1A, 2A, and 3A to assess the overall sampling and measurement precision for this sampling effort. While most of the field duplicate process samples were within the precision limits of RPD less than or equal to 30 percent (for results greater than five times the reporting limit) or differences less than the value of the reporting limit (Appendix J-1), there were seven occasions where RPDs exceeded the limit up to 50 percent for some analytes.

9.2.2.2 Exhaust Emission Samples

No field duplicate samples were collected for exhaust emissions sampling; therefore, field sampling precision for exhaust emission samples could not be directly evaluated using RPDs.

9.3 Laboratory Analytical Data Quality Review

This section presents a detailed evaluation of the laboratory analytical data quality to determine whether the PFAS results generated during the study meet project data quality objectives. The assessment integrates findings from laboratory QA/QC measures including method blanks, LCS/LCSD, MS/MSD, surrogate recoveries, and isotope dilution standards to evaluate accuracy, precision, completeness, representativeness, and comparability of the data. Results were reviewed against method-specific acceptance criteria, with qualifiers applied to indicate any deviations. Subsections below address each data quality indicator individually, with separate evaluations for process and exhaust emission samples across all laboratory methods used in this study.

9.3.1 Accuracy

Accuracy of laboratory analytical data is measured through percent recoveries in calibration verification samples, laboratory control samples including method blanks, LCSs, LCSDs, MS/MSDs, and through isotope dilution standards.

9.3.1.1 Process Samples

For process samples, eight method blanks were prepared and analyzed. Method blanks were non-detects.

LCSs were analyzed for each analytical batch and demonstrated that the analytical system was in control during sample preparation and analysis, with the following exceptions. There was one LCS and two LCSDs which failed with qualifiers. The qualifier for outside acceptance limits low biased is " *- " for LCS and/or LCSD. The qualifier for outside acceptance limits high biased is " *+ " for LCS and/or LCSD. Analytes PFDS, PFNS, 9 Cl-PF3ONS, 11Cl-PF3OUdS, and PFODA had recoveries below acceptance criteria in multiple LCSs and LCSDs associated with process samples. The recoveries for 3:3 FTCA, PFHpS, 5:3 FTCA, ADONA, PFTrDA, PFDoS, and PFHpS were above acceptance limits in the LCS.

MS/MSDs for PFAS analysis were performed on Run 1A process samples. Of the thirteen process sample collection locations, eight locations had multiple analytes with recoveries outside the acceptable limits. A summary of the recoveries is provided in Appendix J-1. The low recoveries indicate that the complex sample matrix may have introduced some uncertainty into the analytical results.

Prior to sample preparation and analysis, isotope dilution standards were added by the laboratory to measure relative responses of target analytes. For a subset of analytes, the recoveries of one or more of these standards were outside the acceptance limits. Though sample cleanup procedures were routinely used, residual interferences due to the complexity of the matrices were the attributed cause. Recoveries outside acceptance limits may be the result of matrix interferences. For analytes with isotope-dilution recoveries of less than 25 percent or over 150 percent, the results for associated target analytes were qualified as estimated and flagged as “J” or “UJ”.

9.3.1.2 Exhaust Emission Samples

This section presents a comprehensive review of the laboratory analytical data quality for exhaust emission samples, evaluated according to the specific analytical methods employed during the study. Each method is assessed for compliance with QA/QC standards, with attention given to any observed deviations and their potential impact on data usability. The subsections include method-specific discussions such as OTM-45, including observations related to calibration checks, ion ratio variances, and qualifier usage. Associated laboratory controls, including media checks and method blanks, are also summarized to assess potential background contamination and confirm the integrity of the analytical process. The goal of this evaluation is to ensure that all reported results meet the required data quality objectives and are suitable for interpretation and reporting.

9.3.1.2.1 OTM-45

Several continuing calibration verifications displayed recoveries outside of the QA criteria for one or more target analytes for the OTM-45 and the process samples. The samples associated with the continuing calibration verification were non-detected for the affected analytes; therefore, the data has been reported. The transition ion mass ratios for PFOS, PFPeA, PFHpS, and/or HFPO-DA in some of the parent samples were outside established limits. The results for these analytes in affected samples were flagged with the qualifier “I”.

9.3.1.2.1.1 Laboratory Media Checks

Laboratory media blanks are samples of sampling media (particulate filter, MeOH/5 percent NH_4OH, DI water, and XAD-2 sorbent trap) that are prepared and archived at the laboratory during the field sample collection campaign. The samples are collected from the same lots of materials that are used for the actual field samples, but they are not taken to the field. The purpose of the laboratory media checks is to identify potential contamination sources in the specific media used to collect field samples.

As shown in Table 9-6, the OTM-45 particulate filter had one detection (PFBS) near the MDL and the XAD-2 sorbent trap had two detections (PFHxA and PFHpA) with concentrations near the MDL. This is in line with previous studies reporting detections in the media blanks for new, clean XAD-2 sorbent traps (Barranco et al. 2020, Gehrmann et al. 2024).

NA = not applicable

9.3.1.3 Laboratory Method Blanks

Laboratory method blanks for OTM-45 are DI water that is run through the analytical process alongside a batch of analytical samples. The purpose of the laboratory method blanks is to identify any potential contamination sources within analytical equipment in the processing of samples. Three method blanks were run in the same analytical batch as parent samples and the results are reported in Table 9-6.

In the first method blank, PFBA was detected at 1.449 ng/sample. The second method blank showed detections for PFHxA and PFHpA at 0.411 and 2.689 ng/sample, respectively. No PFAS were detected in the third method blank. The discussion below addresses how these detections may have impacted the sample results, or if any impacts were observed. The results are reported and no blank subtraction was performed.

PFBA was detected in the impinger portions for Runs 1A, 2A and 3A, at levels ranging from 3.1 ng/sample to 9.4 ng/sample. Additionally, one QA sample (the impinger rinse) contained PFBA at 0.931 ng/sample.

PFHxA was detected in seven samples: 0.397 ng/sample for FH R2A, 0.779 ng/sample in BH R2A, 0.873 ng/sample in impinger R2A, 1.12 ng/sample in impinger R3A, 1.12 ng/sample in BH R1A, 1.66 ng/sample in FH R1A, and 4.16 ng/sample in impinger R1A.

PFHpA was detected in eight samples: 0.837 ng/sample in FH R2A, 2.17 ng/sample in impinger R3A, 2.55 ng/sample in BH R1A, 3.97 ng/sample in BH R2A, 4.06 ng/sample impinger R1A, 6.07 ng/sample in FH R1A, and 6.96 ng/sample in impinger R2A. Of these detections, three sample results — FH R2A, impinger R3A, and BH R1A — were below the method blank level. The remaining five exceeded the method blank, with concentrations ranging from 1.5 times (BH R2A) to approximately 2.6 times (impinger R2A) higher than the method blank.

Three QA samples were also impacted by PFHpA. The media check filter (0.823 ng/sample) and FH proof blank (1.65 ng/sample) were both below the method blank level, while the impinger in proof blank (3.39 ng/sample) exceeded the method blank, with a concentration approximately 1.3 times higher.

9.3.1.3.1 OTM-50

OTM-50 method blanks were performed by analyzing the same nitrogen gas that is used to pressurize the canisters. Analytical results of all method blanks were non-detects.

Pink shading = detected analytical result

9.3.1.3.2 Method 0010

9.3.1.3.2.1 Laboratory Media Checks

Laboratory media blanks are samples of sampling media (particulate filter and XAD-2 sorbent trap) that are prepared and archived at the laboratory during the field sample collection campaign. The samples are collected from the same lots of materials that are used for the actual field samples, but they are not taken to the field. The purpose of the laboratory media checks is to identify potential contamination sources in the specific media used to collect field samples.

All target analytes in both media samples were non-detect.

9.3.1.3.2.2 Laboratory Method Blanks

Each matrix (filter, XAD-2 sorbent trap, and condensate) has its own method blank. The filter method blank is created using filter material from the same batch that was sent to the field. The condensate method blank is created using laboratory DI water. Analytical results for all method blanks were non-detects.

9.3.2 Precision

Precision was evaluated to assess the reproducibility of PFAS measurements in both process and exhaust emission samples. Precision results were compared against the established acceptance criterion of an RPD less than or equal to 30 percent, as detailed below.

9.3.2.1 Process Samples

MS/MSD pairs for the process samples were prepared, analyzed, and reported with the process sample results for PFAS. All MS/MSD recoveries are presented in Appendix J-1. MS/MSD precision met the acceptance criterion of RPD less than or equal to 30 percent for most of the process samples, with some sample locations having RPD of 30 percent for one or more analytes.

Seven LCS and LCSD pairs were analyzed with analytical batches. The corresponding recoveries are presented in Appendix J-2. LCS/LCSD precision met the acceptance criterion of RPD less than or equal to 30 percent for all of the process samples.

9.3.2.2 Exhaust Emission Samples

9.3.2.2.1 OTM-45

Analytical laboratory precision for OTM-45 exhaust emission samples was assessed using method-defined internal QC checks, including surrogate recoveries and LCS performance, as summarized in Appendix J-2. Overall, the consistency of PFAS detections and concentrations across the three runs suggests acceptable precision for the stack sampling and analysis effort.

Three LCS and LCSD pairs were analyzed with analytical batches. The corresponding recoveries are presented in Appendix J-2. For the first pair, precision met the acceptance criteria of RPD less than or equal to 30 percent for all analytes. In the second pair, four analytes exceeded 30 percent, with three around 36 percent and one analyte, PES, at 48 percent. For the third pair, eleven analytes exceeded 30 percent, with the highest exceedance observed for 5:3 FTCA at 75 percent.

9.3.2.2.2 OTM-50

One duplicate OTM-50 sample was analyzed to assess precision. All analytes were non-detect, which is the same as the original sample.

9.3.2.2.3 Method 0010

Analytical laboratory precision for Method 0010 exhaust emission samples was assessed using method-defined internal QC checks, including surrogate recoveries and LCS performance, as summarized in Appendix J-4. Overall, the consistency of PFAS results (all non-detect) across the three runs suggests acceptable precision for the stack sampling and analysis effort.

Three LCS and LCSD pairs were analyzed with analytical batches. The corresponding recoveries are presented in Appendix J-4. For the first pair, precision met the acceptance criteria of RPD less than or equal to 30 percent for all but one of the analytes (2-chloropheono). In the second and third pairs, precision met the acceptance criteria of RPD less than or equal to 30 percent for all analytes.

9.3.3 Completeness

Completeness is a measure of the amount of valid data obtained from a measurement system compared to the amount of data expected under normal conditions. The validity of the sample results is determined through the data validation process. Any rejected (R) sample results are considered to be incomplete. The data that are qualified as estimated or estimated non-detected (UJ) are considered to be valid and usable. The completeness is calculated and reported for each method and analyte combination. The number of valid results divided by the number of possible individual analyte results expressed as a percentage determines the completeness of the data set. The laboratory provided data meeting system QC acceptance criteria for all samples tested. In several instances the laboratory reported both an initial and re-analysis set of results for each process sample for the PFAS analysis. The data validator reviewed each set of results and selected the appropriate result for reporting. A total of 3,230 process sample analytical results with EPA Method 1633, 1,484 results with OTM-45, 2,332 with Method 0010, and 396 with OTM-50 were generated, and 0 were rejected, for a completeness of 100 percent. The completeness goals were met.

9.3.4 Representativeness

This sub-section qualitatively expresses the degree to which data accurately reflects samples collected at the site. Factors that affect the representativeness of analytical data include proper sample collection and preservation techniques, analytical holding times, and use of standard analytical methods.

9.3.4.1 Process Samples

The process samples associated with this study include materials like waste feed materials, chemicals, residual streams, process waters, and other materials consisting of complex matrices. The analytical method chosen for the PFAS characterization of these samples is EPA Method 1633 which is expressly appropriate for aqueous, solids, biosolids, and tissue samples. Therefore, its application is appropriate with some necessary qualifications noted.

The original analyses for all process samples were completed within the most restrictive 28 day holding time requirements of Method 1633. During the data review period certain isotope dilution internal standards were observed to be outside of the target recovery limits for some analytes. Under these

conditions, re-analyses were conducted, albeit not within the original holding time of 28 days. The Method 1633 recommended holding time for samples other than aqueous samples is 90 days when stored with proper refrigeration. Therefore, all of the original analyses and re-analyses of the process samples were conducted within 90 days of sample collection.

The case narratives of the analytical reports (Appendix J-1) provide additional details about the re-extraction handling. Where improved results were observed in the reanalysis, these results were reported and the data was qualified using "estimated" data flags.

9.3.4.2 Exhaust Emission Samples

Exhaust emission sampling activities in this project integrated protocols from EPA's OTM-45 for targeted semi-volatile polar compounds and Modified Method 0010 for targeted and non-targeted semi-volatile nonpolar compounds. OTM-50 was employed for volatile fluorinated analytes. The OTM-45 and OTM-50 methods were applied under controlled, documented procedures consistent with Quality Assurance Project Plan protocols.

Where deviations occurred (e.g., re-extractions past method-specified holding times due to isotope standard recovery issues), initial analyses were conducted within holding times. Some samples were originally reported at a dilution due to concentrations of native analytes. Per client request, samples were re-analyzed undiluted. The re-analysis of these samples was performed outside of the analytical holding time. OTM-45 requires a 28-day holding time from extraction to analysis. These samples were reanalyzed on day 42. OTM-45 also states that extracts may be archived for up to 1 year. Both sets of data are presented in the analytical report (Appendix J-2).

9.3.5 Comparability

Comparability is the extent to which data from one study can be compared directly to either past data from the current project or data from another study. Using standardized sampling and analytical methods, units of reporting, and sampling location selection procedures helps ensure comparability.

To ensure that data derived from this field effort are comparable from run to run, all like media samples were submitted for analysis by the same analytical method (with like analytical parameters and similar detection/reporting limits); units of measure (e.g., microgram per liter, microgram per kilogram) are the same for all reporting; and like media were sampled, handled, and prepared in the same manner according to field collection SOPs. Every effort was made to maintain consistent operations during the testing. The data variability observed reflects the complex and heterogeneous nature of commercial HWI feeds and the effects of the spiked PFAS.

9.3.6 Data Validation

Data validation consists of evaluating the completeness, correctness, and conformance of a data set against the method, SOP or contract requirements in the approved Quality Assurance Project Plan. A third party data validation was conducted on all samples by Terri Bales. The validation was conducted as the protocols listed in DOD Data Validation Guidelines Module 6. The data was validated for compliance with the following primary benchmarks:

- Sample preservation and holding times

- Analytical method requirements
- Laboratory specific requirements (i.e., compliance with laboratory SOPs)
- Project specific requirements, if applicable
- Completeness of the data package submittals

9.3.6.1 Process Samples

Overall, the data quality objectives for accuracy, precision, and completeness were met for the process sample data analyzed by EPA Method 1633. Data quality qualifiers were applied to the data where HFPO-DA was reported as exceeding the calibration range for the Dilution Factor 1. Detailed information on the data quality assessment is included in the Data Validation Report (Appendix L-1) for the process samples (EPA Method 1633) data. Data without qualifiers and data qualified as estimated are usable for the purpose of supporting project objectives. All validated data were also found to be representative and comparable for all samples collected and analyzed for EPA Method 1633. The data quality for the EPA Method 1633 analysis is deemed acceptable for its intended use.

9.3.6.2 Exhaust Emission Samples

This section provides a summary of data quality assessments for exhaust emission samples analyzed using EPA Methods OTM-45, OTM-50, and Method 0010. Accuracy, precision, and completeness objectives were met across all methods. Data qualifiers were applied where applicable, and full validation details are provided in Appendices L-2 through L-4. Overall, the data quality is acceptable for its intended use.

9.3.6.2.1 OTM-45

Overall, the data quality objectives for accuracy, precision, and completeness were met for EPA OTM-45 data. Qualifiers for data quality were applied to the data where HFPO-DA was reported as exceeding the calibration range for the Dilution Factor 1. Detailed information on the data quality assessment is included in the Data Validation Report (Appendix L-2) for EPA OTM-45 data. Data without qualifiers and data qualified as estimated are usable for the purpose of supporting project objectives. All validated data were also found to be representative and comparable for all samples collected and analyzed for EPA Method OTM-45. The data quality for the OTM-45 analysis is deemed acceptable for its intended use.

9.3.6.2.2 OTM-50

Overall, the data quality objectives for accuracy, precision, and completeness were met for EPA OTM-50 data. Qualifiers for data quality were applied to the data related to information provided by the laboratory concerning the independent CO_2 bias test and continuous calibration verification percent differences exceeding the 20 percent criteria. Detailed information on the data quality assessment is included in the Data Validation Report (Appendix L-3) for EPA OTM-50 data. Data without qualifiers and data qualified as estimated are usable for the purpose of supporting project objectives. All validated data were also found to be representative and comparable for all samples collected and analyzed for EPA Method OTM-50. The data quality for the OTM-50 analysis is deemed acceptable for its intended use.

9.3.6.2.3 Method 0010

Overall, the data quality objectives for accuracy, precision, and completeness were met for EPA Method 0010 data. Qualifiers for data quality were applied to the impinger fraction sample data for low surrogate recoveries of an acid extractable surrogate and low surrogate recoveries for specified analytes. Qualifiers were also applied to phenol results for two back-half fraction samples associated with low level phenol results reported in the blank train sample. Detailed information on the data quality assessment is included in the Data Validation Report (Appendix L-4) for EPA Method 0010 data. Data without qualifiers and data qualified as estimated are usable for the purpose of supporting project objectives. All validated data were also found to be representative and comparable for all samples collected and analyzed for EPA Method 0010. The data quality for the M0010 analysis is deemed acceptable for its intended use.

9.3.7 Data Usability Summary

Overall, the data are viable and usable for addressing the stated objectives of this test. Data without qualifiers and data qualified as estimated are usable for purposes supporting project objectives. Validated data were also found to be representative and comparable for all samples.

10 Mass Balance, DRE, and DE Calculations

10.1 PFAS Mass Balance Calculations

A PFAS mass balance around the incineration system is presented in Appendix A-1, Table A-1-2. A mass flow rate for each analyte in each stream was calculated as the measured concentration of the analyte times the mass flow rate of the stream in lb/hr. For liquid streams, analytical results were reported in units of ng/L. Therefore, measured flow rates in lb/hr were converted to flows in liters/hour using density factors for the liquid streams as reported by the CHES Aragonite Laboratory. The density factors for each liquid stream are presented in Appendix I. Mass balance calculations for process streams are presented in Appendix A-1, Table A-1-13 through Table A-1-16. Mass balance calculations for exhaust emissions are presented in Appendix A-1, Table A-1-17 through Table A-1-19.

The relative amounts of total PFAS in each process stream and the exhaust emissions are shown for Run 1A on Figure 10-1. Similar graphs for Runs 2A and Run 3A are almost identical to Figure 10-1 and are presented in Appendix A-1, Figure A-1-2 and Figure A-1-3. Figure 10-1 should be interpreted with the following qualifiers and observations:

- The streams included in the mass balance are waste liquid feeds, treatment chemicals, process water, process residues, and exhaust emissions.
- All process and exhaust emissions streams except waste feed solids were accounted for in developing the PFAS mass balances. Komar solids, containerized solids, and bulk solids were fed during the test program but were not sampled and analyzed for PFAS due to waste non-homogeneity. Therefore, PFAS feed rates in these solids streams could not be calculated and these streams are not shown on Figure 10-1. As previously discussed, excluding the potential PFAS contributions from the solid waste streams likely biases the PFAS mass feed rate low which in turn biases the DRE results low.
- Process water flow rate was not measured directly because there is no flow meter; however, the flow rate was calculated by a mass and energy balance as described in Section 3.2.
- Brine is an internally recycled stream and does not contribute to PFAS mass flow into or out of the battery limits of the incineration process. Therefore, this stream is not shown on Figures 10-1.
- The total PFAS mass balance for all process streams includes the forty PFAS target analytes reported by EPA Method 1633. An additional nine analytes are reported by OTM-45 for exhaust emissions samples and are included in the mass balance. Therefore, the mass balances for the process streams and the exhaust emissions streams are not on the same basis in terms of the specific analytes included. However, these nine additional analytes comprised only 1.99 percent, 0.12 percent, and 2.41 percent of the total PFAS in the exhaust emissions during Run 1A, 2A, and 3A, respectively.
- The tanker direct burn stream was comprised of AFFF concentrate and had high concentrations of many PFAS, particularly PFOS and PFHxS. This stream contributed approximately 78 to 82 percent of the total PFAS mass fed to the incineration system during the test program.

- The PFAS spiking compounds comprised approximately 18 to 22 percent of the total PFAS mass fed to the system during the test program.
- All other waste feed streams (excluding the AFFF and PFAS spikes) that were sampled and analyzed accounted for from 0.001 to 0.003 percent of the total PFAS input.
- Based on the reported HFPO-DA analytical results, 78, 97, and 81 percent of the total PFAS exhaust emissions are comprised of HFPO-DA for Run 1A, 2A, and 3A, respectively. As previously noted in Section 8.3.4 and discussed in detail in Appendix K, most of the exhaust emissions analytical results for HFPO-DA are plausibly due to contamination from an external source and not actual emissions from the incinerator.

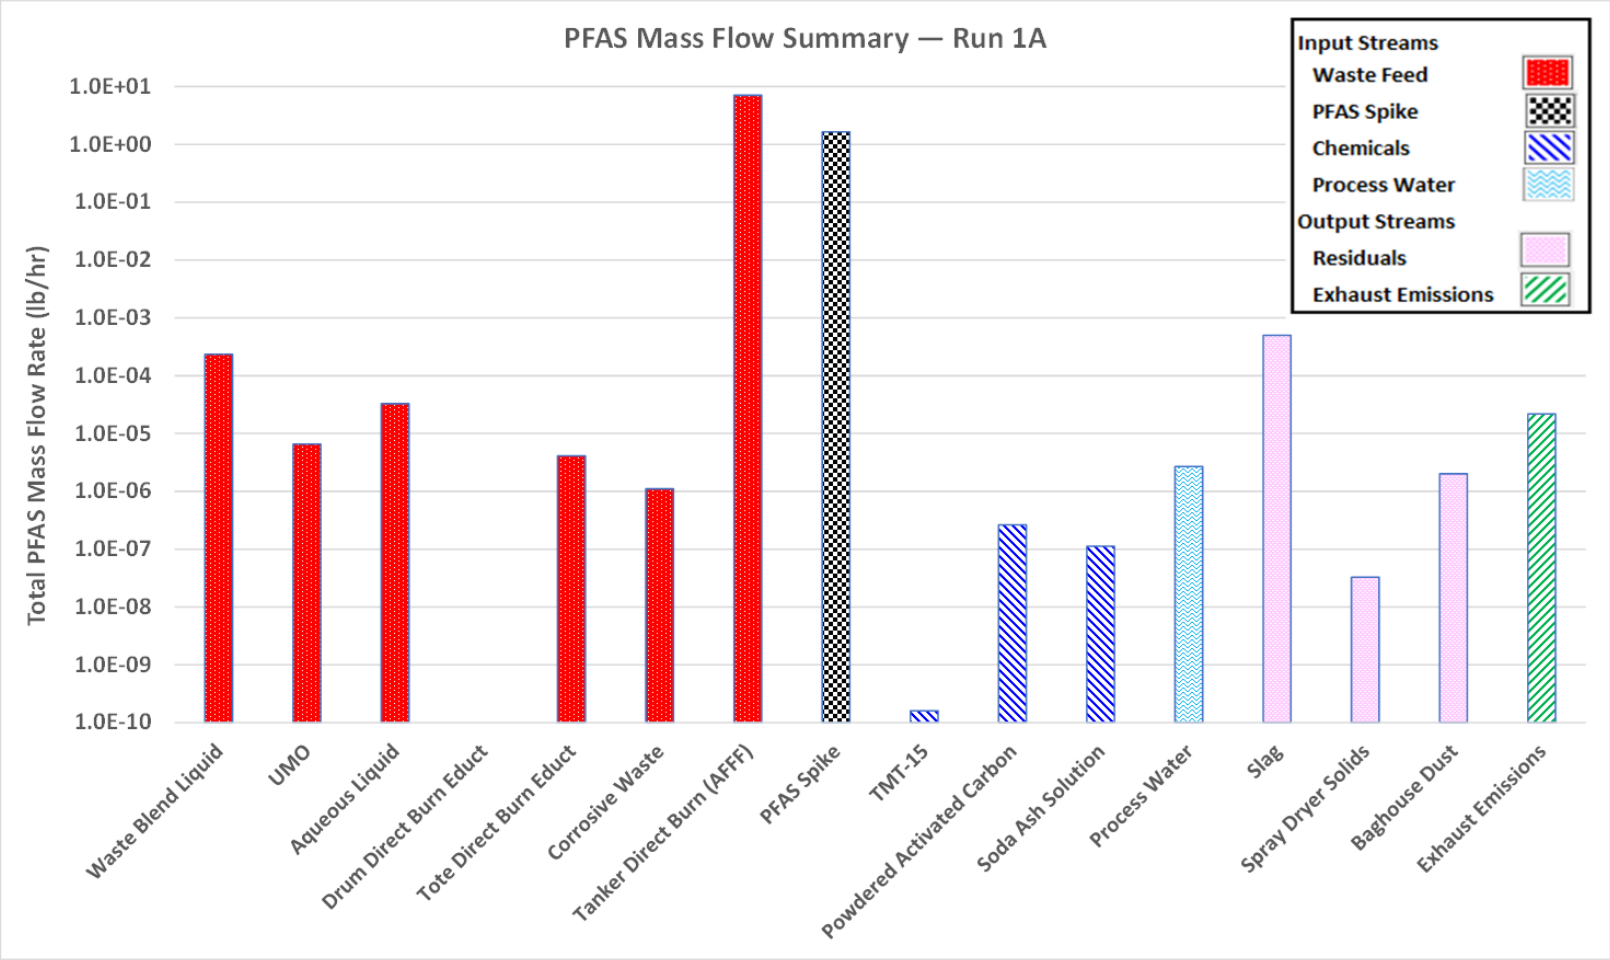

Figure 10-1. Total PFAS Mass Balance – Run 1A

10.2 PFAS Destruction and Removal Efficiency Calculations

One of the strategic objectives for the test program was to spike sufficient masses of the nine PFAS to be able to demonstrate up to 99.9999 percent DRE. To demonstrate DRE at this level, the mass of a PFAS target analyte in the waste feed is required to be at least 1,000,000 times the mass that can be detected in the exhaust emissions at the analytical MDL. This section describes the formulas that were used to calculate DRE values and summarizes the DRE results.

DRE was calculated using Equation 1 and definitions specified in 40 CFR §264.343:

$$DRE = \{1 - (w_{out} / w_{in})\} \times 100 \text{ percent} \qquad \text{(Equation 1)}$$

where:

- W_{in} = mass feed rate of one POHC in the waste streams feeding the incinerator
- W_{out} = mass emission rate of the same POHC present in exhaust emissions prior to release to the atmosphere.

For this report, a POHC is an individual PFAS analyte. Note that PFAS present in treatment chemicals or process water are not included in the W_{in} component of the DRE calculation, since they are not waste feeds and are introduced to the process downstream of the combustion systems. Likewise, PFAS in process residuals are not included in the W_{out} component of the DRE calculation since they are not released to the atmosphere. However, these other mass flows are included in a separate DE calculation that is presented in Section 10.3.

In addition to the spiked PFAS, DRE values were also calculated for the other EPA Method 1633 target analytes for which there was sufficient PFAS mass in the waste feed materials to demonstrate a minimum DRE value of 99.99 percent at the exhaust emissions analytical detection limit. As described in EPA/625/6-89/019, Guidance on Setting Permit Conditions and Reporting Trial Burn Results (January 1989), Section 4.2.1, one of the requirements for planning a DRE test is to ensure that sufficient levels of POHCs are fed so that 99.99 percent DRE can be detected. DRE values were calculated for any analyte for which there was sufficient mass in the waste feed materials to demonstrate a minimum DRE value of 99.99 percent based on the analytical detection limit in the exhaust emissions. A feed sufficiency test was implemented to determine if sufficient mass of each EPA 1633 target analyte was present in the waste feed materials to demonstrate the following levels of DRE:

- 99.99 percent (mass in feed 10,000 times the mass in the exhaust emissions at the analytical detection limit)
- 99.999 percent (mass in feed 100,000 times the mass in the exhaust emissions at the analytical detection limit)
- 99.9999 (mass in feed 1,000,000 times the mass in the exhaust emissions at the analytical detection limit)

The detailed results of the feed sufficiency test are presented in Table 10-1 and the results are summarized below:

- 99.99 percent DRE 16 target analytes
- 99.999 percent DRE 15 target analytes
- 99.9999 percent DRE 11 target analytes

All nine spiked compounds passed the feed sufficiency test at the 99.9999 percent level.

Sixteen target analytes passed the feed sufficiency test at a minimum DRE value of 99.99 percent. This included all PFCAs with 10 carbon atoms or less, all PFSAs, and HFPO-DA. The other 24 target analytes from EPA 1633 did not pass the feed sufficiency test at the 99.99 percent DRE level. In addition, there were nine additional PFAS that are target analytes for OTM-45 but are not target analytes for EPA 1633 for which DRE values could not be calculated because there is no analytical data available for the feed materials.

DRE results for these 16 target analytes are presented in Table 10-2 as Case 1. DRE values range from 99.95 percent up to greater than 99.9999 percent. There are 48 DRE values reported (16 target analytes times 3 runs). 34 of the DRE results are the highest value that can theoretically be demonstrated based on the feed sufficiency test results presented in Table 10-1. Only one DRE value less than 99.99 percent was calculated (HFPO-DA). As discussed in Section 8.3.4, it is plausible that HFPO-DA measured in the emissions is contamination from an external source and not derived from the incinerator off-gas. Therefore, the DRE result for this compound is likely biased low.

In all cases, DRE values were calculated using the most conservative possible assumptions. Analytes that were not detected in the feed materials are included as zero values in the waste feed material mass balance. Analytes that were not detected in the exhaust emissions samples are assumed to be present at the MDL in the mass balance. Exhaust emissions concentrations were not blank corrected, even though detectable amounts of 10 analytes were reported in one or more analytical fractions of the STPB. In addition, PFAS inputs from the bulk and containerized solid waste feed streams to the incinerator could not be measured due to waste heterogeneity and containerization. Therefore, any PFAS that were in the solid waste streams are not included in the DRE calculations. As a result of this group of conservative assumptions, it is likely that the actual DRE values are greater than the calculated values presented in this report. This set of assumptions was used to perform all calculations reported in this document, with the one exception of the sensitivity study discussed in the next paragraph.

A DRE sensitivity analysis was conducted using the MDL in DRE calculations for process samples which had non-detect analytical results. The results of this analysis are shown in Table 10-3 as Case 2. This analysis shows that all but three DRE values exceed 99.99 percent. For analytes which met the 99.99 percent feed sufficiency test shown in Table 10-1, there is virtually no difference in DRE values between Case 1 (Table 10-2) and Case 2 (Table 10-3). This is because these compounds have significant amounts of PFAS detected in the waste feed streams and the added mass from including non-detects in the exhaust emissions is insignificant. Conversely, for those analytes that did not meet the 99.99 percent feed sufficiency test, the mass contributing by using the MDL instead of zero for non-detect is significant and greatly increases the number of compounds meeting the 99.99 percent feed sufficiency test and increases DRE values compared to Case 1.

10.3 PFAS Destruction Efficiency Calculations

DE is not a term that is defined in the U.S. hazardous waste regulations. For this report, DE calculations have been developed to indicate the degree of destruction of each PFAS based on its total mass entering the system in all waste feeds, process chemicals, and process water, and the total out of the system in process residual streams and exhaust emissions. The intent of the DE calculation is to assess how much PFAS is destroyed, not just transferred from one media to another media. DE was calculated using Equation 2.

$$DE = \{1 - [(W_{out} + R_{out}) / (W_{in} + C_{in} + P_{in})]\} \times 100 \qquad \text{(Equation 2)}$$

where:

- W_{in} = mass feed rate of one POHC in the waste streams feeding the incinerator
- C_{in} = mass feed rate of the same POHC in treatment chemical feeds (powdered activated carbon, Na_2CO_3 solution, TMT-15
- P_{in} = mass flow rate of POHC in process water feed
- R_{out} = mass flow rate of POHC out in residual streams (slag/ash, spray dryer solids, baghouse dust)
- W_{out} = mass emission rate of the same POHC present in exhaust emissions prior to release to the atmosphere

A summary of the DE Results is shown in Table 10-4 for Case 1. Detailed DE calculations for all EPA Method 1633 target analytes are presented in Appendix A-1, Table A-1-8 through Table A-1-12. DE values ranged from large negative values to greater than 99.9999 percent. Analytes which have low or negative DE values also had very low concentrations of the analyte in the waste feed materials. The low or negative DE values are primarily a result of how non-detects were handled in calculations, with non-detects for process steams using a zero-concentration value in calculations and using the MDLs for non-detects for exhaust emissions samples.

The DE calculations were repeated, using MDLs for non-detects for both process samples and exhaust emissions samples (Case 2). These results are presented in Table 10-5 and show that the DE values ranged from greater than 99.85 percent up to greater than 99.99 percent. The wide variation in the DE results presented in Table 10-4 and Table 10-5 indicate that DE results are only meaningful if there is a significant mass of PFAS in the waste feed materials to the incinerator.

10.4 C_2F_6 Destruction Removal Efficiency Calculations

During Runs 1B, 2B, and 3B, the incinerator was run with normal waste feeds but without either AFFF waste feed or PFAS spiking. The intent was to create low C_2F_6 background samples to compare to concentrations measured during Runs 1C, 2C, and 3C when C_2F_6 was spiked to the rotary kiln to determine DRE for the spiked C_2F_6. However, the concentration of C_2F_6 was non-detect in all sample canisters from Runs 1B, 2B, 3B, 1C, 2C, and 3C. Non-detect C_2F_6 concentrations were obtained from both

the Eurofins and EPA laboratory analyses of OTM-50 samples. Therefore, no background correction was required to be made for the calculation of DRE values for the spiked C_2F_6.

Three different sets of DRE values were calculated for C_2F_6. All three sets of DRE values used the amount of spiked C_2F_6 as the POHC value. DRE values were calculated using C_2F_6 stack emission rates using OTM-50 data from EPA and Eurofins and the concentrations measured by Spectrum with an FTIR. The average MDL reported by EPA was 0.024 ppb, the average MDL reported by Eurofins was 0.094 ppb, and the MDC # 3 (determination of analytical algorithm errors per ASTM D6348-12 Section A2.3) for C_2F_6 measured by FTIR was 0.62 ppb. Based on these MDL and MDC values, C_2F_6 DRE values of greater than 99.9999 percent, greater than 99.999 percent, and greater than 99.99 percent were calculated using the EPA, Eurofins, and Spectrum data, respectively. These DRE calculations are presented in Table 10-6. These data indicate that C_2F_6 can be destroyed at a very high efficiency at the normal incinerator operating conditions.

11 Dispersion Modeling Results

The EPA screening air dispersion model AERSCREEN was used to estimate the ambient air impacts from the exhaust emissions of 12 PFAS emitted from the CHES Aragonite incinerator stack during the testing. The complete dispersion modeling report is presented in Appendix M.

The 12 PFAS for which ambient impacts were modeled include PFBA, PFHxA, PFOA, PFNA, PFDA, PFDoA, PFBS, PFHxS, PFOS, FOSA, HPFO-DA and 6:2 FTS. These compounds are target analytes for OTM-45 and have ambient concentration guidelines or standards in one or more states. Regulatory standards or guidance values were identified for Michigan, Minnesota, New Jersey, New York, and Texas (Bryan 2025). It should be noted that establishing ambient air standards is an emerging area of PFAS regulation with some States, and there are currently no federal standards.

The dispersion modeling analysis was based on the average PFAS emission rates measured during Run 1A, 1B, and 1C. Safety factors are defined as the ambient regulatory standard or guideline divided by the modeled maximum ambient concentration. The dispersion modeling analysis indicates the safety factors for the 12 PFAS range from two to eight orders of magnitude.

12 Conclusions and Lessons Learned

12.1 Conclusions

The key conclusions from this test program include:

- HWIs can destroy PFAS, resulting in low concentrations in exhaust emissions, mostly below 25.0 ng/m^3, and process residues, below 101 ng/g.
    - 19 PFAS were detected in one or more exhaust emissions samples; concentrations were all below MDL for the remaining 30 compounds. Approximately 69 percent of PFAS exhaust emissions results for individual analytes were non-detect.
    - DRE values ranging from of 99.999 to greater than 99.9999 percent were achieved for all spiked PFAS except HFPO-DA, which ranged from 99.95 to 99.998 percent. The exhaust emissions samples for HFPO-DA had concentrations above background level and the resulting DRE values are likely biased low as a result of this. As described in Appendix K, the exhaust emission levels are likely due to external contamination.
    - DE values ranging from 99.94 percent to greater than 99.9999 percent were achieved for the nine PFAS spiking compounds. For PFAS that were not spiked, DE values ranged from large negative values to greater than 99.99 percent. The large negative DE values were calculated for PFAS that had concentrations below MDLs in several waste feed streams and for which zero values were used for the concentrations in the calculations. A sensitivity study was performed using the MDL instead of zero for non-detects, and these PFAS then had DE values ranging from 99.77 percent to greater than 99.99 percent.
- Eurofins' analyses had no VFCs above the MDL.
- Samples analyzed by EPA ORD had six compounds above the MDL, but below the reporting limit, with two were also in the blanks and are likely from the air used to pressurize the canisters.
- No fluorinated semi-volatile, nonpolar compounds were identified by EPA Method 0010 sampling and analysis.
- The DRE values for C_2F_6 ranged from greater than 99.99 to 99.9999 percent depending on the feed rate of C_2F_6 and the measurement method used.
    - OTM-50 analysis by EPA ORD for C_2F_6 DREs = >99.99986 to >99.99996
    - OTM-50 analysis by Eurofins for C_2F_6 DREs = >99.99947 to >99.99985
    - FTIR by Spectrum for C_2F_6 DREs = >99.99811 to >99.99901.
- Modeled ambient air concentrations were compared to regulatory standards or guidelines from five state regulatory agencies (Michigan, Minnesota, New Jersey, New York, and Texas). The analysis shows that the maximum ambient concentrations for the 12 PFAS that were modeled

range from two to eight orders of magnitude below known state ambient regulatory standards or guidelines.

12.1.1 Destruction and Removal Efficiency Demonstration

This test program and two previous test programs (Crisenbery et al. 2024) at the CHES Aragonite incinerator demonstrate that DRE values in the range of 99.999 percent to greater than 99.9999 percent are readily achievable if sufficient mass of POHC is available in the waste feed material. This generally requires spiking with a POHC, but for some analytes, native concentrations were sufficient to achieve DRE values in this range. The amount of PFAS spiking compound required to achieve the desired DRE can be calculated based on the MDL of the analyte in the exhaust emissions, the exhaust emissions flow rate, and the exhaust emissions sample volume.

12.1.2 Destruction Efficiency Demonstration

DE values in the range of 99 percent to greater than 99.999 percent were readily demonstrated when a sufficient mass of an analyte was available in the waste feed material, either by spiking or as a native concentration. However, for analytes that had low concentrations in the waste feed inputs, calculated DE values varied widely from large negative values if zero values were used for non-detects in calculations up to greater than 99.9 percent if MDLs were used for non-detects in DE calculations.

12.1.3 C_2F_6 as a Spiking Indicator Compound

DRE values in the range of 99.99 percent to greater than 99.9999 percent were demonstrated for C_2F_6. The level of DRE that could be demonstrated depended partially on the C_2F_6 spiking rate but more importantly on the MDL that was achieved by OTM-50 or the MDC achieved by FTIR. OTM-50 was able to achieve MDLs one to two orders of magnitude lower than the MDC determined by FTIR.

The DRE values achieved for C_2F_6 were similar (99.999 percent to greater than 99.9999 percent) to those achieved for spiked PFAS. The high DREs of PFAS, the absence of PIDs, and the high DRE of C_2F_6 indicate that the Aragonite incinerator and emission control system has a high efficacy for PFAS destruction. This result is another data point that demonstrates correlation between high C_2F_6 DREs and high incinerator performance. More data is needed to determine if a there is credence to the potential use of C_2F_6 as a POHC indicator for other PFAS. Implementation of this procedure may mitigate the complexity and cost of future tests at this facility to mainly include another verification that C_2F_6 can still be destroyed at these same levels.

12.1.4 CF_4 as a Potential PID

CF_4 was detected in seven of the nine EPA OTM-50 samples at concentrations near the detection limit and was not present in the blanks. CF_4 was also detected by FTIR during Runs 1A, 2A, and 1B. The presence of CF_4 near the detection limit provides some evidence of the production of a PID from the high concentrations of PFAS added to the kiln.

12.2 Lessons Learned

12.2.1 Problematic Destruction Efficiency Calculation — How to Avoid Negative Values

DE tests are best planned so that there is sufficient PFAS mass in the feed material to demonstrate the desired DE values. To demonstrate 99 percent DE, the mass of PFAS in the inlet streams must be at least

100 times the mass in the outlet streams. If DE tests are conducted without spiking PFAS, the native concentrations of PFAS in feed materials may be very low and result in low DE values. This issue is clearly illustrated in Table 10-5 which shows that DE values of greater than 99.9 percent were achieved for the nine compounds that were spiked and DE values of less than 99 percent were commonly reported for compounds that were not spiked. For the calculations in Table 10-5, a value of zero was used in DE calculations for analytes that were not detected in the input materials.

The DE calculations were repeated using the MDL value for those compounds that were below detection levels. These results are presented in Table 10-6 and show that all DE values exceed 99 percent. One conclusion from these analyses is that DE values are only valid if there is sufficient mass of the PFAS analyte in the feed material to demonstrate the desired level of DE. A second conclusion is that DE values are highly dependent on what values (zero or MDL) are used in calculations for analytical results that are below the detection limit.

12.2.2 Feed Characterization and Variability

Hazardous wastes fed to a large, commercial HWI vary widely in chemical and physical form, as well as instantaneous feed rates. Wastes include bulk solids, packaged solids, and bulk and packaged organic and inorganic liquid wastes. Daily operations at a commercial HWI are based on a “burn plan”, which factors in waste attributes such as heating value, halogen content, mineral ash levels, and material inventory, to ensure that the HWI can be operated consistently and predictably within permit limits, to attain the objective of complete destruction of the hazardous waste. Although each waste accepted for treatment is characterized consistent with regulatory requirements, many bulk and packaged solid waste have an inherent variability, creating short term fluctuations in the chemical and physical properties, particularly with respect to emerging contaminants such as PFAS. This, combined with the operational requirements of the burn plan, can result in fluctuations in feed properties. Hence, despite careful planning of destruction testing, including conservative assumptions and allowances, test results will typically reflect this inherent waste feed variability. Additionally, limitations of analytical methods, particularly for PFAS, can further constrain comprehensive waste characterization efforts. To enhance both waste characterization and fluorine mass balance assessments, incorporating complementary analytical approaches, such as total organic fluorine measurements, can be beneficial.

12.2.3 Stack Sampling Process and Glassware QA/QC

The stack sampling and analytical methods met the quality metrics in the methods and provided data of known and acceptable quality. However, the proof blank had HFPO-DA and some other PFAS in the extracts. The presence of PFAS in the proof blank does cast doubt on the presence of some PFAS in the exhaust emissions, such as HFPO-DA and in compliance tests would invalidate the tests. The search to try to find the cause of the contamination re-emphasized the cautions in OTM-45. The glassware, seals, O-rings, filter support materials, and other train and recovery components can be constructed of materials not mentioned in the method, however, they must be demonstrated to be free of the targeted PFAS. OTM-45 Rev 1 specifically prohibits the use of glass fritted filter supports for this reason. Appendix K provides data for the analyses of various parts of the train to help identify potential contamination. It was found that silicone O-rings, fritted glass filter supports, and other materials did have PFAS on them. This reiterates the importance of ensuring materials and recovery supplies do not contain PFAS, cleaning techniques ensure that potential PFAS contamination is removed, and proof and/or field sample train blanks and other equipment blanks should be collected for components that could be potential sources of contamination.

Additional blanks (e.g., proof blanks and field blanks) would be beneficial to determine whether contamination has occurred and to help ensure the trains are effectively recovered. Although additional blanks add to the time and costs of the testing, the additional data can be extremely valuable in confirming potential sample train contamination.

12.2.4 Data Validation Process Standards

The results of the analyses for this testing campaigns were reviewed for a data quality assessment based on the laboratory's (Eurofins) analytical method procedures, and the requirements outlined by DOD Data Validation Guidelines Module 6: Data Validation Procedure for PFAS Analysis by Quality Systems Manual for Environmental Laboratories Table B-24. With the complex nature of the developing methods for PFAS and the use of draft and OTM methods, the National Functional Guidelines for Organic Superfund Methods Data Review may better apply to the data validation than the DoD procedures. The Superfund guidelines allow for more flexibility with complex analytical methods and would help simplify the data validation.

Comprehensive analysis of PFAS presence from environment to plate

Check for updates

Maria-Eleni Dimitrakopoulou ✉, Manos Karvounis, George Marinos, Zacharoula Theodorakopoulou, Eleni Aloizou, George Petsangourakis, Mihalis Papakonstantinou & Giannis Stoitsis

Per- and polyfluoroalkyl substances (PFAS) pose an emerging environmental risk impacting food products and ecosystems. This study analyzes over 150,000 entries from food safety authorities and scientific publications from 2017 onwards. Our findings show that fish & seafood, and biota have the highest PFAS concentrations due to environmental contamination and bioaccumulation. Surface water samples also frequently contain PFAS, raising concerns about long-term ecological and human health effects. Comprehensive strategies are essential to mitigate these risks.

PFAS (per- and polyfluoroalkyl substances) constitute a group of synthetic chemicals that find extensive application in both industrial and consumer products. They are commonly used in firefighting foam, non-stick cookware, waterproof fabrics, and food packaging, among others. One of the concerning characteristics of PFAS is their persistence and bioaccumulative nature. These chemicals do not readily degrade in the environment, leading to their long-lasting presence, and they can accumulate in the food chain. The persistence of PFAS means that they do not break down easily over time, even in the face of environmental degradation processes. As a result, PFAS can persist in soil, water, and air for extended periods, leading to widespread environmental contamination. The bioaccumulative nature of PFAS raises concerns about potential health risks for both humans and wildlife. Studies have linked exposure to certain PFAS compounds with adverse health effects, including reproductive issues, developmental problems, liver and kidney damage, and an increased risk of certain cancers[1–5].

The available information on PFAS (Per- and Polyfluoroalkyl Substances) health impacts is currently incomplete and fragmented, leading to difficulties in prioritizing which PFAS should be of greater environmental and health concern. There is an ongoing debate about whether to assess PFAS as a collective group from a health perspective or to evaluate individual PFAS based on their specific potential health impacts. PFAS can be categorized into two primary families: polymer and non-polymer PFAS[5]. Health concerns have predominantly been associated with non-polymer PFAS, which includes perfluorinated carboxylic acids (PFCAs) and perfluorinated sulfonic acids (PFSAs)[6].

The determination of PFAS in food products and the environment involves a series of analytical techniques, including sampling, extraction, and analysis. Conventional methods, such as LC-MS/MS, are effective in PFAS analysis but are often expensive and not widely accessible. On the other hand, emerging low-cost methods offer the advantage of affordability but lack sensitivity compared to conventional techniques, sometimes falling short of meeting regulatory detection limits. The development of low-cost sensors has the potential to be a significant change in PFAS analysis, as they can aid in identifying and prioritizing samples for further investigation and swift intervention[7].

Given the widespread occurrence of PFAS in various environmental media and their presence in a wide array of products, it is essential to address this issue comprehensively. Continuous monitoring, research, and regulatory efforts are necessary to minimize human exposure to PFAS and mitigate their potential health and environmental impact. Therefore, the objective of this review is to compile existing data on the occurrence of PFAS, including measured max and mean values, geographical origin, sampling strategies, contamination sources, and recovery values of the applied analytical methods. By gathering this comprehensive information, we aim to gain insights into the prevalence and distribution of PFAS compounds in various regions. This review aims to enhance our understanding of the worldwide prevalence of PFAS and their potential sources of contamination, explore the presence of PFAS compounds in food and environmental samples, and gain insights into the processes of bioaccumulation from the environment to the food chain through an in-depth analysis of publicly available data from public authorities and peer-reviewed literature.

Literature search

Search criteria and search strings

The search protocol used for identification of the relevant scientific publication and reports in Pubmed and ScienceDirect on PFAS in food, limited to the papers published in the last 5 years, contained the following strings:

("polyfluoroalkyl" OR "PFAS" OR "perfluoroalkyl") AND "sample" AND ("food" OR "feed" OR "supplements" OR "drinking water").

On the other hand, the search protocol used for identification of the relevant scientific publication on PFAS in environmental sources, limited to the studies published in the last 5 years, was:

("polyfluoroalkyl" OR "PFAS" OR "perfluoroalkyl") AND "sample" AND ("soil" OR "water" OR "aquatic environment" OR "land") AND

Publications that do not include data in any format (table, supplementary material, links, data sources references) were not considered as relevant for this study. Publications that include a meta-analysis of other studies were not considered as relevant, but they were used to identify references to data sources. The lists of publications were organized in two sheets of the tool, namely 'PFAS food' and 'PFAS environment', along with appropriate metadata fields related to:

- Time period covered by the samples.
- Geographical coverage
- Data is available only in aggregated form in the paper or in a more granular format in a supplementary file
- Foods and environmental media covered by the conducted research.

Exclusion criteria:

- focused on medical issues.
- focused on the detection of PFAS in the population.
- new treatment and removal techniques
- development of a risk assessment strategy
- new technique for the enrichment of food packaging material
- no data available

Search process

The process of selecting studies for inclusion in the review was rigorously evaluated by three independent reviewers (M.P., M.K., and M.D.). Mendeley was instrumental in identifying and eliminating duplicate publications, ensuring that each article was considered only once. The initial screening involved assessing titles and abstracts, guided by predefined inclusion and exclusion criteria. Articles deemed potentially relevant progressed to the subsequent stage for more comprehensive evaluation. In this phase, a second round of selection took place based on a thorough examination of the full text of the publications included. Each author independently reviewed the potentially relevant studies, adhering to predefined eligibility criteria, to determine the final set of studies to be incorporated into the review.

Selected data sources

Table 1 presents the data sources selected for PFAS after applying the prioritization methodology. The total number of records collected for PFAS from external sources is 152.019. Each record represents the analysis of a sample for a specific PFAS compound. Additionally, more records were collected for PFAS from scientific publications[6–44]. Regarding the food samples, we included publicly available data from sources such as locally caught freshwater fish across the U.S. and a contaminated pond in Sweden, as well. These additional sources were selected to capture a range of potential contamination scenarios, including both commonly consumed food products and more localized environmental exposures.

Data collection process

The information extracted from the selected full-text articles and relevant databases for inclusion in the study covered various key parameters. These included details on the analytical method employed, the percent recovery, the sampling strategy, the samples' geographical origin, the matrix under

examination, the maximum resulting concentration of PFAS, the mean value of PFAS, and the identified source of contamination.

Data for PFAS occurrence in foods have been extracted from the existing data platform of Agroknow, literature review, and external data sources. Data from external data sources were identified for PFAS and extracted datasets were selected as the ones that fit best with this study's objectives. Collected data covers high-level food categories, environmental media, 125 PFAS, and a time of more than 20 years from 2000 to 2021.

Temporal gap analysis

In terms of temporal coverage, the data collected and processed from external sources and literature cover the years as illustrated in Table 2. The total records of food samples collected were 85,998, while environmental samples totaled 66,021. Table 2 shows the total records collected per year. Interestingly, after 2005, there was a notable rise in publicly available data regarding PFAS in both food and the environment. However, it is important to highlight that 1866 records within the dataset lack information regarding the sampling year, which underscores the importance of ensuring comprehensive data collection practices for accurate scientific analysis.

Distribution of PFAS in food products and environment

All samples were subjected to analysis using advanced liquid chromatography techniques (high-performance liquid chromatography–tandem mass spectrometry (HPLC–MS/MS), ultra-performance liquid chromatography–tandem mass spectrometry (UPLC–MS/MS)). The recovery rate for these analyses ranged from 70.6% to 99.6%. Out of the total samples analyzed, a substantial proportion were collected using spatial sampling strategies, while the remaining samples were obtained through selective, suspect, and random approaches.

Table 2 | Temporal coverage of the collected data for PFAS analysis in food products and environment

Year	Records
2000	38
2001	9
2002	10
2003	96
2004	169
2005	860
2006	415
2007	697
2008	1416
2009	1105
2010	675
2011	1210
2012	942
2013	1163
2014	1626
2015	2276
2016	7234
2017	14,631
2018	8984
2019	33,096
2020	33,125
2021	40,376

Table 3 presents the results of PFAS presence in various environmental matrices, including surface, wastewater, biota, particulate matter, groundwater, and soil. The "Total samples" column represents the number of samples reported for each environmental matrix. The ">LOQ" column shows the number of samples in each matrix where PFAS concentrations were found to be above the limit of quantification (LOQ). In parallel, the 'Between LOD and LOQ' column specifies the number of samples where concentrations were observed to fall between the limit of detection (LOD) and the limit of quantification (LOQ). For example, among the 17,212 surface samples, PFAS concentrations exceeded the LOQ in 14,906 samples, with an additional 2107 samples registering concentrations between LOD and LOQ. This suggests a significant presence of PFAS in surface environments.

Table 4 presents data on PFAS presence in various food and beverage samples, as well as drinking water. It highlights the potential for PFAS contamination in different food products. Notably, drinking water shows a noteworthy presence of PFAS, with 723 out of 2973 samples having concentrations above the LOQ. This suggests a significant concern for public health, given the direct human exposure to PFAS through water consumption. In contrast, certain food categories display varying levels of PFAS presence. For example, fish and seafood samples show a particularly high incidence of PFAS, with 1323 out of 9015 samples exceeding the LOQ. This is concerning given the common dietary consumption of seafood, as elevated PFAS levels could pose health risks to consumers. Conversely, fruits and vegetables exhibit relatively lower contamination rates, indicating a lower risk of PFAS exposure through consumption. Contaminated soil or water sources used for irrigation could be potential routes of PFAS contamination in these foods. Similarly, among the 5524 dairy product samples tested, 100 samples had PFAS concentrations above the LOQ, while 2760 samples had concentrations between the LOD and LOQ.

Additionally, in this study, a comprehensive statistical analysis was conducted to assess the presence of PFAS in both food and the environment, with a focus on concentrations measured. Tables 5 and 6 display the average and maximum concentrations of PFAS observed from samples detected >LOQ within each category. The maximum PFAS values detected in food samples within the seafood category, exceeded 0,2 mg/kg (ww), while the highest PFAS concentrations found in environmental samples, particularly in ticks categorized as biota, exceeded 2 mg/kg. The detection of PFAS concentrations exceeding 0.2 mg/kg within the seafood category indicates substantial contamination within certain areas of the marine ecosystem. The identification of PFAS concentrations exceeding 2 mg/kg (ww) in ticks, which are part of the biota category, highlights the contamination of certain terrestrial ecosystems.

Presence of PFAS in environment (per analytical compound)

The most prevalent PFAS compounds found in environmental samples include PFOS, PFOA, PFHxs, PFUnA, PFDA, PFHpA, PFNA, PFPea, PFHxA, and PFTrDA. Out of these, six belong to the category

Table 3 | Presence of PFAS in different environmental samples

	Surface water	Rainwater	Wastewater	Biota	Particulate matter	Groundwater	Soil
Total samples	17,212	33,500	186	2559	65	12,216	283
>LOQ	**14,906**	8782	73	771	23	2035	134
Between LOD and LOQ	2107	24718	6	404	10	9982	18
<LOD	199	0	107	1384	32	199	131

Bold indicates the highest number of records >LOQ.

of long-chain PFAS, while four fall into the short-chain category. Table 7. provides comprehensive information on PFAS compounds detected above the LOQ within the two categories exhibiting the highest number of records (surface water) or the highest concentration (biota). The highest number of records >LOQ observed in the category of surface waters is primarily attributed to the PFOS, PFOA, and PFHxS compounds. One significant source can be industrial discharges, as certain industries have historically released PFOS, PFOA, and other PFAS chemicals into the environment as part of their manufacturing processes. Another notable source is aqueous film-forming foam (AFFF), which contains PFOS and can contribute to soil contamination when used during firefighting training exercises or in emergency response situations. Additionally, the disposal of products containing PFOS and PFOA in landfills poses a risk, as these chemicals can leach into the surrounding soil over time. Lastly, PFOS and PFOA can be transported through the air and deposited onto soil surfaces through atmospheric deposition.

Table 4 | Presence of PFAS in different food samples

	Total samples	>LOQ	Between LOD and LOQ	<LOD

Presence of PFAS in food products per analytical compound

The most prevalent PFAS compounds detected in food samples consist of PFOS, PFOA, PFHxS, PFUnA, PFDA, PFOSA, PFNA, PFBA, PFHpA, and PFPeA.) Table 8 presents a comprehensive overview of PFAS presence per individual analytical compounds in drinking water and Fish & Seafood categories. These categories were selected based on the abundance of publicly available data resulted >LOQ (drinking water) and the observed higher concentration levels within them (Fish & seafood). Among these compounds, perfluorooctane sulfonate (PFOS) emerged as the predominant contaminant in these categories. PFOS enters water supplies through various pathways, including industrial discharge and firefighting foam runoff. Its persistence and resistance to degradation make it particularly troublesome for water treatment facilities, as conventional treatment methods may not effectively remove it. Similarly, seafood, poultry and meat products have garnered attention due to their propensity to contain higher concentrations of PFAS compared to some other food types. This phenomenon can be attributed to a combination of factors. Firstly, PFAS compounds possess a remarkable ability to bioaccumulate in organisms, meaning that as they move up the food chain, they become more concentrated. This bioaccumulation process is particularly pronounced in ecosystems. Moreover, some PFAS, like perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA), exhibit exceptional environmental persistence, lingering in water bodies and allowing for their gradual accumulation. Especially, seafood's proximity to contamination sources, its filter-feeding behavior in the case of mollusks, and the global distribution of PFAS all contribute to the higher concentrations found in seafood. In 2020, the European Food Safety Authority (EFSA) proposed a draft opinion setting a tolerable intake of 8 ng/kg/week for the combined sum of these substances, equivalent to an annual dose of 0.42 μg/kg[45]. Diet serves as the primary exposure pathway, with PFOS intake strongly linked to fish and seafood consumption.

Geographical distribution of PFAS in food products and environment

Table 9 provides information about the geographical origin of the total samples analyzed. It is important to note that this data is not representative of the contamination level in each country, but rather reflects the monitoring programs for PFAS in those regions. Records from Australia have been excluded due to Australia's extensive mapping efforts on PFAS contamination, accessible at the following link: https://pfas.australianmap.net/. Increased awareness and monitoring efforts in France and in Italy might contribute to a higher number of reported samples compared to other countries. The high presence of PFAS in the United States, compared to some other countries, can be attributed to a combination of historical factors and proactive monitoring efforts. The US has a legacy of substantial PFAS usage across various industries and manufacturing facilities, dating back decades. Moreover, the use of PFAS-containing firefighting foams at military installations has been a notable source of contamination. A robust regulatory framework and an extensive system for monitoring environmental contaminants have led to increased awareness and testing in the United States, potentially contributing to higher detection rates.

Table 5 | Mean values and max values of PFAS concentration in environmental samples (mg/kg) (ww)

Resulted concentration	Surface water	Rainwater	Soil	Biota	Groundwater	Wastewater	Particulate matter
Max value	0.51	0.182	0.111	**2.32**	0.106	0.057	6.00E−04
Mean value	1.00E−03	1.00E−04	3.00E−03	0.02	1.00E−03	6.00E−03	6.00E−06

Bold indicates the highest resulted concentration.

Table 6 | Mean and max values of PFAS concentration in food samples (mg/kg) (ww)

Resulted concentration	Drinking water	Fish & seafood	Meat & products	Poultry & products	Fruits	Vegetables
Max value	1.00E−04	**0.28**	0.035	0.012	2.00E−06	2.00E−05

Nevertheless, it is essential to recognize that PFAS contamination is a global concern, and many nations worldwide are grappling with similar challenges that require coordinated efforts to address effectively. Italy's National Research Council (CNR) initiated comprehensive monitoring of PFAS presence within the country in 2013. This proactive approach likely contributes to the robust detection of PFAS contamination in Italy. Norway, despite its renowned pristine landscapes, is not exempt from the presence of PFAS compounds. These contaminants find their way into the environment through various sources, including industrial activities, firefighting foams, and the use of PFAS-containing products. Elevated PFAS levels have been detected in some drinking water supplies, prompting regulatory measures to limit exposure. Norwegian authorities are actively engaged in monitoring, research, and remediation efforts to comprehend the extent and impact of PFAS contamination in soil, water, and wildlife[46–48]. Germany's rigorous approach to monitoring PFAS contamination in food is driven by its status as the largest food retail sector in the European Union[49–51]. PFAS can enter the food chain from a variety of sources, including contaminated soil, water, and packaging materials. As a response, German authorities conduct systematic testing and monitoring of a wide range of food items, including fish, meat, dairy, and vegetables, to assess PFAS levels and potential health risks to consumers. Germany adheres to European Union (EU) regulations, which establish maximum residue levels (MRLs) for PFAS in certain food categories, ensuring that food products available in the market comply with established safety standards. Additionally, attention is given to sites with historical PFAS contamination, as they can represent potential sources of PFAS in the food chain, emphasizing the importance of comprehensive monitoring and safety measures to safeguard food quality and public health.

Contamination sources of PFAS

Table 10 provides a comprehensive overview of PFAS occurrence across different contamination source categories. Notably, fire stations are associated with the highest number of records (65), emphasizing the frequent

Table 9 | Top 10 countries with the highest number of records

Country	Records > LOQ	Records < LOQ
France	4938	23,280
Italy	4949	6756
USA	3147	951
Germany	2622	285
Netherlands	1722	1118

Canada	1004	0
Norway	54	560

Table 10 | Number of records per contamination sources

Contamination source category	Number of records
Fire station	65
Industry	49
Military	52
Landfill	39

presence of PFAS contamination in these locations, due to the historical use of PFAS-containing firefighting foams. Industry-related sites, represented by 49 records, are another significant source of PFAS contamination, stemming from industrial processes and materials. Military installations, with 52 records, are notable for their association with PFAS contamination, often linked to the use of PFAS-containing firefighting agents. Landfills, accounting for 39 records, also stand out as contributors to PFAS environmental contamination, with PFAS-containing products disposed of in these sites leaching into the surrounding environment.

Per- and polyfluoroalkyl substances (PFAS) represent a group of water-soluble chemical compounds widely employed for various applications over the past six decades. Notably, perfluorooctane sulfonate (PFOS) and perfluorooctanoic acid (PFOA) are among the most extensively studied within this group[52–55]. Human exposure to PFAS primarily occurs through dietary intake, although in specific instances, drinking water can also be a significant source, along with minor contributions from dust and indoor air exposure[56]. These chemicals have attracted significant attention due to their widespread use across various industrial and consumer applications, raising concerns about their environmental persistence and potential health risks. One of the key areas of focus has been on understanding the environmental behavior of PFAS, particularly their persistence and tendency to biomagnify in food chains. PFAS have been found to resist degradation processes, leading to their accumulation in ecosystems over time. Thus, the collective efforts of researchers worldwide have resulted in a substantial body of literature on PFAS, covering a wide range of topics, including their environmental fate, exposure pathways, toxicity mechanisms, and potential mitigation measures[57–59]. While a majority of the available data originates from studies conducted in the European Union, the United States, Australia, and China, there are still considerable information gaps for many regions worldwide[60].

Analyzing the geographical distribution of PFAS from existing available data, an interesting pattern emerges. The results demonstrate that within the European Union, France, Italy, Germany, the Netherlands, Denmark, Sweden, and Norway exhibit a significant number of samples exceeding the LOQ for PFAS contamination. This observation is consistent with prior studies examining contamination sites across Europe and within scientific literature[61,62]. This geographic disparity offers intriguing insights into the sources and pathways of PFAS contamination. However, a monitoring campaign for chemical contaminants was conducted in France in 2021, while other countries, such as Sweden, Germany, Italy, the Netherlands, and Norway, have established National Monitoring Programs for chemical contaminants. Therefore, the number of records exceeding the LOQ in these specific countries can be attributed to these programs. This underscores the presence of PFAS in both the environment and food, highlighting the necessity for all European countries to implement a comprehensive approach to address this issue[16–64]. The presence of PFAS in the United States, when compared to certain other nations, can be attributed to a combination of historical factors and proactive monitoring endeavors. The United States has a historical legacy of extensive PFAS usage across a range of industries and manufacturing facilities, for many decades. Additionally, the utilization of PFAS-containing firefighting foams at military installations has significantly contributed to environmental contamination[65]. Moreover, in more industrialized nations, fluorochemical production plants (FPPs) have played a significant role in the direct discharge of long-chain legacy PFAS into surface water and the atmosphere[66–68]. Notably, the United States' commitment to comprehensive monitoring and research initiatives has fostered a deeper understanding of PFAS contamination, shedding light on the scope of their presence in various environmental and food matrices. The United States (through the National Health and Nutrition Examination Survey or NHANES), Canada (via the Canadian Health Measures Survey), Germany (with the Human Biomonitoring Commission of the Federal Environmental Agency), and France (under the French Ministries of Health and Environment), have instituted national biomonitoring programs[69]. Thus, besides environmental pollution, also EU's proactive approach to investigation and monitoring plays a significant role in detecting and addressing PFAS contamination in food[49–62,64–75].

The presence of PFAS in surface water and drinking water samples analyzed, underscores the potential contamination of water sources, emphasizing the pervasiveness of these compounds in the environment[76,77]. However, it's notable that PFAS were typically found at low concentrations in these samples. This indicates that while contamination is prevalent, the levels detected are generally minimal. Despite their low concentrations, the presence of PFAS in numerous samples remains concerning due to their enduring presence in the environment, prompting worries about potential long-term effects on ecosystems and human health. Additionally, the high mean values of PFAS detected in food samples indicate a significant concern within this study. PFAS compounds, which have entered water sources, tend to accumulate in the tissues of organisms over time, creating a reservoir of these chemicals. As organisms consume contaminated water and prey on one another, PFAS concentrations increase up the food chain. Consequently, top-level consumers, such as fish and seafood, exhibit much higher PFAS concentrations in their tissues than in the surrounding environment. Apart from the biomagnification of existing PFAS compounds, there were also indications of precursor substances accumulating in the food chain, indicating the possibility of their transformation into more persistent PFAS compounds in higher trophic levels[78,79].

Therefore, the detection of the highest maximum concentrations in Fish & seafood and biota categories demonstrates the bioaccumulation potential, pointing out the need for vigilance in monitoring PFAS in the food chain[80,81]. Thus, the high PFAS levels in the Fish & seafood category indicate widespread contamination in specific areas of the aquatic environment, originating from industrial discharges, urban runoff, or atmospheric deposition. In contrast, ticks are ectoparasites that feed on the blood of various host animals, including mammals and birds. According to literature, PFAS compounds have permeated the terrestrial food web, with ticks acting as bioindicators[82,83]. Elevated PFAS levels in biota are indicative of widespread environmental contamination, which can have cascading effects on wildlife health, ecosystem dynamics, and even potential risks to humans. Besides, our findings align with other studies, collectively highlighting the widespread presence and concerning levels of PFAS contamination across various environmental and food matrices, underscoring the urgent need for comprehensive mitigation strategies[84–89]. Moreover, it emphasizes the crucial role of establishing stringent regulations by regulatory bodies to curb PFAS contamination and safeguard public health and the environment.

In general, PFAS exhibits remarkable stability because all the hydrogen atoms in their carbon–fluorine (C–F) bonds are replaced by fluorine atoms, enhancing their overall molecular energy. The unique structure of PFAS imparts them with hydrophobic and lipophobic characteristics, as well as exceptional chemical and thermal stability, which collectively render them resistant to hydrolysis, photolysis, metabolism, and biodegradation[90]. Our study revealed the prevalence of PFOS and PFOA in most environmental samples, while PFHxS were found in surface water samples. Notably, these compounds were also detected in fish and seafood products, suggesting their transmission to aquatic life through contaminated surface water[91–93].

Moreover, the significant detection of PFAS in drinking water samples indicates potential routes of exposure, with PFAS potentially making its way into poultry and meat products through drinking water or even into crops via irrigation practices. PFOS, PFOA, and PFOSA contain eight carbon atoms, which contribute to their enhanced stability, and this can enlighten their frequent detection in seafood, meat, and poultry products[94]. Additionally, in marine environments, research has shown that organisms at higher trophic levels exhibit a significantly greater ability to convert PFOSA into PFOS, as evidenced by the proportion of these compounds in their PFAS profiles and body burdens[78].

Analyzing the data, it becomes clear that most PFAS compounds detected in food samples mostly belong to the long-chain PFAS category. In contrast, the environmental samples contain both long-chain and short-chain PFAS. Short-chain PFAS with hydrophilic properties exerts more significant effects on surface waters, while long-chain PFAS with hydrophobic characteristics can accumulate in sediments, posing risks to aquatic organisms[95]. This disparity indicates a notable difference in the distribution and prevalence of PFAS compounds in these two types of matrixes. The presence of long-chain PFAS in food samples is significant as they tend to bioaccumulate in living organisms. This is especially concerning as long-chain PFAS are typically associated with a higher potential for health and environmental risks due to their persistence and bioaccumulative properties. In environmental samples, the detection of both long-chain and short-chain PFAS compounds indicates that various sources may contribute to environmental contamination. This reflects the diverse applications and sources of PFAS in the environment, ranging from historical uses to ongoing emissions. The presence of short-chain PFAS in the environment is noteworthy as they are often considered less bioaccumulative and less persistent, but they are still of concern due to their potential to leach into water sources and impact aquatic ecosystems.

Addressing these concerning findings necessitates a multifaceted approach. First and foremost, there is a critical need to identify and investigate potential sources of PFAS contamination in marine and terrestrial ecosystems and the environment, with the aim of preventing further pollution[96,97]. Additionally, comprehensive health risk assessments are imperative to evaluate the potential health implications for consumers of contaminated foodstuff[98,99]. Furthermore, it is essential to assess the ecological impact of PFAS contamination on these ecosystems, considering potential effects on biodiversity and food chains. In parallel, regulatory measures should be contemplated, including the establishment or revision of standards for PFAS levels in food products, to safeguard both the environment and human health. Finally, the development and implementation of mitigation strategies, remediation efforts, and enhanced waste management practices are essential steps in reducing PFAS contamination in affected ecosystems.

In conclusion, given the interconnected nature of environmental challenges, understanding how factors such as PFAS presence intersect with climate change is vital for safeguarding public health and ecosystems. This necessitates a holistic approach involving research, policy, and action to mitigate their combined implications. Moreover, ensuring the availability of public data for laboratory testing of PFAS in environmental and food samples, as well as promoting data sharing, is essential for fostering transparency, collaboration, and informed decision-making in addressing PFAS contamination and its impacts on climate and public health.

The distribution of PFAS in food and the environment, as explored in our study, is subject to notable limitations that warrant acknowledgment. Firstly, while our data sources, drawn from publications and reports, provide a diverse array of information, they inherently carry biases and may overlook certain regions and food categories. Notably, our analysis revealed significant data gaps in regions like Africa and South America, limiting the broader applicability of our findings. Additionally, temporal coverage presents a challenge, with sparse data available from recent years and a scarcity of historical records prior to 2005, impacting both the comprehensiveness and temporal relevance of our analysis. Furthermore, the high contamination prevalence observed in our sample set may be influenced by targeted sampling efforts in areas known for elevated contamination risks, potentially skewing the overall distribution patterns. Methodologically, while we prioritized the inclusion of available public data and categorized samples based on their utility, it's crucial to note that concentrations below the limit of detection in certain categories do not necessarily imply the absence of contamination but rather reflect limitations in data sources. Consequently, our study should be viewed as an in-depth exploration of publicly available data rather than an authoritative account of PFAS distribution and impact. Moving forward, addressing these limitations through refined methodologies is essential for a more comprehensive understanding of PFAS distribution dynamics and informed decision-making in environmental and food safety policies.

Technical BRIEF
INNOVATIVE RESEARCH FOR A SUSTAINABLE FUTURE

Per- and Polyfluoroalkyl Substances (PFAS): Incineration to Manage PFAS Waste Streams

Background

Per- and polyfluoroalkyl substances (PFAS) are a very large class of man-made chemicals that include PFOA, PFOS and GenX chemicals. Since the 1940s, PFAS have been manufactured and used in a variety of industries in the United States and around the globe. PFAS are found in everyday items such as food packaging, non-stick stain repellent, and waterproof products, including clothes and other products used by outdoor enthusiasts. PFAS are also widely used in industrial applications and for firefighting. PFAS can enter the environment through production or waste streams and can be very persistent in the environment and the human body. PFAS have many and varied pathways into waste streams, presenting challenges for ultimate disposal. Determining the appropriate method for ultimate disposal of PFAS wastes is a complex issue due to their volatility, solubility, and environmental mobility and persistence. EPA is currently considering multiple disposal techniques, including incineration, to effectively treat and dispose of PFAS waste.

Options and Considerations for the Disposal of PFAS Waste via Incineration

One potential disposal method for PFAS waste is through high temperature chemical breakdown, or incineration. Incineration has been used as a method of destroying related halogenated organic chemicals such as polychlorinated biphenyls (PCBs) and ozone-depleting substances (ODSs), where sufficiently high temperatures and long residence times break the carbon-halogen bond, after which the halogen can be scrubbed from the flue gas, typically as an alkali-halogen. PFAS compounds are difficult to break down due to fluorine's electronegativity and the chemical stability of fluorinated compounds. Incomplete destruction of PFAS compounds can result in the formation of smaller PFAS products, or products of incomplete combustion (PICs), which may not have been researched and thus could be a potential chemical of concern.

Incineration of halogenated organic compounds occurs via unimolecular decomposition and radical reaction. For unimolecular decomposition, fluorinated organic compounds likely require higher temperatures to achieve 99.99% destruction in 1 second residence time than do their chlorinated counterparts. Unimolecular decomposition of highly fluorinated organics most likely occurs through breakage of C-C or C-F bonds (Tsang et al., 1998). The most difficult fluorinated organic compound to decompose is CF_4, requiring temperatures over 1,400°C, but is easily monitored, making it a potential candidate for destructibility trials.

Fluorinated organic compounds can also be degraded via incineration by free radical initiation, propagation, and branching mechanisms. Although hydroxyl radical reaction with hydrocarbons is a common combustion flame-propagating mechanism, the strength of the C-F bond makes this pathway unlikely and would instead leave atomic hydrogen, formed at high temperatures, as the likely radical reacting with the carbon-bonded fluorine.

Radical reactions are more likely for chloroalkanes than fluoroalkanes, due to the lower bond energy of C-Cl (Tsang et al., 1998). If formed, the extremely high electronegativity of fluorine radicals results in their quick combination with other radical species, preventing flame-sustaining free radical propagation and branching processes. This propensity to terminate free radical chemistry make PFAS effective fire suppressants.

The stability of perfluorinated radicals leads to higher concentrations and correspondingly increased propensity to recombine, creating larger molecules that are products of incomplete combustion (PIC) and distinctive from the original fluorinated organics. These reactions are promoted by partial organic combustion resulting from insufficient temperatures, time, and mixing. In addition, the presence of catalytic surfaces, often metals, promotes further reaction and PIC formation in post-combustion regions. This scenario has been most studied related to the formation of polychlorinated dibenzo-*p*-dioxins and dibenzofurans (PCDDs/PCDFs) in the cool-down regions of waste incinerators.

The effectiveness of incineration to destroy PFAS compounds and the tendency for formation of fluorinated or mixed halogenated organic byproducts is not well understood. Few experiments have been conducted under oxidative and temperature conditions representative of field-scale incineration. Limited studies on the thermal destructibility of fluorotelomer-based polymers found no detectable levels of perfluorooctanoic acid after 2 second residence time and 1,000°C (Yamada et al., 2005; Taylor et al., 2014). Emission studies, particularly for PICs, have been incomplete due to lack of necessary measurement methods suitable for the comprehensive characterization of fluorinated and mixed halogenated organic compounds.

Addressing Gaps in Research for PFAS Waste

The extent to which PFAS-containing waste material in the United States is incinerated is not fully documented or understood. PFAS compounds are not listed as hazardous wastes under the Resource Conservation and Recovery Act (RCRA) nor as hazardous air pollutants under Clean Air Act regulations, so they are not subject to the tracking systems associated with these regulations.

EPA is currently considering multiple disposal techniques, including incineration, to effectively treat and dispose of PFAS wastes. EPA researchers are currently studying PFAS incineration, sampling and analytical methods development, and industrial field sampling. Research on thermal stability of PFAS compounds, the ability to fully capture and identify PFAS compounds and their thermal decomposition byproducts, and the efficacy of emission control technologies are areas of targeted research. These efforts, in cooperation with states and industries, is aimed at proper disposal of PFAS-laden wastes without media-to-media transfer or environmental release.

Executive Summary

This 2024 update of the U.S. Environmental Protection Agency (EPA)'s 2020 interim guidance presents currently available information on the destruction and disposal of perfluoroalkyl and polyfluoroalkyl substances (PFAS) and PFAS-containing materials. It focuses on the current state of science and associated uncertainties for three large-scale capacity technologies that can destroy PFAS or control PFAS release into the environment: thermal destruction, landfills, and underground injection. It also includes a framework for evaluating emerging technologies for PFAS destruction or disposal.

EPA published the first edition of this guidance as required by the National Defense Authorization Act (NDAA) of 2020. The NDAA directs EPA to address the destruction and disposal of PFAS and specific PFAS-containing materials, including aqueous film-forming foam, contaminated media, textiles (other than consumer goods), and various wastes from water treatment. The NDAA also requires EPA to review and update the guidance as appropriate, but no less frequently than every three years.

The primary audience of this guidance is decision-makers who need to identify the most effective means for destroying or disposing of PFAS-containing materials and wastes. The audience may also include regulators, waste managers, and the public, including affected communities. EPA is recommending that managers of PFAS wastes consider the nature of the waste, location, potential for environmental release, and other factors to determine the most appropriate destruction, disposal, or storage method. As a general approach, EPA recommends that decision-makers prioritize the use of destruction and disposal technologies that have a lower potential for PFAS release to the environment, over destruction and disposal technology options with a greater potential for environmental release of PFAS. EPA acknowledges that each destruction and disposal technology has limitations. However, managing PFAS to minimize environmental releases during destruction and disposal activities supports protection of human health and the environment.

While the purpose of an effective destruction and disposal technology is to prevent or minimize environmental releases, it is also important to distinguish between a potential environmental release and a direct human exposure. A PFAS release does not inherently imply direct and immediate human exposure and a release does not necessarily present an unacceptable risk to specific populations.

EPA has developed a fact sheet for the public, including potentially affected communities, that provides a more concise and less technical presentation of key materials.

Key Findings and Updates

EPA describes destruction and disposal options based on each technology's potential to destroy PFAS or control PFAS release into the environment. This approach is consistent with EPA's mission to protect human health and the environment. There are several different types of technologies that have been used for PFAS treatment and disposal, and their potential to destroy PFAS or control PFAS releases is described herein (see Section 1). In general, the following technologies (in no particular order) have a lower potential for environmental release of PFAS compared to other technologies in the same category and are viewed as the more protective technologies:

- **Underground Injection - Permitted Class I non-hazardous industrial or hazardous waste injection wells** are the waste management approach with a lower potential for environmental release when

compared to other destruction and disposal options. These wells may help ensure that injected fluids are confined and cannot enter underground sources of drinking water. However, the limited number of wells currently receiving off-site PFAS and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection.

- **Landfills - Permitted hazardous waste landfills** have the most protective landfill engineering controls and practices for the containment of PFAS waste and would be more effective at minimizing PFAS release into the environment than other landfill types. EPA recommends Subtitle C landfills when PFAS levels of the waste are relatively high and landfill disposal is the selected option. However, for all landfill types, new information demonstrates landfilling could have higher PFAS releases to the environment than previously thought in 2020.
- **Thermal Treatment - Permitted hazardous waste combustors** such as commercial incinerators, cement kilns, and lightweight aggregate kilns and granular activated carbon (GAC) reactivation units with thermal oxidizers may operate under conditions more conducive to destroying PFAS and controlling related products of incomplete combustion. Research suggests that the use of higher temperatures, well mixed combustion environments, and longer residence times may be more conducive to destroying PFAS and controlling related products of incomplete combustion. Although limited data have been obtained since the 2020 version of the interim guidance (including data suggestive of adequate temperature ranges to break down PFAS), uncertainties remain about the effectiveness of thermal treatment. EPA encourages additional testing with EPA-approved or EPA-evaluated methods by waste managers of thermal treatment operations, including for products of incomplete combustion and the presence of PFAS in all associated waste streams, to evaluate whether thermal treatment technologies are minimizing potential environmental releases. EPA's new analytical method, OTM-50, will allow better characterization of products of incomplete combustion (PICs) that will help to address some of these uncertainties when additional data are collected as recommended in this guidance (see Appendix A).

This list includes the three technology categories described in Section 3 and does not preclude new or emerging technologies. When considering the bullets above, it is important to note that real-world performance and testing data are generally limited. Additional performance and testing data—including data on destruction and removal of PFAS in thermal treatment devices, ongoing research activities, and long-term performance data for landfills and underground injection—may change EPA's understanding of each technology's ability to control PFAS. Data needs and priorities are summarized in this update.

EPA continues to seek collaboration with thermal treatment facilities to conduct air emission testing during thermal treatment of PFAS and PFAS-containing materials. EPA provides guidance for this and for independent analysis in Appendix A. In addition to performance and testing data, the 2024 guidance identifies other, high-priority data gaps that need to be addressed by researchers across government, academia, and industry for EPA to provide meaningful updates on effective destruction and disposal practices.

EPA partnered with industry and academia to collect data on four emerging technologies for PFAS destruction: mechanochemical degradation, electrochemical oxidation, gasification and pyrolysis, and supercritical water oxidation. While the results from these studies show promise for PFAS destruction, further work using newly available methods is needed to more fully characterize the outputs of these processes and to evaluate their performance for a wider range of PFAS-containing materials. Managers of PFAS and PFAS-containing materials may consider these or other emerging technologies for PFAS disposal or destruction. To assist PFAS material managers with evaluating whether an emerging destruction (or disposal) technology is suitable for a particular PFAS-containing material, EPA developed

a technology evaluation framework. The framework provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS and PFAS-containing material and includes considerations for communities. EPA recommends that managers of PFAS-containing materials use the technology evaluation framework to evaluate emerging destruction and disposal technologies and to inform their decisions about managing PFAS-containing materials. EPA also encourages technology developers to generate and publicly release data that can be used to complete the framework (see Section 6).

EPA updated tools, methods, and approaches for considering the impacts of potential releases and exposure on communities located near destruction and disposal facilities, including identifying vulnerable populations overburdened by cumulative impacts, incorporating vulnerability into decision-making, and engaging the community (see Section 4).

What's Next?

EPA and other government, academic, and private institutions will continue to conduct research to better understand PFAS destruction and disposal. EPA will consider public comments it receives on this version of the guidance as well as additional advancements in PFAS research and science to revise this interim guidance within the next three years.[1] For information about the Agency's plans and actions related to PFAS, visit EPA's website pages *PFAS Strategic Roadmap: EPA's Commitments to Action 2021-2024* and *Key Actions to Address PFAS*.

[1] EPA may explore opportunities to provide more frequent technical updates as information becomes available.

1. Introduction

This second version interim guidance provides information on technologies that may be feasible and appropriate for the destruction or disposal of perfluoroalkyl and polyfluoroalkyl substances (PFAS) and PFAS-containing materials. It represents the current state of science and the associated uncertainties for large-capacity technologies that can destroy PFAS or control PFAS release into the environment. This is an update to the interim guidance the U.S. Environmental Protection Agency (EPA) issued in 2020.

EPA published the first version of this interim guidance and made it available for public comment.[2] EPA received 77 unique public comments (out of 5,066 total comments) on the interim guidance from states, Tribes, industries, trade organizations, environmental organizations, and members of the public. This updated version incorporates this public feedback.

The 2024 interim guidance contains the following new information:

Section 1: Introduction

- Updated review of PFAS destruction and disposal technologies.

Section 2: Description of PFAS-Containing Materials Identified in the FY 2020 NDAA

- Additional details on spent water treatment materials.
- Updated information on biosolids generation and management.

Section 3: Technologies for the Destruction and Disposal of PFAS and PFAS-Containing Materials

- Additional information on thermal treatment and landfills.
- Additional information on testing and monitoring at thermal treatment facilities.

Section 4: Considerations for Potentially Vulnerable Populations Living Near Likely Destruction or Disposal Sites

- Updated list of tools for vulnerability screening.

Section 5: Research Needs and Data Gaps for Destruction and Disposal Technologies

- Increased focus on research needs to inform future updates to this interim guidance.
- Updated information on ongoing research and development activities.

Section 6: Emerging Technologies for PFAS Destruction and Disposal (NEW)

- EPA efforts to identify, review, and test emerging technologies for PFAS destruction.
- Technology evaluation framework that utilizes a multiple-lines-of-evidence approach to evaluate a technology/PFAS material combination.

Appendix A: EPA Guidance to Conduct PFAS Emissions Field Testing at Commercial Thermal Destruction Sources (NEW)

- EPA request to access commercial sources to conduct air emissions testing during PFAS thermal destruction.
- Guidance for facilities to conduct source testing prior to accepting/processing PFAS materials at full-scale thermal destruction facilities.

Appendix B: Summary of the Clean Harbors Test Data (NEW)

- Two source test campaigns conducted at a hazardous waste combustor.

Appendix C: Summary of the Chemours Thermal Oxidizer Test Data (NEW)

- Source test campaign conducted at a chemical manufacturer.

[2] Interim PFAS Destruction and Disposal Guidance; Notice of Availability for Public Comment. U.S. EPA. 85 Federal Register 83554. December 22, 2020.

Appendix D: Summary of Costs and Considerations (NEW)

- Summary of costs and factors that should be considered when estimating costs to destroy or dispose of PFAS and PFAS-containing materials.

1.a Purpose and audience of this interim guidance

The purpose of this interim guidance is to describe technologies for managing the destruction and disposal of PFAS-containing materials and to recommend practices associated with these technologies that minimize PFAS releases to the environment. This purpose is consistent with EPA's mission to protect human health and the environment and the National Defense Authorization Act (NDAA) for Fiscal Year 2020, Public Law No: 116-92 (hereafter, "FY 2020 NDAA"), signed into law on December 19, 2019.

Section 7361 of the FY 2020 NDAA (see Figure 1-1) directs EPA to publish interim guidance on the destruction and disposal of PFAS and PFAS-containing materials no later than one year from the date of enactment of the FY 2020 NDAA. EPA published the initial interim guidance on December 18, 2020. The FY 2020 NDAA also requires EPA to review and revise the interim guidance at least every three years, if appropriate. This 2024 update fulfills that requirement.

The primary audience of this guidance is decision-makers who need to identify the most effective means for destroying or disposing of PFAS-containing materials and wastes. The audience may also include regulators, waste managers, and technology developers who can use the technology evaluation framework in Section 6 to evaluate emerging technology applicability to PFAS destruction or disposal. This guidance may also interest the general public; particularly communities near PFAS destruction and disposal sites who may have an opportunity to offer input or provide consultation to decision-makers regarding destruction and disposal decisions based on relevant decision-makers determination. EPA has developed a fact sheet for the public, including potentially affected communities, that provides a more concise and less technical presentation of this guidance.

This interim guidance meets one of many commitments EPA made under the Agency's PFAS Strategic Roadmap. The PFAS Strategic Roadmap, released in 2021, describes EPA's whole-of-Agency approach to address PFAS and identifies concrete actions EPA is taking to safeguard public health, protect the environment, and hold polluters accountable. For more information on EPA's actions to address PFAS, visit *PFAS Strategic Roadmap: EPA's Commitments to Action 2021-2024* and *Key Actions to Address PFAS*.

SEC. 7361. PFAS DESTRUCTION AND DISPOSAL GUIDANCE.

(a) IN GENERAL.—Not later than 1 year after the date of enactment of this Act, the Administrator shall publish interim guidance on the destruction and disposal of perfluoroalkyl and polyfluoroalkyl substances and materials containing perfluoroalkyl and polyfluoroalkyl substances, including—

(1) aqueous film-forming foam;
(2) soil and biosolids;
(3) textiles, other than consumer goods, treated with perfluoroalkyl and polyfluoroalkyl substances;
(4) spent filters, membranes, resins, granular carbon, and other waste from water treatment;
(5) landfill leachate containing perfluoroalkyl and polyfluoroalkyl substances; and
(6) solid, liquid, or gas waste streams containing perfluoroalkyl and polyfluoroalkyl substances from facilities manufacturing or using perfluoroalkyl and polyfluoroalkyl substances.

(b) CONSIDERATIONS; INCLUSIONS.—The interim guidance under subsection (a) shall—

(1) take into consideration—
(A) the potential for releases of perfluoroalkyl and polyfluoroalkyl substances during destruction or disposal, including through volatilization, air dispersion, or leachate; and
(B) potentially vulnerable populations living near likely destruction or disposal sites; and
(2) provide guidance on testing and monitoring air, effluent, and soil near potential destruction or disposal sites for releases described in paragraph (1)(A).

(c) REVISIONS.—The Administrator shall publish revisions to the interim guidance under subsection (a) as the Administrator determines to be appropriate, but not less frequently than once every 3 years.

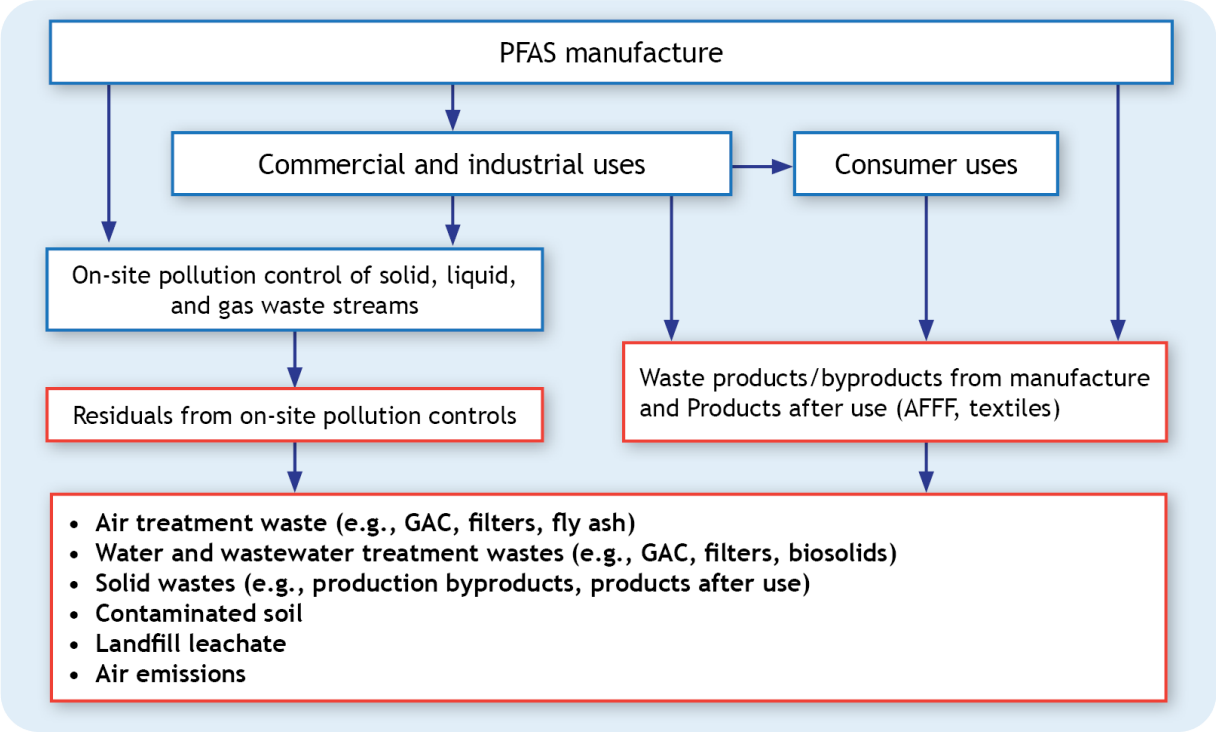

Figure 1-1. FY 2020 NDAA Section 7361.

1.b Scope and use of interim guidance

1.b.i PFAS and PFAS-containing materials in this interim guidance

Section 7361 of the FY 2020 NDAA (see Figure 1-1) lists six types of PFAS-containing materials and wastes. Although the information included in this interim guidance is likely to be suitable for other types of PFAS and PFAS-containing materials, this interim guidance addresses destruction and disposal centering on these six material types, which are described in more detail in Section 2. In this document, the PFAS-containing materials covered by the FY 2020 NDAA that will be destroyed or disposed of are referred to as "waste."

Figure 1-2 shows conceptually how manufacturing activities could result in material streams that are within the intended scope of this interim guidance, including GAC and aqueous film-forming foam (AFFF).

Note: The red-outlined portions show where the FY 2020 NDAA material types occur in the course of manufacture, use, and disposal of PFAS and PFAS-containing materials that are within the scope of this interim guidance.

Figure 1-2. Generation of PFAS materials identified in the FY 2020 NDAA.

1.b.ii Destruction and disposal technologies addressed in this interim guidance

This interim guidance presents three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS and PFAS-containing materials. Advances in scientific understanding allow EPA to make some recommendations, however, filling information gaps and addressing uncertainties will improve the scientific understanding and could lead to additional guidance in the future. EPA updates this guidance at least every three years.

This interim guidance describes technologies with the potential to destroy PFAS or control releases of PFAS into the environment. Other waste management options are not discussed, because they are not within the intended scope of this interim guidance. For example, land application of biosolids containing PFAS does not control PFAS releases into the environment.

Current technologies. In developing this second version of the interim guidance, EPA focused on the three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS wastes—thermal treatment, landfills, and underground injection. EPA also focused on reviewing data and information about the ability of each of these technologies to manage PFAS-containing materials through containment or destruction (i.e., breaking carbon–fluorine bonds and mineralization) while limiting releases of PFAS to the environment. In doing so, EPA prioritized addressing the scientific issues and uncertainties highlighted in the 2020 interim guidance and, when possible, relied on publicly available, peer-reviewed data and information (see Section 3).

Emerging technologies. Concerns about the effectiveness of current, widely-used technologies for managing PFAS and PFAS-containing materials have motivated efforts to develop new technologies and apply existing technologies to PFAS materials. EPA is aware of and, in some cases, has participated in efforts to identify, develop, and test non-thermal destruction technologies for PFAS-containing materials (see Section 6).

In some cases, managers of PFAS and PFAS-containing materials may consider emerging technologies for PFAS destruction. When considering the use of emerging technologies, managers of PFAS waste should work with state, territorial, or Tribal government agencies. To assist PFAS material managers with evaluating whether an emerging destruction (or disposal) technology is suitable for a particular PFAS-containing material, EPA developed a technology evaluation framework (see Section 6). The framework provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS materials, including considerations for communities, including vulnerable populations.

In 2024, EPA is neither recommending nor discouraging the use of any emerging technology for managing the PFAS-containing materials specified in the FY 2020 NDAA. Instead, the Agency recommends that managers of PFAS-containing materials use the technology evaluation framework to evaluate emerging destruction and disposal technologies and to inform their decisions about managing PFAS-containing materials. EPA also encourages technology developers to generate and publicly release data that can be used to complete the framework (see Section 6).

Generally, destruction and disposal of PFAS-containing materials are currently not federally regulated. PFAS-containing materials may be managed in non-hazardous and hazardous waste treatment and disposal systems. Some exceptions exist, such as risk management requirements in cases where permits for production of new chemicals specify methods to be used for destruction or disposal following the review of a Toxic Substances Control Act (TSCA) new chemicals notice. Unless governing regulations require specific actions to the contrary, this guidance recommends selecting an approach with a higher potential to control PFAS releases into the environment, as possible.

Table 1-1. Destruction and Disposal Technologies Discussed in This Interim Guidance, with Examples of PFAS-Containing Materials

Destruction and Disposal Technology, by Physical Phase of Materials	Examples of PFAS-Containing Materials (within the Scope of the FY 2020 NDAA) That Could Be Managed Using These Technologies

Solid phase:
Landfill disposal
Thermal treatment
	• Drinking water, groundwater, and wastewater treatment residuals
	  ○ Biosolids/sewage sludge
	  ○ Spent GAC
	  ○ Ion exchange resins
	• Air waste stream treatment residuals
	  ○ Spent GAC
	  ○ Fly ash
	• Contaminated soil
	• End-of-life products (e.g., textiles)
	• Solidified liquid wastes

Liquid phase: Underground injection Thermal treatment	• Sewage sludge (liquid) • Landfill leachate • AFFF (spent or concentrate)

Destruction and Disposal Technology, by Physical Phase of Materials	Examples of PFAS-Containing Materials (within the Scope of the FY 2020 NDAA) That Could Be Managed Using These Technologies
	• End-of-life products (e.g., spent cleaning solvents) • Pollution control residuals (e.g., concentrates) from PFAS production and use
Gas phase: Thermal treatment	• Landfill gas (LFG) • Emissions from manufacture, use, or destruction of PFAS

1.b.iii Use of this interim guidance

This interim guidance provides information and suggested considerations for evaluating destruction and disposal options. This second version of the interim guidance is based on currently available research and information in 2023 and is responsive to the scope of the FY 2020 NDAA. It presents background information on the manufacture and uses of PFAS, as well as solid, liquid, and gas waste streams containing PFAS, including those materials identified in the FY 2020 NDAA: AFFF, soils and biosolids, textiles, spent water treatment materials, landfill leachate, and PFAS waste streams from facilities manufacturing or using PFAS (see Section 2). Most significantly, it provides up-to-date information on potential releases during the destruction and disposal of PFAS and PFAS-containing materials (see Section 3) and identifies data gaps to be filled that can inform future EPA guidance (see Section 5). This version also incorporates information received during the 2020 Interim Guidance's public comment period.

This version of the interim guidance takes the following into account:

- It is based on currently available information on technology performance and capabilities for destruction and disposal of the PFAS and PFAS-containing materials specified in the FY 2020 NDAA (see Section 1.b.i).
- It focuses on three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS wastes (i.e., thermal treatment, landfills, underground injection) (see Section 3).
- It advises how to assess and consider the impacts of potential releases and exposure on communities, including identifying vulnerable populations, incorporating vulnerability into decision-making, and performing community engagement (see Section 4). The FY 2020 NDAA states that the interim guidance should take into consideration potentially vulnerable populations living near destruction or disposal sites.
- It identifies research needs to inform future updates to this interim guidance and provides updated information on ongoing research and development activities (see Section 5).
- It discusses the development of emerging technologies and includes a framework for evaluating technology/PFAS material combinations (see Section 6).
- It does *not* establish what concentrations of PFAS in wastes, spent products, or other materials or media would necessitate destruction or disposal. Regulatory mechanisms are more appropriate for establishing such concentrations.
- It provides references to destruction and disposal facility locators that decision-makers can use to request cost estimates. EPA recommends obtaining cost estimates from applicable destruction and disposal facilities as described in Section 1.c.ii. In addition, Appendix D provides some cost

information that PFAS material managers may want to consider when evaluating different techniques to destroy or dispose of PFAS and PFAS-containing materials. Note that cost information presented in this appendix has a relatively high level of uncertainty associated with it. Moreover, the cost of PFAS destruction and disposal may change based on demand and evolution of available technologies. Additionally, overall costs may vary widely based on the type of materials or the distance to a facility.

This interim guidance is not a regulation. Any discussion of EPA's regulatory authorities is for the purpose of describing controls relevant to the destruction or disposal of PFAS and should not be considered a description of the applicability of those authorities or affect EPA's or any other agency's ability to enforce under these authorities in the future. For information about EPA's other plans and actions related to PFAS, visit EPA's *PFAS Strategic Roadmap: EPA's Commitments to Action 2021-2024* and *Key Actions to Address PFAS*.

1.c Considerations for managing PFAS and PFAS-containing materials

The information presented in this interim guidance can help managers of PFAS or PFAS-containing materials make informed decisions regarding destruction and disposal. To assist decision-makers, EPA reviews destruction and disposal options for thermal treatment, landfills, and underground injection based on the relative potential for releasing PFAS to the environment. This approach highlights destruction and disposal options with lower potential for PFAS releases to the environment compared to other options. This approach is consistent with EPA's mission to protect human health and the environment and is designed to facilitate decisions that protect human health and the environment as much as possible.

EPA recognizes that the potential to control PFAS releases to the environment is one of several factors to consider when selecting among options for destroying or disposing of PFAS and PFAS-containing materials in a way that is consistent with maximizing protection to public health and the environment. Other factors include whether it is imperative to destroy or dispose of the waste immediately, availability of interim storage or destruction and disposal options, the type and volume of waste materials, the concentrations of PFAS in the waste, and the presence of and potential impacts to communities, including vulnerable communities. In the following sections, EPA provides guidance for these decisions in terms of technology considerations and infrastructure considerations.

1.c.i Technology Considerations - Relative potential for PFAS releases to the environment

Using the information presented in Section 3, and considering the significant uncertainties that remain, EPA listed destruction and disposal options in terms of relative potential for releasing PFAS to the environment. When considering the data and information presented in Section 3, EPA considered the type of data available (e.g., laboratory-, pilot-, or field-scale studies), the amount of data available (e.g., data from different operating conditions), and the quality of the data.

When considering the order, it is important to note that available performance and testing data are generally limited. Additional performance and testing data—including data on destruction and removal of PFAS in thermal treatment devices, and long-term performance data for landfills and underground injection—are needed to support more specific guidance. When these data and information become available, EPA may reconsider and revise the order presented below.

As a general approach, EPA encourages managers of PFAS and PFAS-containing materials to prioritize destruction and disposal options with a lower potential for releasing PFAS to the environment over the use of destruction and disposal technology options with a higher potential for environmental release of PFAS. EPA also encourages testing with EPA-approved methods of thermal treatment operations, including products of incomplete combustion and the presence of PFAS in all associated waste streams (see Appendix A), to evaluate whether site-specific conditions are minimizing potential environmental releases.

While the purpose of an effective destruction and disposal technology is to prevent or minimize environmental releases, it is also important to distinguish between a potential environmental release and a direct human exposure. A PFAS release does not inherently imply direct and immediate human exposure and a release does not necessarily present an unacceptable risk to specific populations.

EPA encourages managers of PFAS and PFAS-containing materials to make decisions in consideration of factors discussed in this guidance to select current or future disposal or destruction technologies that protect human health and the environment as much as possible. Based on currently available information cited in this guidance, EPA has listed the following disposal and destruction options from lowest to highest based on their relative potential to release PFAS to the environment:

- **Interim storage with controls.** While not a destruction or disposal method, interim storage may be a short-term option if the destruction or disposal of PFAS and PFAS-containing materials is not imperative, on-site storage capacity is readily available, and interim storage has proper controls in place to reduce releases into the environment. Storage may be more appropriate for some PFAS materials than others. For example, EPA recommends interim storage of low volumes of containerized or high PFAS-concentration materials. In contrast, some materials may be less appropriate for storage because they are continuously generated or are typically high-volume. With proper engineering controls in place, interim storage can control PFAS releases in the short-term.
- **Underground injection (Class I non-hazardous industrial and hazardous waste wells).** EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high concentration liquid PFAS waste has a lower potential for environmental release when compared to other PFAS destruction and disposal options, and there is relatively low uncertainty in this determination. The standards associated with the construction, operation, and monitoring of these Class I wells are designed to isolate liquid wastes deep below the land surface and ensure protection of underground sources of drinking water (USDWs). Class I hazardous waste wells operators must conduct mechanical integrity testing more often than Class I non-hazardous industrial waste operators. They also must establish and follow additional procedures for reporting and correcting mechanical integrity problems. Class I hazardous waste well operators must also develop and follow a waste analysis plan and conduct annual tests of cement at the base of the well. While the standards associated with Class I hazardous wells are more stringent than for non-hazardous industrial wells, EPA has determined that the probability of failures for both has been demonstrated to be low. While Class I wells are an option for managing PFAS-containing fluids, this technology may not be appropriate everywhere. The limited number of wells currently receiving PFAS, well location, and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection. Additional Class I wells may need to be constructed where geologically suitable, and existing well permits may need to be modified to meet the capacity needs for PFAS disposal (see Section 3.c.v).

- **Hazardous waste landfills (Resource Conservation and Recovery Act (RCRA) Subtitle C).** This class of landfills has the most stringent environmental controls in place for minimizing environmental releases and migration of some PFAS from disposed waste. EPA recommends Subtitle C landfills when PFAS levels of the waste are relatively high and landfill disposal is the selected option. Permitted hazardous waste landfills have relatively low quantities of landfill leachate[3], which lessens the probability of mobilizing PFAS that is reversibly bound to the waste. These landfills are required to handle and treat leachate as listed hazardous waste (hazardous waste number F039 per 40 CFR 261.31), lessening the likelihood of environmental release. Because hazardous waste landfills generally do not receive organic wastes that decompose, PFAS migration via LFG is anticipated to be relatively low but LFG collection and destruction equipment could be installed if anaerobic decomposition is shown (see Section 3.b). While recent studies have improved understanding of PFAS migration, additional research is needed to resolve uncertainties (see Section 3.b.vi).
- **Landfill disposal in all landfill types: Landfill disposal of stable polymeric PFAS**. Stable polymeric PFAS, such as polytetrafluoroethylene (Teflon™) and fluorinated ethylene propylene (FEP), are large molecules that are not susceptible to hydrolysis or oxidation. They are neither volatile nor water soluble and, as a result, they are expected to remain within the waste mass for long periods of time. This PFAS category tends not to migrate with the leachate and is unlikely to volatilize with the LFG; therefore, permitted hazardous and municipal solid waste (MSW) landfills (MSWLFs) may provide a good disposal option. Some data are available to support this assessment, but more data are needed to resolve uncertainties (see Sections 3.b.i and 3.b.vi).
- **GAC reactivation units with thermal oxidizers operating under certain conditions**. Carbon reactivation systems, with the associated use of off-gas incineration (i.e., afterburners operating at temperatures >1,100°C[4]) and gas scrubbing units, can potentially destroy PFAS without significant environmental releases, or without PFAS remaining on the reactivated carbon. However, as discussed in Section 3.a.i, more data are needed for confirmation, particularly regarding reactor conditions, differing carbons, and products of incomplete combustion (PICs). There is uncertainty associated with this option because it is based on limited research. While recent studies have improved understanding, additional research is needed to resolve uncertainties on PFAS emissions from full-scale reactivation facilities (see Section 3.a.v).
- **Thermal treatment units operating under certain conditions.** Hazardous waste combustors (HWCs), including commercial incinerators, cement kilns, lightweight aggregate kilns (LWAKs), and thermal oxidizers, that operate under certain conditions (i.e., feeding liquid PFAS-containing materials, higher temperatures >1,100°C[4], well mixed, and adequate residence time) may be more effective at adequately destroying (mineralizing) PFAS and minimizing PICs. There is uncertainty associated with this option because it is based on limited research and observations, there are limited data for the treatment of solid materials or containerized wastes, and there are limited emissions data (e.g., no data for PIC formation and the presence of PFAS in air pollution control device residuals) at full-scale facilities (see Section 3.a.v) due to previous methodology limitations.
- **Landfill disposal in MSWLFs that have composite liners and leachate and gas collection and treatment systems: Landfill disposal of volatile or water soluble PFAS.** MSWLFs receive non-hazardous waste and most have composite liners and gas collection systems. Soluble PFAS in these

[3] EPA defines landfill leachate as the liquid that is formed when rain water filters through wastes placed in a landfill. When this liquid comes in contact with buried wastes, it leaches, or draws out, chemicals or constituents from those wastes (*https://www.epa.gov/landfills/municipal-solid-waste-landfills*).

[4] Maximum PIC destruction was observed at and above 1,090°C as described by Shields et al., 2023.

landfills are likely to be released over time in landfill leachate if they are not adequately bound or sequestered in immobile solids. Further research is needed on the ability of various solidification techniques to retain soluble PFAS for extended periods under conditions found in MSWLFs. Although MSWLFs generally have leachate collection and management processes in place, the typical practices employed are not expected to prevent further PFAS migration. In addition, MSWLFs generally receive significant quantities of organic wastes (e.g., food scraps) that decompose, and thereby can cause PFAS migration via LFG. Multiple studies have reported elevated levels of PFAS in leachate and LFG. Studies estimate that up to 15 percent of mobile PFAS disposed in MSW landfills is emitted to the environment over time. EPA does not recommend MSWLF disposal of media containing relatively high concentrations of soluble or volatile PFAS. While recent studies have improved understanding of PFAS migration in MSWLFs, additional research is needed to resolve uncertainties (see Section 3.b).

- **Thermal treatment at lower temperatures** including municipal waste combustors (MWCs), sewage sludge incinerators (SSIs), or HWCs operating at lower temperatures or feeding solid or containerized PFAS-containing materials. Some HWCs operate at temperatures near or below 1,100°C, MWCs typically operate between 850 and 1,000°C, and SSIs typically operate at even lower temperatures. There is uncertainty associated with this option because it is based on very limited research. While limited, existing datapoints suggest the potential for air emissions of PFAS and PICs orders of magnitude above detection limits at temperatures below 1,000°C (Shields et al., 2023). There are no data on the treatment of solid materials or containerized wastes at lower temperatures. There are currently insufficient data and information to conclude anything about PIC formation or PFAS air emissions from full-scale combustion units operating at these lower temperatures or when feeding solid materials or containerized wastes. Because there are insufficient data available, there is low confidence in the reliability of this technology to control PFAS releases (see Section 3.a).
- **Construction and Demolition (C&D) landfills: Landfill disposal of volatile, water soluble, or oxidizable PFAS.** This class of landfills may not have a composite liner or leachate collection system. Because of the potential for environmental releases, EPA does not recommend that PFAS waste, other than wastes containing stable polymeric PFAS, be disposed of in this type of landfill. While few studies have documented emissions of PFAS from C&D landfills, the known mobility of PFAS in landfills and lack of engineered controls at C&D landfills make them unsuitable for PFAS disposal. For these reasons, EPA does not expect that C&D landfills will minimize PFAS releases to the environment (see Section 3.b).

1.c.ii Infrastructure considerations – communities, costs, and capacity

Waste management infrastructure in the United States is a complex and varied system, crucial for managing the vast amounts of waste generated, including PFAS-containing waste. Therefore, in addition to considering potential for environmental release, decision-makers should consider site- or project-specific factors that may influence decisions about managing PFAS-contaminated wastes. Specific factors include, but are not limited to, the composition of the waste, the types and concentrations of PFAS, transportation costs, destruction and disposal costs, and impacts to communities.

EPA emphasizes the importance for decision-makers (managers of PFAS-containing materials making decisions about destruction and disposal) to consider potential impacts to nearby communities, including vulnerable populations, when evaluating destruction, disposal, and storage options. Those concerns are amplified because the uncertainties in the effectiveness of these options to limit or control environmental releases can contribute to adverse impacts, including potentially disproportionate and

cumulative impacts, for vulnerable communities. Therefore, EPA recommends decision-makers screen communities located in the vicinity of potential releases from the destruction, disposal, and storage options (considering fate and transport) in order to consider the potential for community impacts, including adverse and disproportionate impacts (see Section 4), and to consider potential measures to address such impacts. Depending on site-specific circumstances (e.g., PFAS concentrations, impacted media, and potential exposure pathways), the size and shape of this area (vicinity) will vary. In deciding how to address PFAS waste, site-specific considerations and waste characteristics should factor into the decision. For example, destruction or disposal of waste with a high concentration of PFAS using a method that has a higher potential for environmental release may not be well suited for a site where there is greater likelihood of potential exposure to vulnerable populations.

The waste management infrastructure's design and operation are heavily influenced by regional needs, local regulations, and technological advancements. As a result, waste management options vary by the type of waste and by location due to factors like availability, feasibility, and transportation requirements. For instance, urban areas may incur higher disposal costs due to limited space while rural areas may face higher transportation costs to distant disposal facilities. Furthermore, technological advances specifically related to the management of PFAS-containing materials can potentially reshape the cost and operational landscape of PFAS waste management. EPA recommends that decision-makers request cost estimates directly from potentially applicable destruction and disposal facilities. In addition, decision-makers can refer to Appendix D, which summarizes costs and factors to consider when estimating costs to destroy or dispose of PFAS and PFAS-containing materials.

Decision-makers seeking lists of waste management sites in the United States can access various resources depending on the type of waste and location. It is important to note that often the most direct source is local government websites, such as county or city environmental services or public works departments. These websites typically provide comprehensive lists and maps of local facilities, along with their types, hours of operation, and accepted waste materials. For specialized waste like hazardous or medical waste, state environmental protection agencies or EPA are valuable resources. EPA's website, in particular, offers databases and tools such as *RCRAInfo*, which provides detailed information about facilities managing hazardous waste.

A general yet incomplete list of potential treatment and disposal facilities may also be available through the EPA Incident Waste Decision Support Tool (*I-WASTE DST*). This list includes landfills (hazardous waste, MSW, industrial, and C&D), HWCs, and nonhazardous combustors (sewage sludge and municipal waste) but does not include all technologies available for PFAS destruction and disposal (e.g., cement kilns, carbon reactivation facilities, and underground injection facilities). I-WASTE DST is updated periodically and is limited to information available online.

Similar to cost estimation, management capacity estimates can also be challenging. Facilities that can potentially manage PFAS-containing waste are not evenly distributed. Their number and capacity vary by region. Some areas across the United States face challenges due to limited available landfill space or capacity limits. Incineration and underground injection capacities can also be greatly influenced by technological capabilities and local regulations.

2. Description of PFAS-Containing Materials Identified in the FY 2020 NDAA

The FY 2020 NDAA identifies six types of materials that commonly contain PFAS (see Figure 1-1 and the Executive Summary). This section discusses each FY 2020 NDAA material type, its origin, potential sources of PFAS, current disposal and treatment methods, and potential releases to the environment.

Data on FY 2020 NDAA-relevant material types come from a variety of sources, and more PFAS data will be available from EPA-managed datasets in the near future. For example, EPA's Chemical Data Reporting (CDR) dataset includes production volumes for manufactured and imported amounts and conveys certain industrial processing and use activities. One data element distinguishes amounts that are recycled instead of discharged or released to a waste stream. In the 2020 CDR reporting cycle, submitters began using Organization for Economic Cooperation and Development (OECD)-based industrial processing and use codes to better harmonize those data (U.S. EPA, 2020a).

In 2022, EPA issued two memoranda recommending EPA and state National Pollutant Discharge Elimination System (NPDES) permitting authorities and publicly owned treatment works (POTW) pretreatment program authorities conduct certain activities to align wastewater and stormwater NPDES permits, pretreatment program implementation activities, and biosolids monitoring with the goals in EPA's *PFAS Strategic Roadmap* (U.S. EPA, 2022a, 2022d). The memoranda recommend that EPA and state permitting authorities use the most current sampling and analysis methods in their NPDES programs to identify known or suspected sources of PFAS and to take actions using their pretreatment and permitting authorities, such as imposing technology-based limits on sources of PFAS discharges. The memoranda will also help the Agency obtain comprehensive information through monitoring regarding the sources and quantities of PFAS discharges, informing other EPA efforts to address PFAS.

Additionally, EPA's Toxics Release Inventory (TRI) program collects data related to industrial releases and waste management of certain chemicals. The TRI dataset includes, among other information, quantities of environmental releases to all media above certain thresholds (including on-site disposals and land application), as well as quantities transferred to off-site waste management facilities, including POTW. Under Section 7321 of the FY 2020 NDAA, certain PFAS were added to the TRI list beginning with Reporting Year 2020 (U.S. EPA, 2020b). As of Reporting Year 2023 (reporting forms due by July 1, 2024), a total of 189 PFAS are on the TRI list. TRI reporting data can be accessed at *https://www.epa.gov/toxics-release-inventory-tri-program/tri-data-and-tools*.

In October 2023, EPA finalized the PFAS 8(a)(7) reporting rule under TSCA (88 FR 70516, October 11, 2023). In accordance with obligations under TSCA, as amended by the FY 2020 NDAA, the PFAS 8(a)(7) reporting rule requires any person that manufactures (including import) or has manufactured (including imported) PFAS or PFAS-containing articles in any year since January 1, 2011, to electronically report information regarding PFAS uses, production volumes, disposal, exposures, and hazards. The PFAS 8(a)(7) rule will help EPA better understand the sources and quantities of PFAS manufactured in the United States and provide EPA with the most comprehensive dataset of PFAS manufactured in the United States. EPA will begin receiving reports under the PFAS 8(a)(7) rule in 2025.

2.a Solid, liquid, or gas waste streams containing PFAS from facilities manufacturing or using PFAS

PFAS do not occur naturally. They are synthesized for use in a diverse array of industrial and commercial applications. Industrial waste streams containing PFAS stem from two main sources: (1) primary manufacturing facilities of PFAS and (2) secondary industries that use PFAS or manufacture finished products that contain PFAS. A 2009 survey by OECD identified 27 primary manufacturers and processors of PFAS globally (OECD, 2011). At the time of that survey, more than 90 percent of the global annual production of PFAS was generated by eight manufacturers (Posner et al., 2009), all of which participated in EPA's 2010/2015 Perfluorooctanoic Acid (PFOA) Stewardship Program (U.S. EPA, 2006).

The goal of the PFOA Stewardship Program was to reduce PFOA facility emissions and their use in products by 95 percent by 2010, compared with 2006 baseline levels, and to eliminate PFOA from all facility emissions and products by 2015 (U.S. EPA, 2006). Companies that did not participate in the PFOA Stewardship Program likely continue to use these chemical substances. Long-chain PFAS and their precursors may still be produced as unintentional byproducts and may persist in facility emissions and as product impurities in small quantities (3M Company, 1999; Boucher et al., 2019; Lehmler, 2009; Kissa, 2001). Perfluoroalkyl sulfonic acids containing six or more carbons and perfluoroalkyl carboxylic acids with seven or more carbons are generally considered to be long-chain PFAS. PFOA and PFOS are examples of long-chain PFAS, and PFBS and PFHxA are examples of short-chain PFAS. Furthermore, information on the toxicity and environmental fate and transport of alternative PFAS chemistries is limited (Sun et al., 2016; Wang et al., 2014).

For the 2020 CDR reporting cycle, 52 sites reported a total domestic manufacture and import production volume of 339,000 tons for PFAS in 2019. This represents the aggregate production volume for PFAS produced and imported into the United States across all industries. Although the aggregate production volume might not include all PFAS sources (for instance, a specific chemical or site may not meet reporting obligations), it provides a proxy quantity of all PFAS domestically produced and imported.

PFAS might be released into the environment at every step in the production process, including during synthesis, polymerization, application, transport, usage, waste stream management, and disposal (3M Company, 2000b).

Table 2-1 lists examples of PFAS uses and the resulting solid, liquid, and gas waste streams for primary and secondary manufacturers of PFAS-containing materials and certain service sectors as indicated by industry, national and global inventories, and research. However, this list is not exhaustive or representative of all current uses, applications, recovery and recycling practices, or treatment technologies that could affect the volume and characteristics of the resulting waste streams. EPA recognizes the need for continued research to better characterize the multi-media PFAS-containing materials targeted for destruction or disposal, as discussed in Section 5.a.

2.a.i Solid phase wastes

Primary manufacturing and secondary industrial use of PFAS can generate solid waste streams with PFAS-containing materials (OECD, 2011, 2015). For example, some PFAS synthesis processes can produce tars and polymers consisting of high-molecular-weight byproducts that are either fully or partially fluorinated. These byproducts can be recycled back into the process or treated as waste (3M Company, 2000a, 2000b). Solid wastes such as fly ash (e.g., thermal treatment) or spent GAC (e.g., drinking water treatment) can also be produced from PFAS incineration and other treatment processes.

Other important solid-phase materials include sludges and biosolids (see Section 2.c) that result from stabilizing or treating process waters and wastewaters, either on site or at a municipal wastewater treatment plant (WWTP)[5] that receives influent from industrial sources (Venkatesan & Halden, 2013). In addition to solids produced via treatment, spent water treatment media (such as activated carbon and ion exchange resins) are part of this waste stream (see Section 2.e). Other direct industrial sources of solid wastes containing PFAS include intentional residuals, such as cuttings and fibers from textile manufacturing (see Section 2.d), and materials unintentionally produced outside of product specification. The concentrations and composition of PFAS in solid wastes generated from primary and secondary industrial sources vary by facility and depend on factors such as facility- or industry-specific production processes and the types and quantities of PFAS produced or used (ITRC, 2020).

The characteristics of these solid phase PFAS-containing wastes vary significantly, depending on several factors. As discussed in Section 3.b, the type of PFAS (e.g., polymeric, soluble, or volatile PFAS) as well as the type of waste with which the PFAS is comingled (e.g., biodegradable or non-biodegradable) will dictate the potential and pathways for environmental release. The type of environmental release will, in turn, inform the most appropriate disposal option(s) for each type of PFAS-containing solid waste.

2.a.ii Liquid phase wastes

Primary manufacturers and secondary industrial users of PFAS can generate liquid phase wastes in the form of: (1) liquid byproducts of PFAS synthesis to be recycled or disposed of (e.g., to a landfill) following stabilization, solidification, or another management method; (2) process wastewater resulting from activities using PFAS as a processing aid (e.g., surfactant, emulsifier, mist suppressant, sizing agent) and production of finished products containing PFAS; (3) spills or unintentional releases of liquid wastes and products containing PFAS; and (4) AFFF/water/foam mixtures from the use of fire-extinguishing agents (see Section 2.b) for emergency response activities and emergency response trainings at industrial facilities.

Table 2-1 provides examples of liquid wastes containing PFAS generated by industrial sources and their uses. This is not an all-inclusive list of industries nor waste streams.

Another liquid phase waste stream is wastewater effluent discharged directly from a primary manufacturer or secondary industrial PFAS user. Effluent from wastewater treatment facilities that receive wastewater from industrial PFAS sources may also contain PFAS. According to several studies, conventional wastewater treatment technologies are generally ineffective at destroying or controlling PFAS (Schultz et al., 2006) and may result in higher measurable PFAAs (e.g., PFOA, perfluorooctane sulfonate [PFOS], and their homologues) when precursor compounds (e.g., fluorotelomers) are degraded during the treatment process (Buck et al., 2011; Dauchy et al., 2017a; Schultz et al., 2006; Sinclair & Kannan, 2006). Less often, primary industrial PFAS manufacturers have opted to transport liquid wastes off site for incineration (North Carolina Department of Environmental Quality, 2017).

2.a.iii Gas phase wastes

Studies suggest that PFAS in air emissions from manufacturing facilities are a source of both localized (i.e., within a short radius of the facility) and long-distance (i.e., global) transport of PFAS within the environment (Davis et al., 2007; Dreyer et al., 2009). Non-volatile forms of PFAS, such as the anionic

[5] Regulations at 40 CFR part 122.2 and part 403.3 identify these “municipal wastewater treatment plants" as treatment works treating domestic sewage (TWTDS) or publicly owned treatment works (POTW), dependent on their ownership.

PFAAs (e.g., PFOA, PFOS, their homologues), are associated with airborne particulates when emitted as aerosols from stack emissions at primary manufacturing facilities (Barton et al., 2006; Dreyer et al., 2015). Gas phase emissions of volatile and semivolatile PFAS, and the subsequent transformation of precursor compounds into persistent PFAAs, are a potential mechanism for the atmospheric transport of PFAS. For example, volatile fluorotelomer alcohols (FTOHs) and perfluoroalkyl sulfonamides can transform into perfluoroalkyl carboxylic acids (e.g., PFOA and homologues) and perfluoroalkyl sulfonates (e.g., PFOS and homologues); these can be deposited at significant distances from their origin, which may result in soil and groundwater contamination (Dreyer et al., 2009; Ellis et al., 2004; Martin et al., 2006; Schenker et al., 2008).

Table 2-1. Examples of PFAS Waste Streams by Industry Type.
This is not an all-inclusive list of industries or waste streams.

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Primary chemical manufacturing	PFAS synthesis, feedstocks for primary products, feedstocks for secondary users, processing aids (fluoropolymers)	Process byproducts (tars), sludges/residuals, off-spec materials[b], treatment residuals (GAC/anion exchange resins), spill residues (replacement and legacy), *particulate emissions*	Degraded/stabilized process wastes, wastewater effluent, *stack emissions condensate*	Stack emissions, fugitive volatiles	3M Company (1999, 2000b)
Secondary Manufacturing (Industry Users of PFAS-Containing Materials)[c]					
Adhesives manufacturing	Component of solvent- and water-based adhesives, rubber to allow bonding to steel, and urea-formaldehyde adhesive resins for wood particleboard bonding	*Used filter media and filter residues, residues of cured adhesives, empty containers, used shop rags (from cleaning), contaminated soil (from spill cleanup residues)*	*Residues of liquid adhesives, off-spec products[b], contaminated wastewater (from spill cleanup residues)* *For cleaning: equipment startup, cleaning, and flushing wastes; spent cleaning solvents; and contaminated wastewater*	Stack emissions, fugitive volatiles	ASC (n.d.), RadTech International North America (2010)
Cleaning product manufacturing	Component of household cleaners; car wash products; automobile waxes; wiper fluid; strongly acidic or basic cleaners for concrete, masonry, airplanes		*Off-spec products[b], liquid residues from empty containers, and spills*	Stack emissions, fugitive volatiles	3M Company (1999)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
	Used for removal of adhesives, dry cleaning of textiles or metal surfaces, machine parts cleaning after nickel plating, and removal of calcium sulfate from reverse osmosis membranes				
Computers/ electronics manufacturing	Component of sealant for electric circuits, zinc battery electrolyte, wetting agents in solders, polar solvents used before welding Used for removal of cured epoxy resins from integrated circuit modules, treatment of insulated wire, alkaline manganese battery MnO_2 cathode treatment, production of polymer electrolyte membrane for fuel cells, cleaning of electronic components, and coating of the surface of magnetic recording devices	*Collected airborne particulates for cleaning/surface preparation*	*Spent acid solution for cleaning/surface preparation, liquid residues from empty containers, and spills*	Stack emissions, fugitive volatiles	U.S. EPA (1990)
Film/ lithography manufacturing	Used in coatings for surface tension, static discharge, and adhesion control for films, papers, and printing plates, and as a surfactant in mixtures used to process imaging films	Rags and wipes discarded by applicator; solids coated with PFAS from processing, sampling, quality assurance; off-spec products[b]	Solvent waste, liquid residues from empty containers, spills, and unused application mix	Coating application exhaust	3M Company (1999), Bowden et al. (2002)
Metal plating/ fabrication	Used as a surfactant, wetting agent, and mist suppressing agent; as a wetting agent fume suppressant for chromium plating and chromium anodizing; as a dispersion product used to coat metals; as a	*Off-spec products*[b]	Spent plating or etching baths, rinse water effluent, liquid residues from empty containers, and spills	Stack emissions, fugitive volatiles	3M Company (1999), U.S. EPA (2009b)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
	blocking agent for aluminum foil; in plating baths; and to treat metal surfaces				
Oil and gas drilling/ extraction/ refinery/ support	Component of chemical barrier used for containing oil spills Used as a surfactant for recovery in oil/gas recovery wells, a jet fuel/hydrocarbon solvent, and in hydraulic oils Used as a gasoline/petroleum product evaporation inhibitor in storage tanks in the following forms: a floating layer of cereal grains treated with PFAS, an aqueous layer containing PFAS		Applied product[d] (oil spills, oil and gas recovery wells), *liquid residues from empty containers, and spills*		UNEP (2011), Kissa (2001)
Paint/coating manufacturing	Component of coatings, paints, varnishes, dyes, ink jet printer inks, and ski waxes	*Pigment dust*	*Unused paint products, off-spec products[b], liquid residues from empty containers, and spills*	*Fugitive volatiles, atomized paint*	Waste Management and Research Center (1992)
Paper products/ packaging manufacturing	Waterproofing and grease proofing for products including food contact paper (e.g., plates, popcorn bags, pizza box liners, food containers, wraps), non-food contact applications (e.g., folding cartons, carbonless forms, masking papers)	Dusts; *solids coated with PFAS from processing, sampling, quality assurance; off-spec products[b]*	Spillage, cleanup, and releases during opening, rinsing, and cleaning of PFAS totes	Fugitive volatiles	U.S. EPA (2009a)
Pesticide/ fertilizer/ other agriculture chemical manufacturing	Pesticide and herbicide ingredients and packaging	*Particulate emissions*	*Liquid residues from empty containers, spills, off-spec products[b], cleaning of equipment, and process wastewaters*	*Fugitive volatiles*	U.S. EPA (2023b)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Plastic materials/ resins/ rubber product manufacturing	Used to make membranes used in fuel cells; chlor-alkali cells; water, caustic soda, and caustic potash electrolyzers; silicone rubber sealants; composite resins; polytetrafluoroethylene (PTFE, or Teflon); and polyvinylidene fluoride or polyvinylidene difluoride (PVDF) Processing aid for PVDF manufacture, mold-release agent in foam molding, and antiblocking agent for rubbers	Dusts, spillage (micropowders and resins), cuttings, scrap, debris, and off-spec products[b]; particulate emissions	*Liquid residues from empty containers, spills, and unused application mix*	Fumes from PTFE heating (volatile)	Ebnesajjad (2015)
Textiles/ apparel/ leather/ carpets/ fiber manufacturing	Dispersion products that coat fabrics: jackets, shoes, umbrellas, carpets, upholstery, leather, tents, sails	Solids coated with PFAS from cutting, shearing, packaging, lab and color sampling, quality assurance; flakes or dust containing PFAS; *off-spec products*[b]	Spills, wastewater effluent from product adhering to inside of drum, and unused application mix	Releases of vapors and aerosols during application of surface treatment and mechanical finishing	U.S. EPA (2009a)
Aerospace component manufacturing	Mechanical components such as tubing, hoses, and seals; brake and hydraulic fluid additive; wire and cable insulation; used in coating and paint		*Wastewater effluent*		FluoroCouncil (2019)
Automotive component manufacturing	Mechanical components such as tubing, hoses, and seals; brake and hydraulic fluid additive; anti-mist film on windshields; used in coating/paint; used in coatings or surface treatments of textiles and upholstery		*Wastewater effluent*		FluoroCouncil (2019), ITRC (2020)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Semiconductor manufacturing	Etching solutions for photolithography, glass etching, plastics etching, fused silica, aluminum; liquid etchant in photo mask rendering		Spent plating or etching baths, PFOA residues from photoresist developers associated with semiconductor liquid waste streams, liquid residues from empty containers, and spills Photoresists and antireflective coatings stripped off from semiconductor devices before shipment are present in waste solvent streams	Photoresists and antireflective coatings stripped off from semiconductor devices before shipment are present in waste gas streams	Bowden et al. (2002), Tremblay (2015)
Building and construction materials manufacturing	Component of cement and primers used to coat cement mortar; used in wire and cable insulation and coatings for wood particleboards	*Cuttings and debris, off-spec materials*[b]	*Wastewater effluent*		Buck et al. (2012), FluoroCouncil (2019), U.S. EPA (2009a)
Mining industry	Surfactant for recovery of metals from ores; used in ore flotation to separate metal salts from soil, electrowinning of metals, and nitrogen flotation to recover uranium	Contaminated rock from applied product[d]	Applied product[d]		ITRC (2020)
Medical uses	Video endoscopes; catheters; saline solutions for in vitro diagnostics; treatment/coatings for textiles such as hospital gowns, curtains, drapes; dialysis machines	*Laboratory/medical solid wastes (e.g., tubing, filters, films)*			FluoroCouncil (2019), Posner (2012)
Cosmetics and personal care product manufacturing	Used in cosmetics, hair conditioning formulations, hair creams, and toothpaste	*Off-spec materials*[b]	*Wastewater effluent*		Danish EPA (2018), FluoroCouncil (2019), Schultes et al. (2018)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Fire suppression systems[e]	AFFF and certain dry fire-extinguishing agents	Contaminated soil and debris from applied product[d]	Applied product[d]		See Section 2.b for more information. Gaines (2023)

[a] The italicized waste streams may contain PFAS, given what wastes the relevant industry sectors are known to generate and given applications of PFAS. The presence and concentration of PFAS have not been quantified.

[b] "Off-spec materials" or "off-spec products" are materials or products that do not meet specified standards or requirements and are discarded rather than sold or used.

[c] Some industries listed under "Secondary Manufacturing" may also include primary manufacturing of PFAS. The waste streams resulting from manufacture of PFAS in these industry sectors are addressed in the first row, "Primary chemical manufacturing."

[d] "Applied product" refers to the intentional application of a PFAS-containing product to the environment.

[e] Fire suppression systems, which include AFFF, are commonly found in manufacturing, storage, extraction and refining, and national defense facilities, as well as airports, fire departments, and other federal facilities (e.g., facilities operated by the National Aeronautics and Space Administration [NASA] and the U.S. Department of Energy [DOE]). Although this is an industrial use, not an industrial sector, the prevalence of AFFF in the above primary and secondary PFAS manufacturing industries warrants highlighting these waste streams.

2.b Aqueous film-forming foam

AFFFs are a group of PFAS-containing fire extinguishing agents for low-flashpoint hydrocarbon fuel fires (Tuve et al., 1964). AFFFs are intended for use where a significant flammable liquid fire hazard exists (FFFC, 2016).

AFFFs are based on synthetic fluorosurfactants that provide unique low surface tension and positive spreading coefficient characteristics. When mixed with water and applied, AFFFs form an aqueous film and a foam solution to coat the liquid fuel, seal fuel vapor, and reduce oxygen availability, extinguishing the fire and preventing burnback (FFFC, 2016; SERDP, 2020; Sheinson et al., 2002).

Until application, AFFF is managed as a concentrated product containing less than 2 percent PFAS fluorosurfactants by weight for a typical 3 percent AFFF concentrate (ITRC, 2020). AFFF is stored in either fixed, structural dispensing systems, such as those in hangars and aboard vessels, or in mobile, vehicle-based systems (i.e., aircraft rescue firefighting [ARFF] vehicles) (Field et al., 2017). Reserve AFFF concentrate inventory may be stored in hangars or warehouses. The amount of AFFF concentrate in the finished foam varies by manufacturer and application circumstances, but is usually between 1 and 6 percent, meaning the fluorosurfactants are diluted to less than a fraction of a percent (FFFC, 2016; ITRC, 2020).

A 2004 inventory estimated that there were 4.6 million gallons of legacy PFOS-containing AFFF in the United States (Darwin, 2011). AFFF inventory depletion is determined by frequency of use for firefighting, training, or testing; transfers between locations; and other factors. However, AFFF's characteristically long shelf life means there should be little disposal due to expiration (FFFC, 2016), increasing the possibility that legacy PFOS-containing AFFF concentrate remains in service or reserve inventories. Fluorotelomer-based AFFF surfactant products became available in the 1970s (Prevedouros, 2006). In 2017, the U.S. Department of Defense (DoD) edited its military specification for AFFF to include

no more than 800 parts per billion (ppb) of PFOA and PFOS in the concentrate, the limit set by DoD Quality Systems Manual 5.1. However, this specification does not mention any other PFAS standards.

In the United States, AFFF and associated systems are or have been in service at federal facilities, civil airports, and oil refineries. Civilian fire departments also use or have used AFFF. The federal government is working to identify areas of current and former federal properties where PFOS- or PFOA-containing AFFFs have been used (Darwin, 2011; DoD, 2020). Through September 30, 2023, DoD has determined that 715 active military installations, base realignment and closure (BRAC) locations, National Guard facilities, and formerly used defense sites (FUDS) properties require an assessment of PFAS use or potential release. DoD is performing preliminary assessments/site inspections (PA/SIs) at these installations, which is the first phase of the cleanup process and may take two to three years to complete. As of September 30, 2023, DoD has completed the PA/SI phase at 570 installations. The Department has determined that no further action is required at 118 of these installations, while 452 are proceeding to the next step in the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process (DoD, 2024).

The FY 2020 NDAA prohibits AFFF use at any military installation, effective October 1, 2024 or up to two years later if the Secretary of Defense deems a waiver necessary. DoD issued a policy in January 2016 to discontinue land-based AFFF training and testing activities, unless the AFFF could be captured and properly disposed. Since then, DoD has managed any mission-critical AFFF use in response to an emergency event as a spill response to mitigate impacts to the environment (DoD, 2019, 2020). DoD, among other entities, is also investing in research and development for fluorine-free AFFF alternatives (SERDP, 2020). In 2023, DoD issued a new military specification for fluorine-free foam (MIL-PRF-32725) (DoD, 2023).

Examples of AFFF users and locations in the United States are listed in Table 2-2. Note that the list of sources in the table is non-exhaustive.

Table 2-2. Examples of AFFF Users and Locations in the United States

AFFF User	Locations	Comments
DoD	• Hundreds of military installations (active and former) with AFFF use • In-service systems installed at an estimated 1,350 locations in aircraft hangars and on an estimated 3,000 ARFF vehicles	• In 2016, DoD discontinued AFFF use for military installation training and testing unless the AFFF could be captured and properly disposed and is investing in fluorine-free alternatives • The FY 2020 NDAA requires DoD to end any land-based AFFF by October 1, 2024 (with extensions possible until 2026) • Sources: DoD (2017, 2019, 2020); CBO (2019); SERDP (2020)
NASA	• Multiple properties with ARFF apparatus • Five properties with fixed systems	• In late 2018, NASA issued order to cease training with AFFF • Source: SERDP (2020)

AFFF User	Locations	Comments
DOE	• Lawrence Berkeley National Laboratory • Brookhaven National Laboratory • Los Alamos National Laboratory • Strategic Petroleum Reserve facilities (Gulf of Mexico)	• Sources: DOE (2021 *DOE Initial Assessment of PFAS at DOE Sites*); Darwin (2011)
Airports and supporting facilities	• 523 Federal Aviation Administration (FAA)-certified civilian airports in 2018 • Since 2006, an annual average of nearly 600 certified airports • Supporting facilities include firefighting training sites, such as the FAA Technical Center's Fire Training Area	• Starting in 1972, FAA regulations allowed for the use of AFFF among a number of different extinguishing agents at civilian airports; since 2006, FAA guidance (FAA, 2006) provides that AFFF must conform to the applicable military specification (AC 150/5210-6 and MIL-F-23485F) at most civilian airports [a] • 80 percent of respondents to a 2017 survey of U.S. and Canadian airports reported training-related discharge directly to the ground; two-thirds reported testing-related discharge directly to the ground • FAA has taken steps to reduce AFFF discharges during testing since 2019 • Sources: DOT (2019); FAA (2006, 2019); Thalheimer et al., (2017); U.S. EPA (2020c)
Fire departments	• At civilian fire departments throughout the United States	• AFFF may be present at fire departments • Some states have begun inventorying and reporting having AFFF (e.g., Michigan, New Hampshire) • Some states have take-back programs to help local fire departments identify AFFF in inventory and assist with removal and disposal (e.g., Vermont) • Sources: Michigan PFAS Action Response Team (n.d.); New Hampshire Department of Environmental Services (2020); Vermont Agency of Natural Resources (n.d.)
Oil refineries and processing facilities	• Oil refineries and related facilities (e.g., storage facilities)	• Little information is available about AFFF in this sector, though published industry guidelines recommend AFFF for pipeline emergencies • Survey-based data suggest this sector is the second largest consumer of AFFF after federal agencies • Sources: Darwin (2011); Noll & Hildebrand (2016)

AFFF User	Locations	Comments
Ships and other vessels	• Ships and other marine vessels, including the U.S. Coast Guard	• Little information is available about AFFF quantities on ships • There has been a shift toward non-fluorinated AFFF for some uses including testing and training, though the Coast Guard has indicated that certain uses (e.g., required inspections) must continue to use fluorinated AFFF • Source: U.S. EPA (2020e)

[a] An exception exists for airports with low departure traffic and serving aircraft less than 90 feet in length. See 14 Code of Federal Regulations (CFR) 139.317 for more information (FAA, 2006).

Fate and transport of PFAS in AFFF after use depends on the release circumstances and chemical-specific properties. Though sometimes classified as incidental releases (Thalheimer et al., 2017), equipment failure, accidental releases, or operator error can result in substantial leaks (Anderson et al., 2016; Resolution Consultants, 2016; Leidos, 2016).

Engineering controls (such as dikes, barriers, or basins) may be installed at facilities with significant flammable liquid hazards to contain foam solution and runoff for later disposal (FFFC, 2016). Where such hazards do not significantly exist, or installed engineering controls are otherwise not practicable, firefighting personnel may block sewer drains or deploy portable dikes as containment measures (FFFC, 2016). Runoff can then be pumped out, and the affected environmental media can be removed for disposal (ITRC, 2020). C&D debris originating from facilities where AFFF was historically released may also be a source of PFAS in landfills and groundwater (Solo-Gabriele et al., 2020).

Though subject to site-specific characteristics and conditions, studies demonstrate AFFF use at airports is a source of PFAS in soil and groundwater (Ahrens et al., 2015; Dauchy et al., 2017b; Høisæter et al., 2019). Further, PFAA precursors from original AFFF concentrate products may transform in the environment to more mobile products over time (Houtz et al., 2013), expanding plumes long after AFFF use is discontinued.

In the 2022 EPA-issued memoranda that recommended NPDES and POTW pretreatment program permitting conditions (U.S. EPA, 2022a, 2022d), EPA recommended that NPDES stormwater permits contain best management practices (BMPs) to address and minimize AFFF discharges, as included in the Naval Air Station Whidbey Island MS4 NPDES Permit[6]:

- Prohibiting the use of AFFFs other than for actual firefighting.
- Eliminating PFOS- and PFOA-containing AFFFs.
- Requiring immediate clean-up in all situations where AFFFs have been used, including diversions and other measures that prevent discharges via storm sewer systems.

[6]Naval Air Station Whidbey Island MS4 NPDES permit: *https://www.epa.gov/sites/default/files/2020-12/documents/r10-npdes-naval-air-station-whidbey-ms4-was026611-final-permit-2020.pdf*

2.c Soils and biosolids

As required by Clean Water Act Section 405(d), EPA established requirements for the final use or disposal of sewage sludge when it is: (1) applied to land as a fertilizer or soil amendment; (2) placed in a surface disposal site, including sewage sludge-only landfills; or (3) incinerated. The regulation at 40 CFR part 503 defines sewage sludge as "solid, semi-solid, or liquid residue generated during the treatment of domestic sewage in a treatment works." Sewage sludge includes scum or solids removed in primary, secondary, or advanced wastewater treatment processes and any material derived from sewage sludge (e.g., a blended sewage sludge/fertilizer product) but does not include grit and screenings or ash generated by the incineration of sewage. Sewage sludge treated for land application is commonly referred to as "biosolids."

Part 503 considers domestic septage as sewage sludge and sets separate requirements for domestic septage applied to agricultural land, forests, or reclamation sites. Influent containing PFAS that enters wastewater treatment facilities may result in the presence of PFAS in biosolids (Thompson et al., 2023; Helmer et al., 2022; Venkatesan & Halden, 2013). When biosolids are applied to land, there is the potential for leaching or runoff (Schaefer et al., 2022; Navarro et al., 2016; Lindstrom et al., 2011; Sepulvado et al., 2011; Washington et al., 2010). If landfilled instead, there are concerns with PFAS releases via landfill leachate and gaseous emissions, especially for highly organic material (Section 3.b). Alternatively, if incinerated, there is the potential for PFAS to be emitted as PICs (Section 3.a). Research needs and resources on possible emerging PFAS destruction technologies for biosolids (e.g., pyrolysis/gasification coupled with a thermal oxidizer and supercritical water oxidation) are shared in Sections 5 and 6. Across disposal and destruction technologies, there are capacity concerns and more research is needed on potential PICs/products of incomplete destruction (PIDs).

Total nationwide biosolids generation and management statistics in 2021 (reported to EPA's biosolids program as of January 9, 2023) and data considerations are presented in Table 2-3. EPA does not have data on the volume of biosolids that contain PFAS; however, EPA is planning for the next National Sewage Sludge Survey in collaboration with the Effluent Guidelines Program Plan 15's upcoming POTW influent study, both of which will focus on monitoring for PFAS. Additionally, EPA is currently conducting a refined risk assessment for PFOA and PFOS in biosolids (U.S. EPA, 2024), as well as recommending exposure mitigation measures and pretreatment program BMPs to reduce PFAS sources (U.S. EPA, 2022d).

Table 2-3. Biosolids Generation and Management in 2021

NPDES permits issued to POTW[a]	**16,109**
Biosolids NPDES permits[b]	9,834
Biosolids annual reporters (2021)[c]	2,519
Sewage Sludge generated in 2021 (metric tons)[d]	**4,548,462**
Land application of biosolids (metric tons)	1,955,684
Land disposal (also called surface disposal) (metric tons)	94,522
Incineration (metric tons)	633,054
Landfilling (metric tons)	1,808,136
Other management (metric tons)	57,066

[a] An NPDES permit is typically a license for a facility to discharge a specified amount of a pollutant into a receiving water under certain conditions. A POTW is a treatment works treating domestic sewage (TWTDS) that is owned, and usually operated, by a local or regional government agency (U.S. EPA, 2020b).

[b] Biosolids permits apply to any person or treatment works that prepares sewage sludge, applies sewage sludge to the land, or fires sewage sludge in a sewage sludge incinerator and to the owners/operators of surface disposal sites, as well as the exit gas from sewage sludge incinerator stacks (U.S. EPA, 2019).

[c] Annual reports are required for POTW that have a design flow rate equal to or more than one million gallons per day, that can serve populations of 10,000 or more, that are required to have approved pretreatment programs (Class I Sludge Management Facilities), or that are otherwise required to report (U.S. EPA, 2023a).

[d] Total amount of biosolids generated is reported by each TWTDS and may not equal the sum of component amounts reported for each management method. Biosolids totals do not represent PFAS presence in biosolids.

In addition to land application of PFAS-containing materials (e.g., biosolids), there are other scenarios where PFAS release to soils can occur. Direct release of PFAS into soils can occur through use of PFAS-containing products such as AFFF, and the discharge or application of treated industrial or municipal wastewater containing PFAS. PFAS can also be in soils due to unintentional contact, such as spills or leaks during the production, handling, transport, or use of PFAS-containing materials (see Table 2-4 for examples of industrial sources of PFAS in soils). Both direct and indirect soil impacts might also occur via the atmospheric deposition of PFAS released from stack emissions and atmospheric transformation products of volatile precursors, respectively (Davis et al., 2007; Dreyer et al., 2009; Schenker et al., 2008). Remediation wastes such as soils excavated during the cleanup of sites or during decommissioning of facilities where PFAS was manufactured, used, or applied may contain diverse mixtures of PFAS in elevated concentrations.

2.d Textiles, other than consumer goods, treated with PFAS

Because PFAS can repel oil, water, and stains, the textile industry uses these chemicals in a broad range of textile products other than consumer goods (apparel or household textiles). For example:

- PFAS can be used to treat outdoor equipment such as tents and sails (UNEP, 2011).
- Technical or occupational textiles, such as protective clothing for firefighters, can be treated with PFAS or woven from fluoropolymers (OECD, 2013).
- Medical garments can be treated with fluorinated polymers (OECD, 2013).
- Fluoropolymers can be spun into fibers and used to make sailcloth and fabric for fire suppression needs (Tokarsky & Uy, 2003).

- PTFE can be woven to make architectural fabrics, such as roofs, and can also be used to coat fiberglass for tensile structures or long-life structures (Fabric Architect, 2020).
- Textiles made from fiberglass coated with or saturated with PFAS are used for high-temperature or corrosive industrial environments. Kevlar and perfluoroplastic composite textiles are used for similar industrial environments (Robco, 2020).

Examples of typical PFAS-containing waste streams generated from textiles include discarded industrial or commercial textiles such as apparel, carpets, or personal protective equipment; solids coated with PFAS from cuttings and shearings; and fugitive volatiles from spray applications of textile surface treatments. The destruction and disposal technologies used for these waste streams include landfill disposal and thermal treatment. For examples of industrial waste streams from the textiles/apparel manufacturing industry, see Table 2-4.

2.e Spent water treatment materials

EPA published a proposed rule for a PFAS National Primary Drinking Water Regulation (NPDWR) for six PFAS in March 2023 that will require compliance once finalized and promulgated. Additionally, 12 states have established standards limiting the presence of various PFAS in drinking water. EPA has identified "best available technologies" for treating drinking water for PFAS to comply with the NPDWR; these technologies will produce residuals. The 2024 Interim Guidance details options available to manage these residuals while minimizing environmental exposures and releases to the extent feasible. EPA notes that there are multiple approaches for water systems to manage PFAS residuals that are generated when PFAS is removed from drinking water. As of December 2023, there are no specific federal regulatory requirements for PFAS disposal, and the presence of PFAS in treatment residuals does not impose any additional federal requirements, but they may be subject to regulatory attention. EPA's PFAS actions are updated on the webpage *Key EPA Actions to Address PFAS*.

Conventional drinking water treatment methods such as coagulation, flocculation, sedimentation, disinfection, and filtration do not remove PFAS found in source water. Therefore, residues from these processes such as grit, spent membrane, or filter elements are unlikely to contain significant PFAS.

Although novel technologies for removing PFAS from drinking water sources and groundwater are being developed, current processes known to be effective are activated carbon, anion exchange resins, and high-pressure membranes (reverse osmosis [RO] and nanofiltration [NF]) (U.S. EPA, 2022b, 2022c). This section discusses the residual streams of these three processes (see Section 3 for discussions on treatment and disposal considerations, Appendix D for costs and considerations, and Section 5 for discussions of research needs for more novel treatments) and regulatory considerations for drinking water treatment utilities.

Table 2-4 shows the primary residual streams by water treatment process, with options for reactivation, destruction, and disposal of these residuals.

Table 2-4. Destruction and Disposal Options for Drinking Water Treatment Residuals Containing PFAS

Treatment Process	Residuals Generated	Destruction/ Disposal Option(s)	Section Reference
Granular Activated Carbon	Spent GAC	Reactivation	3.a.i.2
		Incineration	3.a
		Landfill	3.b

Treatment Process	Residuals Generated	Destruction/ Disposal Option(s)	Section Reference
Powdered Activated Carbon (PAC)	Spent PAC	Incineration	3.a
		Landfill	3.b
Ion Exchange	Single use and regenerative ion exchange: spent resins	Incineration	3.a
		Landfill	3.b
	Regeneration brine	Interim Storage	1.c
		Underground Injection	3.c.ii.1
RO/NF	Brine	Permitted discharge, direct or indirect	Not described in this guidance. Refer to permit.

The practices discussed in Table 2-4 are not in a hierarchical order and should be chosen based on site-specific conditions. The practices presented in Table 2-4 may help reduce and/or control unintentional PFAS releases to the environment.

2.e.i Activated carbon

Activated carbon (discussed more extensively in Section 3.a.i) is manufactured from carbon-rich sources such as coal or wood and is used to treat water or air by filtering contaminants (U.S. EPA, 2012). Activated carbon can be used in either PAC or GAC form. In PAC treatments, carbon is powdered and added to the water for treatment, and then chemicals in the water stick to the powdered carbon as the water passes through and typically carries the PAC along. In GAC treatments, chemicals in water adsorb to small pieces of carbon in a bed as the water passes through.

PAC application will remove some PFAS from water, though the amount of PFAS removed depends on many factors. For PAC treatment, the residual stream is the sedimentation sludge or the filter backwash solids that contain the PFAS-laden PAC along with the coagulant, coagulant aids (if used), natural particulates, and enmeshed organic carbon (Dudley et al., 2015). Given the many conditions that affect treatment, the weight percent PFAS in a PAC residual stream varies by many orders of magnitude but will be in the same range as GAC treatment, as discussed below.

For GAC, the range of PFAS concentrations on spent media can be estimated in several ways (Crone et al., 2019; U.S. EPA, 2020d). A conservatively high loading of PFAS onto GAC (using a GAC with a high-capacity potential, a strongly adsorbing PFAS, few competitive contaminants, low organic levels, and a high concentration in the feed water treated) is on the order of 2 percent by weight (e.g., 0.02 grams PFOS per gram of GAC). For more common treatment scenarios, or for PFAS that are adsorbed more weakly (i.e., the shorter-chain PFAS), the weight percent of PFAS will be orders of magnitude lower—about $1x10^{-5}$ grams PFAS per gram of GAC.

GAC can be reactivated and reused (see Section 3.a.i.2 for a discussion on GAC reactivation). If the GAC is landfilled, PFAS can desorb off the carbon into the landfill leachate if the GAC comes into contact with a water stream that contains low PFAS, or more strongly adsorbing constituents that can displace the PFAS. Desorption will occur due to the disequilibrium between the liquid and solid phases and will accelerate at higher temperatures where adsorption becomes less favorable for exothermically adsorbed contaminants. Therefore, the resulting PFAS concentrations in the landfill leachate impacted by spent GAC will vary greatly depending on conditions.

Typically, deep bed GAC does not require backwashing because the particulates in the water are removed ahead of the GAC system, but there may be instances where particulates deposit onto the GAC, creating a headloss that will require backwashing. If so, the backwash water may contain a PFAS foam that may need to be managed.

2.e.ii Ion exchange resins

Like GAC, ion exchange resins are utilized in fixed bed adsorbers. Similarly, the residual stream from this treatment is the spent media; however, ion exchange resins cannot be thermally reactivated like GAC. Due to several factors, the market is moving toward single-use media for anion exchange resin treatment with incineration as the final disposal point for the spent resin.

Final PFAS loadings onto resins vary widely. A conservatively high estimate of loading (calculated using a PFAS-selective resin, few competitive constituents, and a PFAS known to adsorb well) is expected to be in the order of 10 percent by weight for the strongly adsorbing PFAS (e.g., 0.1 gram PFOS per gram of resin). The higher percent weight than GAC is due to the high capacities of PFAS-selective resins. Like GAC, more typical scenarios for PFAS that are more weakly adsorbed (i.e., shorter-chain PFAS) will yield much lower average weight percent of PFAS.

Assuming single-use resin is used, landfilling may be less expensive than incineration. If the resin is landfilled, PFAS can desorb off the resin if the resin comes into contact with a water stream whose counter ions can displace the PFAS. The resulting leachate concentrations will vary tremendously depending on conditions. In rare cases, it may be appropriate to regenerate the ion exchange resins with a brine; however, the latest science has shown that an alcohol solvent is needed along with the inorganic exchange ion. This is difficult to do at the full-scale, especially for drinking water facilities. If done in this manner, the resulting regenerate brine will have high concentrations of PFAS and will need to be disposed of appropriately. In rare cases, there may not be a ready disposal option for this regenerate brine and interim storage may be appropriate. Before selecting interim storage, it is important to consider that generating routine volumes of waste can pile up over time, which may become more difficult to store than originally envisioned. Otherwise, regenerate brine may be handled like other high-strength liquid PFAS wastes.

Typically, resin beds do not require backwashing because the particulates in the water are removed ahead of the resin system, but there may be instances where particulates deposit onto the resin, creating a headloss that will require backwashing. If so, the backwash water may contain a PFAS foam that may need to be managed.

2.e.iii High-pressure membranes (reverse osmosis and nanofiltration)

High-pressure membranes are extremely effective for removing many PFAS from water to a high degree (Crone et al., 2019; U.S. EPA, 2020d). As high-pressure membranes are based on a rejection phenomenon, water treatment with them creates a waste stream with potentially high concentrations of PFAS as well as treated water with a lower pH. These waste streams also have high concentrations of salts, other contaminants, and dissolved organic matter.

Treatment of the concentrated residual stream can be challenging, and the cost will likely be high, similar to those for landfill leachates, ion exchange spent regenerates, and waters from highly contaminated sites. Many variables could affect the cost of treating these waste streams. At this time, there is no obvious treatment technology choice, especially given that the concentrated retentate

stream is typically 20 percent of flow (Baruth, 2005). This represents a sizeable flow, especially for large membrane treatment systems, such as those used by large municipalities (e.g., treating 20 million gallons per day [4 million gallons per day] concentrate flow). This large-volume flow would prevent the use of batch treatment processes, which have higher efficiencies because they can process the water multiple times before discharge.

When the membranes lose their integrity or foul to the point of needed replacement, they will need to be disposed of. It is not anticipated that the materials of construction are high in PFAS unless they are specifically made of PFAS materials (e.g., Nafion). Also, the mass of PFAS remaining on the membrane surfaces should be minimal except in extreme cases.

2.e.iv Regulatory considerations for drinking water treatment utilities

Sites with reject water from high pressure membranes typically have a NPDES permit[7]. To meet NPDES statutory requirements to obtain an NPDES permit prior to discharging any pollutant to waters of the United States, drinking water treatment utilities using membranes must follow all NPDES permit or pretreatment program requirements, including those applicable to PFAS, for any permit or control mechanism issued for their facility. For more information, see EPA 2022d.

2.f Landfill leachate containing PFAS

Landfill leachate (discussed in more detail in Section 3.b.iii.5) is the liquid formed by rainwater percolating through waste in landfills. Leachate generation may continue even after a landfill's closure period, as a result of liquids inherent in the waste or if the cap system fails. There are different types of solid waste landfills characterized by the wastes managed, which also dictate the environmental controls employed. Hazardous waste landfills and most MSW landfills are required to collect the liquid leachate captured within the landfill liner and subsequently manage or treat the leachate. While PFAS concentrations in different landfill leachates have been documented (see Table 3-3 in Section 3.b), there are no monitoring or reporting requirements at the federal level for PFAS in landfill waste or leachate. Thus, existing treatment methods are being used to process leachate irrespective of PFAS concentrations.

Landfill leachate can be treated on site or off site. The most prevalent off-site management approach is to export leachate to a TWTDS, where it is mixed with wastewater and treated. However, as noted in Section 2.a.ii, conventional wastewater treatment technologies are generally unable to treat or control PFAS (Schultz et al., 2006). Other off-site treatment methods include incineration and underground injection (see Sections 3.a and 3.c, respectively). The on-site leachate treatment technologies employed at landfills are explored in Table 3-2 in Section 3.b.i. Some management approaches and treatment technologies represent significant pathways for PFAS release. Unlined impoundments, release to constructed wetlands, and land applications can release PFAS and potentially contaminate groundwater. Additional research is needed to determine the efficacy of landfill leachate treatments for PFAS (see Section 5).

[7] The Clean Water Act prohibits anybody from discharging "pollutants from a point source" to a "Water of the United States" unless they have an NPDES permit. See 40 CFR Section 122.1(b)(1). The terms "pollutant," "point source," and "Waters of the United States" are defined at 40 CFR Section 122.2.

2.g Summary

PFAS are synthetic chemicals that are used in a diverse array of industrial and commercial applications. Industrial waste streams containing PFAS stem from two main sources: (1) primary manufacturing facilities of PFAS chemistry and (2) secondary industries that use PFAS-containing products and/or manufacture finished products containing PFAS. Ultimately, PFAS end up in solid, liquid, or gas waste streams from industrial facilities that manufacture or use PFAS and PFAS-containing products. Other common PFAS-containing waste streams include AFFF, biosolids, textiles, spent water treatment materials, and landfill leachate. Any of these waste streams can contribute to PFAS entering environmental media, including soil and groundwater. The potential destruction, disposal, and treatment technologies for processing these streams are discussed in Section 3.

3. Technologies for the Destruction and Disposal of PFAS and PFAS-Containing Materials

EPA has identified three existing and potentially available destruction and disposal technologies that may be effective for managing PFAS and PFAS-containing materials. These technologies are thermal treatment (Section 3.a), landfilling (Section 3.b), and underground injection (Section 3.c). Each subsection describes various considerations for these technological solutions, including types of treatment, potential for releasing PFAS into the environment, and uncertainties. References appear at the end of each subsection. See Section 6 for a discussion of emerging technologies that show potential to destroy PFAS. See Appendix D for a summary of costs and considerations.

3.a Thermal treatment

As the industrial and commercial use of fluorinated organic compounds grew over the past 70 years, their presence, compositions, and concentrations in materials that need to be destroyed or disposed of also grew. Organic fluorine-containing materials including flame suppressants, refrigerants, long- and short-chain PFAS, fluoropolymers, and their precursor chemicals have been commonly treated using a variety of thermal treatment technologies. These range from permitted HWCs and industrial furnaces to MWCs, SSIs, and thermal oxidizers designed to treat material and process gas emissions. Compared to landfills and underground injection, thermal treatment offers the potential advantage of mineralizing PFAS and preventing further release into the environment.

The carbon–fluorine bond is much stronger than the carbon–chlorine bond. Breaking the carbon–fluorine bond requires 1.5 times more energy and therefore higher temperatures and reaction times. Based on calculated bond energies, the most difficult fluorinated organic compound to decompose is carbon tetrafluoride (CF_4), which requires temperatures over 1,400°C (2,550°F) (Tsang et al., 1998). This is due to the compound's four carbon–fluorine bonds and symmetrical structure. The presence of carbon–carbon or carbon–hydrogen bonds (as in hexafluoroethane [C_2F_6] or fluoroform [CHF_3]) provides a weak point in the structure and thus significantly lowers temperatures needed for decomposition. Due to their thermal stabilities, short-chain fluorinated carbons such as CF_4, CHF_3, C_2F_6, and octafluoropropane (C_3F_8) may be good indicators of broader PFAS defluorination. In addition, these compounds may be relatively easy to monitor by Fourier transform infrared spectrometry (FTIR) and are targets measured in whole gas samples by Other Test Method 50 (OTM-50)[8], which makes them potential low-risk candidate surrogates for thermal destructibility trials.

Further, fluorinated organic compounds can be destroyed in flames by free radical initiation, propagation, and branching mechanisms. To increase the efficiency of these processes, it is important to provide high concentrations of hydrogen radicals (as in flames) to promote hydrogen fluoride (HF) formation, reducing the strong flame inhibition effects of fluorine radicals. There is concern that carbon–carbon bonds can be broken at moderate temperatures, leaving carbon–fluorine fragments. The fate of these carbon–fluorine radicals will depend on the local temperatures and concentrations of

[8] EPA recently released the OTM-50 methodology *https://www.epa.gov/emc/emc-other-test-methods*.

other free radicals. If the local energies and free radical concentrations are low, these carbon–fluorine fragments may recombine to form fluorinated PICs. However, if the local temperatures and concentrations of free radicals (particularly hydrogen radicals) are high, as occurs in flames, the carbon–fluorine species is more likely to degrade further to CO_2 and HF.

The stability of perfluorinated radicals and their propensity to recombine present the potential for the creation of PFAS PICs distinctive from the original fluorinated compounds. These reactions are promoted by partial combustion caused by insufficient temperatures, time, and turbulence. Many PFAS are composed of very stable fluorinated carbon chains and relatively weak non-fluorinated functional groups. Often, the functional group is easily removed, allowing the fluorinated chain to react with other radicals and create a variety of compounds, which complicates the determination of destruction and removal efficiencies (DREs) and the identification of PICs (Wang et al., 2015). In addition, the presence of catalytic surfaces, often metals, may promote further reaction and PIC formation in post-combustion regions. PFAS PICs may be smaller in molecular weight than the original species or larger in molecular weight when formed via the recombination of two large radicals.

Thermal treatment units generally use high-temperature combustion and incineration to destroy organic materials and control organic pollutants. Incineration is an effective and permitted method for destroying certain halogenated organic chemicals including chlorinated solvents, polychlorinated biphenyls (PCBs), dioxin-laden wastes, brominated flame retardants, refrigerants, and ozone-depleting substances.

Combustion is described by complex sets of physical processes and elementary reactions involving many intermediate and free radical species. Even combustion of a simple fuel, such as methane, involves several hundred elementary reactions. For more complex fuels, or systems that include additional elements, such as fluorine, elementary reactions can number in the thousands or more. These elementary reactions describe pathways or mechanisms whereby large molecules, such as PFAS, decompose and transform during combustion.

Thermal treatment of halogenated organic compounds generates the corresponding halogen acid when sufficiently high temperatures and long residence times break the carbon–halogen bonds and the resulting halogen atoms react with available hydrogen. Thermodynamically, for a reacting system containing carbon, hydrogen, fluorine, and oxygen, chemical equilibrium favors the formation of carbon dioxide, water, and hydrogen fluoride. Unfortunately, complete decomposition is almost impossible to achieve due to kinetic (temperature) and transport (mixing) limitations. If temperatures are insufficient or mixing is incomplete at any point, complete conversion to hydrogen fluoride and carbon dioxide may not be achieved. This incomplete decomposition is the genesis of many pollutants from hydrocarbon fuels PICs. Certain thermal technologies can potentially achieve the operating conditions necessary to break down fluorinated organic compounds, but not every unit typically operates at these conditions. Data are lacking about the effectiveness of the characteristic operating conditions of the different thermal destruction technologies currently used to treat PFAS materials. Also, more measurement methods are needed to evaluate technology performance for both the destruction of specific chemical species and the formation of byproducts. As a result, EPA does not know if/which thermal treatment technologies are fully able to achieve adequate PFAS destruction and minimization of PFAS PICs.

Hazardous waste combustion technologies (commercial incinerators, cement kilns, and LWAKs) can potentially achieve temperatures and residence times sufficient to break apart the PFAS contained in the waste stream being thermally treated, but not every unit currently operates at those conditions and

those that do may not operate at those conditions at all times. To assess the capability of HWCs to destroy the materials fed into them and ensure that harmful emissions into the environment are minimized, it is standard practice to evaluate the DRE of one or several principal organic hazardous constituents (POHCs) during a trial burn. POHCs are selected to be at least as difficult to destroy as the feed material, based on an incinerability index scale of how difficult a compound is to destroy. The existing index does not include PFAS compounds. Permitted hazardous waste facilities have stringent regulatory controls on temperatures and other important operating parameters and require greater than 99.99 percent DRE for each selected POHC. Data from pilot-scale experiments conducted by EPA researchers indicate that "several operating conditions above 1090 °C resulted in high destruction efficiency (DE)[9] and few detectable fluorinated PIC emissions. However, several conditions below 1,000 °C produced DEs greater than 99.99 percent for the quantifiable PFAS and mg/m^3 emission concentrations of several nonpolar PFAS PICs. These results suggest that DE alone may not be the best indication of total PFAS destruction, and additional PIC characterization may be warranted" (Shields et al., 2023).

For HWCs, DRE is calculated based on the amount of a specific chemical entering an incinerator and the amount of that same chemical exiting the incinerator. While the compound selected for DRE determination in an HWC is chosen based on the difficulty of destroying it, DRE does not account for chemical reactions or transformations into new/different organic compounds (i.e., PICs). Because DRE does not account for chemical transformations, it is not an accurate indicator, by itself, of complete PFAS destruction. Recent research (Shields et al., 2023) has demonstrated that PIC formation can occur even when high DRE is measured at temperatures below 1,000 C. It is not accurate to state that a high DRE by itself indicates complete destruction of PFAS and that no other PFAS are being emitted. Complete PFAS destruction, also referred to as "complete mineralization," results in the production of only HF and CO_2 and does not include the production of other PFAS or other fluorinated organic compounds. The term "adequate destruction" is used in this guidance because it is not feasible to measure complete mineralization due to methodological limitations.

To fully evaluate whether adequate destruction is occurring, EPA and other investigators need to sample and analyze for a range of chemicals exiting a thermal treatment device, including the specific PFAS in the feed material, other PFAS beyond those in the feed (i.e., potential PICs), and HF. EPA currently lacks test methods for measuring most PFAS before and after the incineration process, but new methods are being advanced that will provide more information in the coming years. Currently, standard methods are available for HF (e.g., EPA Method 26A) and a targeted list of semivolatile PFAS (i.e., Other Test Method 45 [OTM-45]), and other test methods are in development for a relatively small percentage of PFAS as surrogates for the class of PFAS compounds (see Section 3.a.iv).

For this second version of the interim guidance, PFAS destruction is defined as the severing of all carbon–fluorine bonds in a PFAS molecule and the mineralization of carbon and fluorine to CO_2, HF, and water. HF and some of the other products of combustion can be effectively removed in pollution control devices designed for acid gas removal. The PFAS Thermal Treatment Database (PFASTT) is a growing database that contains more than 2,000 records of 80 sources documenting the treatability of PFAS in different media via various thermal processes.

[9] Destruction efficiency differs from destruction removal efficiency because samples were collected before any pollution control devices.

EPA currently has limited data characterizing emissions from HWCs that burn PFAS (Focus Environmental, 2021, 2022), along with data from a pilot-scale study at an EPA research facility (Shields et al., 2023). These studies are summarized below and provide some insight on the potential efficacy of thermal treatment in an HWC. To date, the commercial facility studies have focused on the removal of easily transformed PFAS target compounds, which is a significant limitation.

Clean Harbors Environmental Services. Two testing campaigns (2021 and 2022) were conducted at Clean Harbors Environmental Services' hazardous waste incinerator located in Aragonite, Utah (EA Engineering, Science, and Technology, Inc., PBC., 2021, 2022). Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented PFAS Feed (Condition 2, where known amounts of four or five target PFAS were fed to the incinerator), and Post-spiking Normal Operations (Condition 3, where AFFF was included in the incinerator feed). Clean Harbors used OTM-45 (*Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources*) for stack gas sampling and analysis. The 49 targeted PFAS analytes were measured using liquid chromatography/tandem mass spectrometry (LC/MS/MS) with isotope dilution. Utilizing the available analytical methods at the time, the Clean Harbors study demonstrated a DRE for the legacy PFAS in the 99.9999 percent range at high temperatures. Of the 49 compounds detected by OTM-45, 34 were non-detect in the stack gas and only 15 were detectable at extremely low concentrations. The tests appear to demonstrate that the facility's primary objective was met: "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions." Although a high DRE was achieved (greater than 99.999 percent) for the five selected PFAS compounds that were subjects of these studies, these tests did not collect data to fully support demonstration of adequate destruction as the production of PICs were not evaluated due to methodology limitations.

EPA PFAS thermal destruction research. Recently, EPA's Office of Research and Development (ORD) completed an initial study examining the relationship between destruction efficiency (DE) and PICs (Shields et al., 2023). This study used a pilot-scale research furnace and atomized a PFOS-dominant AFFF at various furnace locations and combustion environments. These included atomization through the flame with the natural gas auxiliary fuel and at various post-flame locations so that the AFFF would experience decreasing peak temperature exposures ranging from ~1,200°C to ~800°C (2,192°F to 1,472°F). Stack measurements included OTM-45 and a new draft GC/MS-based Other Test Method for non-polar volatile PFAS (OTM-50). Instead of DREs, this study calculated DEs, because samples were collected before any pollution control, i.e., removal equipment, including fabric filter and alkaline wet scrubber. Analysis of the AFFF and OTM-45 samples was used to calculate DEs for 10 PFAS quantified in the AFFF. OTM-50 was used to quantify concentrations of 30 PFAS PICs. Results indicate that several idealized operating conditions with peak temperatures above 1,090°C (1,976°F) resulted in high DEs (greater than 99.99 percent) and low PIC emissions that were near or below the detection limits. However, several conditions below 1,000°C (1,832°F) produced DEs greater than 99.99 percent for the quantifiable PFAS while simultaneously measuring emission concentrations of several volatile PFAS (mg/m^3). The study concluded that DE alone may not be the best indication of PFAS destruction.

Additional studies are necessary to more fully measure and evaluate the ability to approach complete mineralization and eliminate potential formation of PICs. EPA is working to advance new measurement methodologies (see Section 3.a.iv.1) and gather additional information to conclude whether potential PICs are adequately controlled (see Appendix A).

This section focuses on considerations associated with thermal treatment of PFAS and PFAS-containing materials. It discusses:

- The types of thermal treatment units that manage PFAS-containing materials and their ability to effectively destroy PFAS.
- The potential for environmental releases during these thermal treatment operations.
- PFAS monitoring methods relevant to these thermal treatment operations.
- Uncertainties and unknowns associated with thermally treating PFAS-containing materials, including the ability to effectively measure and monitor thermal treatment performance.

3.a.i Types of thermal treatment

The following subsections describe the types of thermal treatment devices that may have directly or indirectly received and treated the PFAS-containing materials identified in Section 2.a. These subsections focus on design and operation parameters that are important for destroying PFAS. Treatment devices described here include HWCs, non-hazardous waste combustors, carbon regeneration and reactivation units, and thermal oxidizers. Waste incinerators are typically classified by the type of waste they combust. Suggested resources for locating such facilities are included in Section 1.c.ii.

3.a.i.1 Hazardous waste combustors

HWCs include hazardous waste incinerators (HWIs), cement kilns, LWAKs, boilers, and hydrochloric acid production furnaces that burn hazardous waste. Two types of HWCs that have treated PFAS waste in the United States are commercial[10] incinerators and LWAKs.

All HWIs, LWAKs, and cement kilns are subject to RCRA and Clean Air Act (CAA) permitting requirements[11,12] that provide additional regulatory oversight and include operating requirements and emission limitations to safely and effectively treat regulated hazardous contaminants that may not be required for non-permitted facilities. These types of HWCs are subject to CAA Title V permitting requirements, and to maximum achievable control technology standards pursuant to Section 112 of the CAA (40 CFR part 63, subpart EEE). These standards include emission limitations for metals, dioxins/furans, particulate matter, hydrogen chloride and chlorine gas, and carbon monoxide or hydrocarbons, as well as limits on minimum organic DRE, but do not include emission limitations for PFAS. Also, under the authority of RCRA's "omnibus" clause (Section 3005(c)(3); see 40 CFR 270.32(b)(2)), RCRA permit writers may impose additional terms and conditions on a site-specific basis as may be necessary to protect human health and the environment. Due to these additional safeguards, permitted HWCs may operate under conditions more conducive to destroying PFAS and controlling related PICs relative to thermal treatment units that do not have both RCRA and CAA permits. Further, incinerators permitted to incinerate liquid PCBs are required to meet even more stringent operating requirements with respect to time and temperature (40 CFR 761.70(a)(1)) when incinerating PCBs, and these operating conditions may be even more conducive to destroying PFAS and controlling PIC

[10] Commercial thermal treatment units primarily treat waste received from other facilities.

[11] Hazardous waste is regulated pursuant to RCRA authority. See 42 U.S.C. 6903. The regulatory definition is found in 40 CFR 261.3. PFAS is currently not a listed or characteristic hazardous waste, but a PFAS-containing waste may meet the regulatory definition of hazardous waste if PFAS is mixed with a listed hazardous waste or if a PFAS-containing mixture exhibits a hazardous characteristic (e.g., corrosivity or another characteristic stemming from the material that is mixed with PFAS) Waste managers must comply with RCRA hazardous waste requirement for the specific regulated hazardous waste, including storage limits, land disposal restrictions, and utilizing disposal and destruction facilities that are permitted to receive hazardous wastes.

[12] Hazardous-waste-burning cement kilns and LWAKs are a small subset of the total cement kiln and LWAK universe—i.e., most kilns do not burn hazardous waste.

formation. The following sections generally describe design and operational parameters of commercial HWIs, LWAKs, and cement kilns, focusing on parameters that are important for destroying PFAS. Design and operation information summarized for HWCs is generally based on background support documents for previous rulemakings (U.S. EPA, 2005b). Information on the numbers of HWC facilities is based on a 2019 national hazardous waste capacity assessment report (U.S. EPA, 2019). The capacity assessment report also provides a list of these facilities.

3.a.i.1.1 Commercial hazardous waste incinerators

Currently, there are 10 commercial HWI facilities operating in the United States. HWIs are designed to optimize temperatures, residence times, turbulence, and other parameters to ensure compliance with organic DRE requirements.[13] Three of these facilities are also permitted for incineration of PCBs. Most commercial HWIs use rotary kilns as primary combustion chambers to facilitate the thermal treatment of containerized wastes (e.g., in drums) and solid wastes such as contaminated soils. Low-heating-value aqueous wastes may also be pumped into the rotary kiln. The kiln maintains a continuous standing flame fueled by high-heating-value wastes and auxiliary fuels that maintain high temperatures. Typically, solids retention time in the kiln is 0.5 to 1.5 hours, while gas residence time through the kiln is usually around two seconds. Kiln flame/solids temperatures range from 650°C to 1,650°C (1,200°F to 3,000°F) (U.S. EPA, 2005b).

After combustion in the rotary kiln, wastes may be moved to an afterburner or secondary chamber. If an afterburner is used, additional high-heating-value gaseous and liquid wastes and auxiliary fuels may be added. The afterburner/secondary chamber is typically operated at about 1,100°C to 1,370°C (2,000°F to 2,500°F) with a gas residence time from one to three seconds to maximize organic destruction and minimize the formation of PICs (U.S. EPA, 2005b). Depending on the fuels used and waste streams introduced, combustion products might include carbon dioxide, water, nitric oxide, a variety of acid gases (sulfur dioxide, hydrochloric acid, HF, etc.), organic PICs, fly ash, and bottom ash constituents. Bottom ash is removed at the end of the kiln and from the bottom of the afterburner/secondary chamber and is typically disposed of in hazardous waste landfills (see Section 3.b). Fly ash entrained in the gas is removed downstream by fabric filters (FFs) or electrostatic precipitators, and acid gases are removed by gas scrubbers. Some HWIs use activated carbon injection systems to control mercury, dioxin/furan, and other emissions, and some also use TMT-15 (1,3,5-triazine-2,4,6(1H,3H,5H)-trithione, trisodium salt) injection for additional mercury and metals emissions control.

Limited studies of PFAS treatment in HWIs have been conducted (EA Engineering, Science, and Technology, Inc., PBC., 2021, 2022). These studies demonstrated treatment of five selected PFAS compounds in the feed material. However, these test data are not able to demonstrate adequate destruction of PFAS (Taylor, 2022) due to the lack of data concerning PIC formation.

3.a.i.1.2 Hazardous-waste-burning cement kilns

Currently, there are 11 hazardous-waste-burning cement kiln facilities in the United States. A cement kiln is a long, cylindrical, slightly inclined rotating furnace designed to calcine a blend of raw materials such as limestone, shale, clay, or sand to produce a key ingredient of Portland cement. These cement kilns burn hazardous-waste-derived fuels to replace some of the fossil fuels. Most burn liquid waste; some may also burn solids and small containers containing viscous or solid hazardous waste fuels.

[13] DRE = $[1 - (W_{out} / W_{in})] \times 100\%$, where: W_{in} = mass feed rate of an organic compound into the combustion device and W_{out} = mass emission rate of the same organic compound in exhaust emissions. HWCs are required to achieve at least 99.99% DRE.

Extreme combustion conditions (e.g., temperatures above 1,650°C [3,000°F]), turbulent mixing, and long gas phase residence time (from four to as high as 16 seconds in long kilns) may effectively treat hazardous waste. Cement kilns use either electrostatic precipitators or baghouses to collect particulate and metal emissions, referred to as cement kiln dust (CKD). Portions of the CKD can be fed back into the kiln as a raw material feed or used in other industries as neutralizers or additives, but usually the excess CKD is land-disposed. Add-on acid gas air pollution control devices, such as wet or dry scrubbers, are typically not used. The high alkaline content of the raw material feeds already prevents or minimizes the formation and release of acid gases by providing for in situ absorption of chlorine and other halogens and sulfur.

Several laboratory studies have examined the potential benefit of treating PFAS wastes in cement kilns where the calcium in the raw limestone can react with fluorine to form calcium fluoride (CaF_2). These studies indicate that calcium species react readily with PFAS at relatively low temperatures (400-800°C) to promote mineralization of PFAS waste (Wang et al., 2011, 2013, 2015; Reidel et al., 2021). However, the currently available lab-scale data are insufficient to determine with confidence the effectiveness of treating PFAS waste in commercial cement kiln operations.

3.a.i.1.3 Hazardous-waste-burning lightweight aggregate kilns

There is one LWAK facility operating in the United States that burns hazardous waste. LWAKs thermally process raw material (clay, shale, and slate) in slightly inclined, rotating furnaces to produce a coarse aggregate used in lightweight concrete products. In hazardous-waste-burning LWAKs, liquid wastes are either blended directly with conventional fuels burned in the hot end of the kiln or pumped separately into the hot end flame. High combustion gas flame temperatures (above 1,650°C [3,000°F]) and high kiln gas residence times (over two seconds) are used to destroy hazardous organics. Kiln exhaust gases leave the cold upper end of the kiln at a temperature from 205°C to 540°C (400°F to 1,000°F). LWAKs use FFs to control dust contained in the exhaust gas. The collected dust can be recycled back into the kiln (at the hot or cold end) or mixed into the lightweight aggregate product. Some LWAKs also use wet or dry scrubbing for acid gas emissions control. For example, the currently permitted hazardous-waste-burning LWAK has dry scrubbing for acid gas control. There are insufficient data to determine the effectiveness of commercial LWAK facilities in treating PFAS waste.

3.a.i.2 Carbon regeneration and reactivation units

Carbon reactivation units or “furnaces” use high temperatures to thermally desorb contaminants from GAC, which allows for the carbon to be used again. Over a dozen large-scale companies and utilities in the United States reactivate sizeable quantities of GAC. In all, these entities operate about 17 commercial furnaces (Roskill Information Services Ltd., 2017). Four of these commercial furnaces operate under RCRA permits and applicable air permits. RCRA permits provide additional regulatory oversight and include operating requirements and emission limitations to promote safe and effective treatment of the hazardous contaminants; non-RCRA-permitted carbon reactivation furnaces may not be subject to such requirements. Due to these additional safeguards, RCRA-permitted furnaces may operate under conditions more conducive to destroying PFAS and controlling related PICs, relative to furnaces without RCRA permits. This discussion focuses on RCRA-permitted furnaces because EPA has more design and operational information on these devices as a result of the RCRA permitting process.

Reactivation[14] of spent carbon is generally carried out in multiple-hearth ("multi-hearth") or rotary kiln furnaces, although fluidized bed and infrared furnaces are also options. While the furnace designs vary, they all use high temperatures and residence times designed to eliminate the adsorbed contaminants and return the carbon to a virgin state for reuse.

During reactivation, spent GAC is typically exposed to drying, desorption, pyrolysis, and oxidation as it moves through the furnace. The drying stage eliminates moisture via evaporation and occurs when hot combustion gases at temperatures ranging from 100°C to 110°C (212°F to 230°F) contact the carbon. During the desorption stage, hydrocarbons, hydrogen, and water vapor escape the pores of the granular carbon at temperatures of 315°C to 400°C (600°F to 750°F). The pyrolysis stage eliminates any volatile compounds adsorbed within the carbon porosity, including residual moisture, and thermally decomposes other less-volatile compounds. Pyrolysis occurs when the carbon is exposed to temperatures up to 800°C (1,472°F) under inert conditions (i.e., low oxygen). A residue of carbonized char is formed from the adsorbed compounds during pyrolysis, which occupies some of the carbon porosity and must be removed in the next stage. The oxidative stage involves the controlled gasification of the pyrolyzed carbon at temperatures of around 800°C (1,472°F) in the presence of a mildly oxidizing atmosphere, usually steam or carbon dioxide or a mixture of both. This results in the elimination of most of the charred residue and exposes the original carbon-pore structure (Miguel et al., 2001).

The residence times required for carbon reactivation vary by unit design and the contaminant loads and concentrations. For example, two facilities using multi-hearth furnaces have residence times of at least 38 minutes at one facility and between 90 and 120 minutes at the second facility (Kentucky Energy and Environment Cabinet, 2019; U.S. EPA, 2018).[15]

To ensure adequate destruction and removal of any remaining contaminants, reactivation furnaces are typically equipped with afterburners/thermal oxidizers. To meet regulatory requirements, afterburners are designed to achieve 99.99 percent DRE via thermal oxidation. DRE for a reactivation/regeneration furnace is evaluated on a "total hydrocarbon" basis rather than for a specific most-difficult-to-destroy component, as is done for HWCs. This adds additional uncertainty to the question of whether a thermal treatment unit can effectively destroy PFAS. The temperature required to achieve 99.99 percent DRE depends on residence time as well as on the concentration of contaminants, but minimum temperatures are around 885°C (1,625°F) and maximum temperatures are as high as 1,316°C (2,400°F), with a minimum residence above one second (U.S. EPA, 2018).

Depending on the process or waste streams treated, a reactivation furnace can be equipped with add-on air pollution control equipment to ensure environmental standards are met. Equipment can include venturi scrubbers for particulate matter control, packed-bed scrubbers for acid gas and particulate matter control, and wet electrostatic precipitators or baghouses for additional particulate matter control. As discussed in Section 3.a.ii, carbon reactivation systems can degrade PFAS even at the lower temperatures (150°C–700°C, or 302°F–1,292°F).

[14] "Reactivation" refers to a regeneration process that requires high temperatures. Regeneration also includes low-temperature processes, such as those using brines, solvents, oxidants, biological treatment, etc. These processes may not be as effective as reactivation for GAC (AWWA, 2018); therefore, they are not considered for this discussion.

[15] These two references are RCRA permits for Evoqua Water Technologies LLC and Calgon Carbon Corporation, two companies that accept spent activated carbon from off-site sources. They each hold RCRA permits, which allow them to treat spent carbon that meets the definition of hazardous waste.

3.a.i.3 Non-hazardous-waste combustion sources

Non-hazardous-waste incineration units in the United States includes SSIs at wastewater treatment facilities and MWCs. Under Section 129 of the CAA, these units are regulated for emissions of particulate matter, carbon monoxide, dioxins/furans, sulfur dioxide, nitrogen oxides, hydrogen chloride, lead, mercury, and cadmium. Because of this, the air pollution control devices employed by these units are intended to control these nine pollutants primarily. The following sections generally describe these incinerator types and their design and operational parameters that may influence the treatment of PFAS-containing waste (U.S. EPA, 1995).

3.a.i.3.1 Sewage sludge incinerators

An SSI unit is a combustion device that is used to burn dewatered sewage sludge. There are currently 170 SSI units operating at 86 facilities in the United States (U.S. EPA, 2016). The main types of SSIs are multi-hearth furnaces and fluidized bed combustors (FBCs).

The basic multi-hearth furnace is a vertical cylinder divided into zones. The sludge is dried at temperatures from 425°C to 760°C (800°F to 1,400°F) (U.S. EPA, 1995). Sludge combustion occurs as the temperature is increased to about 925°C (1,700°F) in successive zones. The gas residence times are typically four or five seconds. Emission controls on multiple hearths can include wet scrubbers, wet electrostatic precipitators, afterburners, and regenerative thermal oxidizers.

An FBC consists of a vertically oriented outer steel shell with nozzles designed to deliver fluidizing air at the base of the furnace within a refractory-lined grid. Air is injected into the furnace to fluidize the sludge and the sand. The combustion of the sludge occurs at temperatures from 750°C to 925°C (1,400°F to 1,700°F). The gas residence times are typically two to five seconds. Emission controls on FBCs can include venturi scrubbers, multicyclones, FFs, activated carbon injection, and carbon bed absorbers. There is substantial variation in the design and operation of SSIs and it has not been shown that standard operating conditions are effective for the treatment of PFAS. The data currently available are insufficient to make a determination about the effectiveness of SSIs in treating PFAS.

3.a.i.3.2 Municipal waste combustors

There are 193 MWC units operating at 75 facilities in the United States (Michaels & Krishnan, 2018). Three main classes of technologies are used to combust MSW: mass burn, refuse-derived fuel (RDF), and modular combustors. Mass burn and RDF combustors are the predominant designs.

With mass burn units, the MSW is combusted without any preprocessing other than removal of items too large to go through the feed system or hazardous materials, such as pressurized containers. In a typical mass burn combustor, refuse is placed on a grate that moves the waste through the combustor. The grates typically have three sections. On the initial grate section, referred to as the drying grate, the moisture content of the waste is reduced before ignition. Evaporated moisture is combined with the moisture from combustion and treated with the resulting combustion gases. The second grate section, referred to as the burning grate, is where most of the active burning takes place. The third grate section, referred to as the burnout or finishing grate, is where remaining combustibles in the waste are burned. Typical combustion temperatures for mass burn units can range from 800°C to 1,100°C (1,500°F to 2,012°F) (Reddy, 2016).

RDF combustors burn waste that has been processed to varying degrees to raise its heating value and provide a more uniform fuel. Most boilers designed to burn RDF use spreader stokers and typically

operate at around 680°C (1,250°F). RDF-fired FBCs typically operate at bed temperatures of around 815°C (1,500°F) (Reddy, 2016).

Residence times of gases within MSW combustors vary from unit to unit, depending on design and operational factors such as furnace volume, excess combustion air percentage, whether flue gas recirculation is employed, and combustor operating load parameters (Scavuzzo, 1990; Themelis & Reshadi, 2009). Overall combustion air residence times have been calculated in the 7- to 10-second range for a small sampling of MWC design loads (Themelis & Reshadi, 2009). At temperatures above 980°C (1,800°F), the approximate residence time is about two seconds for full combustor loads (Scavuzzo, 1990).

Emission controls on MWCs can include spray dryer or dry sorbent injection, electrostatic precipitators, FFs, selective or non-selective catalytic reduction, and activated carbon injection.

There is substantial variation in the design and operation of MSW combustors. The data currently available are insufficient to make a determination about the effectiveness of MSW combustors to treat PFAS.

3.a.i.4 Thermal oxidizers

Thermal oxidizers are used to treat process gases and destroy volatile organic compounds (VOCs) and organic hazardous air pollutants (HAPs) at a manufacturing or production facility. Some types of thermal oxidizers are also able to accept liquid feed streams. Each thermal oxidizer is designed to optimize temperatures, residence times, and turbulence to address the composition of the particular feed stream at that unit and meet the requirements of a regulation or permit. Depending on the type of thermal oxidizer (direct-fired, regenerative, recuperative, or flameless), the operating temperature ranges from 760°C to 1,200°C (1,400°F to 2,190°F). The residence time of thermal oxidizers ranges from 0.5 to two seconds, depending on site-specific criteria. Catalytic thermal oxidizers operate at lower temperatures than other types of thermal oxidizers—typically at about 400°C (750°F) with similar residence times to non-catalytic thermal oxidizers—while achieving the same efficiency in destruction of VOCs.

Emission controls for thermal oxidizers vary widely depending on the facility and the composition of the feed streams. Existing thermal oxidizers may have no additional pollution controls or may use prefiltration (to prevent fouling of the oxidizer) and/or wet or dry scrubbers or FFs. Thermal oxidizers have historically not been designed with destruction of PFAS as the primary focus, so most currently installed thermal and catalytic oxidizers may not be optimized for PFAS destruction. However, some thermal oxidizers are being used for halogenated wastes, including PFAS precursors. The operating conditions for some thermal oxidizers have the potential to effectively treat PFAS, but the data currently available are insufficient to make a determination about effectiveness.

Chemours. Two testing campaigns (2020 and 2022) were conducted on a thermal oxidizer installed to control PFAS emissions at a Chemours chemical and plastics manufacturing plant located in Fayetteville, North Carolina. The objective of the tests was to determine how the thermal oxidizer and 4-stage scrubber system would achieve a 99.99 percent emission reduction, including the use of a surrogate for all PFAS, such as the hexafluoropropylene oxide (HFPO). The test reports demonstrate a PFAS destruction efficiency above the 99.99 percent for the specific compounds that were tested. HFPO was tested as a surrogate for all species of PFAS, but there are no concrete data showing the performance of the thermal oxidation process for PFAS species outside of the compounds tested. There was also no discussion of possible products of incomplete combustion in the reports. The thermal oxidizer at the

Chemours facility appropriately destroys the five PFAS compounds of interest that have been identified at the facility. However, removal processes for products of incomplete combustion or of destruction of potential compounds not studied but potentially found in the facility waste streams are still unclear.

3.a.ii Limitations and considerations in thermal treatments

Incinerator designs vary, resulting in differing operational and waste feed approaches (see Section 3.a.i). HWIs typically operate at very high average temperatures and employ auxiliary, primary, and secondary flames. MWCs typically operate at lower temperatures and often do not employ auxiliary primary or secondary flames. SSIs vary in design, often operating as dryers with very low temperatures. Even within the same incinerator, wastes can be introduced at different locations and can experience different time, temperature, and mixing histories. PFAS introduced into a hazardous waste rotary kiln incinerator's main burner, along with auxiliary fuel, may experience very different conditions than the same waste introduced to the kiln as contained charges with solid wastes. These factors are expected to affect PFAS destruction and PIC formation. Limited studies have investigated the influence of various factors on PFAS destruction and PIC formation (see Section 3.a).

Carbon reactivation systems can degrade PFAS even at the lower temperatures (150°C–700°C, or 302°F–1,292°F) seen in bench-scale research studies (Watanabe et al., 2018). Experimental data suggest that thermal destruction of PFAS occurs in two stages: first during reactivation of the GAC, and then when the off-gas is introduced into a high-temperature zone with temperatures as high as 1,000°C (Forrester, 2018; Watanabe et al., 2016, 2018; Xiao et al., 2020). DiStefano et al., (2022) showed >99.99 percent destruction of PFAS at a full-scale commercial reactivation facility with a large percentage of the PFAS destruction occurring in the furnace. The fluoride mass balance was reported to be 61.4 percent. Although this low percentage could be due to a number of factors, it may be due to the formation of PICs that were not quantitated in the analytical method. While carbon reactivations systems, with the concomitant use of off-gas incineration (i.e., afterburners) and gas scrubbing units, have the potential to remove PFAS from the activated carbon and destroy it, there is insufficient data to make a determination on its effectiveness. However, as discussed elsewhere in this interim guidance, more work is needed for confirmation, particularly with regard to full-scale reactor conditions, differing carbons, and PICs.

Thermal oxidizers have historically not been designed with destruction of PFAS as the primary focus, so most currently installed thermal and catalytic oxidizers may not be optimized for PFAS destruction. However, some thermal oxidizers are being used for halogenated wastes, including PFAS precursors. Thermal oxidizers are being employed to destroy PFAS-containing and gaseous streams, but the data are insufficient to allow conclusions on the overall efficiency of thermal oxidizers in PFAS destruction. For example, the two tests at Chemours Company's Fayetteville Works (Focus Environmental, Inc., 2020, 2022) focused on five specific PFAS of interest found in waste gas streams at the facility. While the tests seem to prove a DRE of 99.999 percent for the five PFAS compounds, they do not present data on overall PFAS destruction or potential formation of PICs. (See Appendices B and C for summaries of the Clean Harbors and Chemours test data.) EPA is currently unaware of any catalytic oxidizers being used specifically for the destruction of PFAS, particularly in light of their site-specific design and optimization. Though the efficacy of thermal and catalytic oxidizers in destroying PFAS is currently unknown, a properly optimized thermal oxidizer can readily achieve a DRE of 99.99 percent for VOCs.

In addition to incinerators and thermal oxidizers, cement kilns are also used for the destruction of hazardous wastes. Cement kilns operate at very high temperatures (exceeding 1,800°C [3,270°F]),

exhibit very large gas and solid residence times, and have the added advantage of providing a caustic environment for halogen reaction and acid neutralization. A cement kiln in Australia has received an operating permit from the government of Queensland to burn PFAS wastes. The permit requires annual monitoring for 21 PFAS (Department of Environment and Heritage Protection, 2018). Test results from 2017 indicate that a DRE in excess of 99.99 percent is possible for specific PFAS compounds at the conditions of the test (Cement Australia, 2017), but the results do not present data on overall PFAS destruction or potential formation of PICs.

Processes involving calcium and alumina may have benefits and may require lower energies to destroy PFAS. Recent research (Wang et al., 2011, 2013, 2015) has investigated PFAS interactions with calcium oxide (CaO) and calcium hydroxide ($Ca(OH)_2$) at moderate temperatures (200°C to 900°C, or 390°F to 1,650°F) and found that these calcium species exhibit a pseudo-catalytic effect promoting PFAS destruction and fluorine capture at relatively low temperatures. Similar studies by the electronics industry indicate that alumina catalysts can effectively convert residual CF_4 and related species (generated by plasma arc techniques for etching purposes) to CO_2 and HF at comparable temperatures.

It is not well understood how effective high-temperature combustion is at completely destroying PFAS or whether the process can form fluorinated or mixed halogenated organic byproducts. Few experiments have been conducted under oxidative and temperature conditions representative of different field-scale incineration devices used for PFAS destruction. Limited studies on the thermal destructibility of fluorotelomer-based polymers found no detectable levels of PFOA after two seconds of residence time at 1,000°C (1,830°F) (Yamada et al., 2005; Taylor et al., 2014). Two recent field studies examining the performance of a specially designed thermal oxidizer in destroying PFAS in process gases at a Chemours production facility near Fayetteville, North Carolina, indicated greater than 99.999 percent destruction of five PFAS (Focus Environmental, Inc., 2020, 2022). Similarly, the recent Clean Harbors studies appear to show that the facility was able to achieve its primary objective: “demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions.” A high DRE was achieved (> 99.999 percent) for the five selected PFAS compounds that were subjects of these studies (EA Engineering, Science, and Technology, Inc., PBC., 2021, 2022). However, these test data did not include characterization of potential PICs due to previous methodology limitations.

The Chemours and Clean Harbor test results indicate the PFAS compounds measured were changed by the treatment, but the tests did not investigate whether the compounds were changed to carbon dioxide and hydrofluoric acid to show adequate destruction of the original PFAS. As discussed previously, emission studies, particularly for potential PICs, are largely incomplete due to lack of validated sampling and measurement methods for the potentially large number of fluorinated and mixed halogenated organic compounds that might be formed. EPA continues to seek information on PFAS that may be present in air pollution control device media (e.g., scrubber water, particulate matter control device media) and the presumed effectiveness of these air emission controls. (See Section 5 for more information about ongoing research and research needs.)

Incineration may be a viable PFAS destruction technology if done under certain conditions. The preliminary research on thermal treatment of PFAS suggests that the minimum conditions for PFAS destruction include well mixed environments with temperatures greater than 1,100°C and optimized combustion stoichiometry (Shields et al., 2023). These conditions may adequately destroy PFAS and minimize PICs. However, evaluations have only been done on liquid fired materials at a pilot scale. No comparative studies that include PIC measurements on solids or containerized wastes have been

performed. Liquids should preferably have direct flame contact or at least well mixed exposure to temperatures greater than 1,100°C.

EPA encourages additional tests be performed to demonstrate the ability of a thermal treatment technologies to mineralize PFAS. EPA encourages testing to demonstrate destruction of parent compounds (OTM-45) and volatile PICs (OTM-50) based on suggested procedures in Appendix A) to show efficient thermal destruction of atmospherically transformative PICs of health and environmental concern.

3.a.ii.1 Other thermal treatment byproducts of concern

Thermal treatment systems including HWIs, MWCs, and SSIs are configured such that gas phase effluent from the combustion chambers passes through a series of pollution control devices to remove acid gases, particulate matter, and sometimes mercury and other specific HAPs. The behavior of PFAS and PFAS-related PICs in these unit operations is largely unknown (see Section 5 for more information about research on this topic and others). Additionally, these control devices produce secondary waste streams in the form of fly ash and scrubber blowdown solutions, and PFAS and PFAS-related PICs may be present in these solid and liquid effluents depending on their vapor pressure and solubility.

Thermal oxidation processes used for treating PFAS-containing waste, such as incineration, generate HF as the most stable product from combustion of fluorocarbon compounds. HF is a CAA-listed HAP. Highly corrosive, HF creates significant operation and maintenance issues by damaging thermal system materials such as furnace refractory and metal ductwork. Both wet scrubbing and semi-dry scrubbing processes have been applied to control HF emissions from thermal treatment sources.

A thermal oxidizer with a potential for HF emissions typically uses a wet scrubber integrated with the oxidizer to control HF emissions. Hot flue gas exiting the oxidizer is cooled rapidly in a quenching unit, and HF (which has high water solubility) is removed by the quenching water. The cooled flue gas then flows up through a multistep wet scrubbing tower for further HF removal by scrubbing water. Flue gas is scrubbed by a sodium hydroxide solution to neutralize the residual HF as the final scrubbing step. After exiting the tower, flue gas is emitted through a stack. All effluents, including those from the quenching unit and scrubber tower, are mixed with a $Ca(OH)_2$ solution in a reactor where calcium is combined with fluorine and precipitation of water-insoluble calcium fluoride (CaF_2) occurs. After dewatering, dry CaF_2 is sent to a landfill for disposal (see Section 3.b) or used to produce fluorine gas for new PFAS production, and wastewater is discharged from the plant after it is treated by activated carbon to remove trace fluorinated contaminants. Rapid cooling of hot flue gas is known to be effective in reducing catalytic reformation of chlorinated PICs such as dioxins during cooling of incineration flue gas.

A thermal oxidizer equipped with a quenching unit to treat PFAS-containing wastes may also limit catalytic reformation of fluorinated PICs if they are actually formed in the oxidizer. Those PICs may be subsequently transferred into the liquid phase in the wet scrubber. Those PICs could then be partitioned between solid CaF_2 and water in the precipitator, and most of the PICs retained in water are then removed by activated carbon adsorption. EPA is not aware of peer-reviewed studies that measure levels of fluorinated contaminants remaining in both the treated scrubber water stream and the dry CaF_2 stream. Such measurements could be useful for evaluating the potential environmental impacts of byproducts and residuals generated from thermal oxidation of PFAS-containing wastes.

Spray dryer absorber (SDA) technology has been applied to control emissions of halogen acids (including HCl and HF) from both MWCs and HWIs. This semi-dry scrubbing process is designed to inject an alkaline

slurry, typically lime, to control acid and fly ash. Water in the fine slurry droplets is vaporized by heat carried by the flue gas, and the lime carried in the droplets neutralizes the halogen acids simultaneously in this two-phase reaction process. The cooled flue gas carries the dried acid neutralization product downstream to a particle collection device, typically an FF. PAC may also be injected into flue gas upstream of the FF to control emissions of mercury and chlorinated dioxins/furans from both MWCs and HWIs. Fly ash, dried acid neutralization product, and PAC are captured by the FF. The SDA/FF with PAC injection flue gas cleaning train produces no scrubber water. The addition of lime (a calcium compound) into the flue gas is known to be effective for forming CaF_2 through hydro-defluorination of PFOS at a moderate temperature of about 350°C (660°F) (Wang et al., 2015); this suggests that the SDA may provide a potential co-benefit of controlling fluorinated PICs. The injection of PAC upstream of the FF may create another potential co-benefit for capturing fluorinated PICs. Studies evaluating PFAS mitigation via SDA/FF with PAC injection (e.g., see research activities in Section 5) will help develop data on this potentially viable technology option.

3.a.iii Potential for releases for thermal treatment technologies

Thermal treatment devices that may be used to treat PFAS-containing waste (see Section 3.a.i for descriptions of these devices) are located in both rural and more densely populated areas throughout the United States. Two possible sources of PFAS emissions from thermal treatment are stack emissions and the management of scrubber water and bottom ash/fly ash. As previously discussed, emissions from thermal treatment activities may contain PFAS if adequate combustion conditions are not achieved or if adequate acid gas scrubbers or other pollution control devices are not used. EPA is aware of a limited number of peer-reviewed studies that have investigated the extent to which emitted PFAS are transported and deposited to surrounding areas (see Section 2.a.iii). EPA plans to conduct research in this area to better characterize the extent to which PFAS deposition may occur near thermal treatment devices (see Section 5 for more information about these types of research activities).

Volatile PFAS releases from thermal treatment equipment (e.g., fugitive emissions) and waste storage activities are another potential source of PFAS releases, if they are not adequately controlled.[16] There is also the potential for releases from management of thermal treatment process residuals, such as air pollution control device media, incinerator bottom ash, and liquids from acid gas scrubbers. For example, incinerator bottom ash disposed of in a landfill would be a possible source of release if the ash contained PFAS and the landfill lacked adequate controls (see Section 3.b for more information on landfill types and controls, and Section 4 for more information about environmental releases and vulnerable populations). HWIs, however, typically dispose of incinerator bottom ash in hazardous waste landfills, minimizing the potential for the release of PFAS to the environment. Again, information on partitioning of PFAS in control technology residuals is lacking at present.

Potential impacts to communities from releases from HWIs should also be considered. Considerations should include which media may be impacted by releases, and the potential exposure pathways resulting from releases. The characteristics of the potential exposed communities (demographics, socioeconomic status, other environmental exposures, health conditions, etc.) provide information regarding the potential for disproportionate and adverse impacts.

[16] For example, CAA and RCRA regulations applicable to HWCs require controls to prevent/minimize combustion system leaks (e.g., due to positive pressure events in the combustion chamber), as well as controls to minimize releases from equipment and tanks that store or manage hazardous waste. See 40 CFR 63.1206(c)(5) and 264.1050–1090.

3.a.iv Testing and monitoring

Validated measurement methods are limited and under development for reliably identifying and quantifying if PFAS are released into the air from stationary sources. The limited scope of standardized methods to measure PFAS emissions and the limited availability of data using these methods to evaluate PFAS destruction at a variety of treatment devices introduce uncertainty in the understanding of the efficacy of thermal treatment approaches for destroying PFAS.

Ongoing method development by EPA has a broad focus that will address PFAS in various waste streams, stack and fugitive emissions, and ambient air (see Section 5 and Appendix A). Method development also includes identification of PFAS that are potential PICs, not targeted in established water methods such as Methods 533 and 537.1. Due to the number and complexity of PFAS that have already been identified, a simpler class-specific measurement is also being investigated to determine if measurement of a single compound or a small group of compounds is adequate to characterize the completeness of thermal treatment for both targeted PFAS and potential PICs.

These factors raise important risk communication challenges, particularly for communicating the potential significance of testing and monitoring results to adjacent communities. But the importance of encouraging appropriate information access for and dialogue with communities—and, in particular, with potentially vulnerable communities —cannot be overemphasized. Suggestions for risk communication are included in Section 4.

3.a.iv.1 Semivolatile PFAS sampling and analysis

Initial development of methods to measure PFAS in air or air sources has focused on compounds whose physical state is liquid or solid at room temperature. Methods for air have included the target compounds commonly found in water methods. The basis for measuring PFAS compounds from air or air sources involves evaluating and then modifying existing sampling and analysis methods for semivolatile organic compounds.

Filtered particulate, solid sorbent, and aqueous impinger media sampling procedures have been used to collect and recover a wider range of PFAS and associated byproducts in ambient air and source emissions (Barber et al., 2007; Martin et al., 2002). However, these sampling methods have some limits, including poor retention or chemical conversion of the PFAS during sampling and poor recovery during sample preparation prior to chemical analysis (Arp & Goss, 2008).

Ambient sampling for semivolatile PFAS roughly follows either the high-volume air sampling protocol described in EPA compendium Method TO-13a (U.S. EPA, 1999) or the National Atmospheric Deposition Program (NADP) approaches for wet and dry deposition sampling (NADP, 2020). High-volume air samples collect both water-soluble PFAS acids and salts and water-insoluble telomer alcohols. NADP sampling has focused on condensable and particulate-bound targeted PFAS captured in polypropylene buckets to evaluate deposition due to rain.

Current sampling of stationary source air emissions for semivolatile PFAS targets is based on EPA SW-846 Method 0010. Analysis of samples for a list of PFAS compounds is based on EPA Method 533—modified to include collection of both targeted and non-targeted PFAS in a single sampling system. Sampling includes heated or stack temperature probe extraction of emission gases followed by collection on filters, XAD sorbent media, and aqueous impingers. EPA released OTM-45, *Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources,* in January 2021 (U.S. EPA,

2021). OTM-45 experience indicates the method works well to measure targeted PFAS. OTM-45 is an effective and sensitive method to measure a list of PFAS included in the method. In coordination with the release of this guidance, EPA recently released OTM-50, which enables analysis of non-polar volatile PFAS.

These field sampling procedures collect samples that are subsequently transported to a laboratory for extraction and analysis. Analysis procedures include established water methods for targeted compounds and/or non-targeted analysis (NTA) for unknown PFAS. NTA is a research tool that can be used on OTM-45 and OTM-50 samples to investigate semivolatile polar and nonpolar PFAS recovered by these methods. High-resolution mass spectrometry can be used for both targeted analysis and NTA. Qualitative identification of PFAS by NTA reveals PICs/degradants formed during the thermal treatment of PFAS-contaminated media (Aleksandrov et al., 2019; McCord & Strynar, 2019; Newton et al., 2020). NTA currently relies on mass spectrometry, which generates qualitative information about the molecular formula of unknown PFAS. NTA is an important component in characterizing thermal treatment emissions because it provides an approach for identifying unknown PFAS or PICs.

3.a.iv.2 Gaseous volatile PFAS sampling and analysis

Volatile PFAS targets and thermal treatment byproducts from ducted emissions or in ambient air have been sampled using a variety of whole gas sample collection approaches, such as Tedlar® bags and passified canisters, as well as sorbent traps and cryogenic solvents. EPA and private sector investigators have sampled with specialized commercial sorbent traps and Tedlar® bags in laboratory-scale thermal destruction and ambient volatile PFAS measurement of targeted and non-targeted PFAS (Wang et al., 2013, 2015; Yamada et al., 2005). Issues such as sample reactivity, breakthrough volumes, and quantitative transfer to the analysis instrument complicate these approaches. Direct instrumental methods for measuring volatile PFAS (such as FTIR) can suffer from lack of sensitivity compared with extractive methods that allow concentration prior to analysis.

To develop more sensitive methods for measuring volatile fluorocarbon compounds, EPA has evaluated the use of steel canisters for targeted volatile PFAS as well as PICs during multiple-source emissions tests, including at a thermal treatment facility for AFFF-contaminated soil (U.S. EPA, 2020b). Canisters have been used to sample source emissions and perform targeted measurements for PFAS, including both industrially produced compounds (such as FC-116, HFC-23, HFC-125, E1, and E2) and potential PIDs (such as CF_4 through octadecafluorooctane). EPA is developing the ability to characterize a more diverse set of possible PFAS PICs and measure volatile PFAS at trace concentrations. The ability to measure trace concentrations will allow investigators to introduce a known concentration of a hard-to-destroy fluorocarbon and evaluate the behavior of this compound when exposed to specific thermal environments. EPA's preferred approach is to introduce a known concentration of a hard-to-destroy fluorocarbon and evaluate the behavior of this compound when exposed to specific thermal environments in order to characterize a more diverse set of possible PFAS PICs. Though insufficient by itself, this approach is consistent with the EPA approach for determining the DRE of fluorinated greenhouse gas abatement equipment in electronics manufacturing (U.S. EPA, 2010). NTA has also been performed on the same samples. Simultaneous with the release of this 2024 interim guidance, EPA will release OTM 50, which provides an approach and procedures for using silanized steel canisters to sample and analyze volatile PFAS compounds from thermal treatment sources. This and OTM-45 are examples of monitoring methods that could be considered for addition to a potential PFAS waste management system or permit (e.g., RCRA).

EPA continues to evaluate FTIR as a suitable real-time measurement technique for CF_4 and C_2F_6 in stationary source emissions. In addition, in ambient air, EPA also investigated chemical ionization mass spectrometry (CI/MS) to monitor individual PFAS in real time (Riedel et al., 2019). EPA found the technique sufficiently sensitive for fugitive emissions measurements or leak detection.

The quantitative measurement of total organic fluorine (TOF) is also being evaluated to represent all, or most, of the PFAS class of compounds. This approach represents a simpler and more comprehensive measurement alternative to target list approaches that focus on a limited number of PFAS. Several potential techniques warrant consideration and additional evaluation, including (but not limited to) combustion–ion chromatography (CIC), particle-induced gamma emission spectrometry (PIGE), and X-ray photo-electron spectroscopy (XPS). For air and thermal treatment emissions, TOF must measure highly volatile as well as semivolatile PFAS. TOF analysis is an ongoing research area: data users must recognize the benefits of receiving general screening data for a wide array of potentially present PFAS, while also recognizing the limitations and uncertainties inherent in not knowing which PFAS or class of PFAS is present in the sample, including uncertainties associated with potential health risk. In addition, to minimize the risk of PFAS false positives, techniques within a validated method or methods must be developed that demonstrate effective separation and removal of inorganic fluorine from organic fluorine (Koch et al., 2020). TOF is not specific to PFAS, and any fluorine-containing compounds (e.g., pesticides, pharmaceuticals) that are retained during extraction would be included in the organic fluorine measurement.

HF measurement is included in stationary source measurements to evaluate control efficiency of HF as a HAP at emission outlets. Multiple studies of PFAS thermal decomposition and HF monitoring have demonstrated that EPA compliance methods for HF measurement are adequate to meet this need. However, HF is difficult to transport through treatment and control equipment and is therefore not a candidate for mass balance to evaluate PFAS destruction efficiency.

3.a.v Uncertainties/unknowns

EPA is planning to collect additional information and conduct additional research to better understand PFAS destruction and evaluate emission control efficiency (see Section 5). EPA is working to develop a standardized validated methodology for measuring PFAS gaseous emissions (see Section 3.a.iv); however, EPA also lacks detailed information on the amounts and concentrations of PFAS-containing materials that are generated and managed in thermal treatment devices.

Development of sampling and analytical methodologies must continue (see Section 5 research activities) so that emissions and other media from thermal treatment devices burning PFAS-containing materials can be adequately characterized.

When evaluating thermal treatment options, decision-makers (e.g., permit writers, waste managers) should consider potential impacts to communities, including vulnerable populations. Uncertainties such as the overestimation of destruction and disposal capabilities, or a failure to account for potential PIC production and subsequent transformation back to PFAS of concern could have consequences for all nearby communities, including for vulnerable communities that may be disproportionately impacted. EPA recommends decision-makers screen communities located in the vicinity of potential releases from the destruction, disposal, and storage options (considering fate and transport) in order to consider the potential for adverse and disproportionate impacts (see Section 4), and to consider potential measures to prevent, reduce, or address such impacts. Depending on site-specific circumstances (e.g., PFAS

concentrations, impacted media, and potential exposure pathways), the size and shape of this area (vicinity) will vary.

In order to provide more detailed recommendations, further data on the ability of thermal treatment units to completely mineralize PFAS-containing materials is necessary (see Appendix A and Section 5.a). Performance testing of all types of combustors is lacking. EPA recommends that full-scale thermal destruction facilities conduct performance testing prior to accepting and processing PFAS materials. Objectives of the testing should include:

- Demonstrate destruction of parent compounds and potential production of semivolatile and volatile PICs (using OTM-45 and OTM-50) to show efficient thermal destruction.
- Characterize PFAS being fed, including the feed rate, whether it is a concentrated or diluted stream, and how the PFAS are fed (e.g., containerized or direct feed).
- Demonstrate utilization of key combustion parameters (temperature, residence time, other conditions that impact mineralization) and include relevant data in the report.
- Characterize release of PFAS and PICs through the system by sampling at multiple points in the process (e.g., before and after a scrubber) and sampling all relevant effluent streams (e.g., scrubber blowdown and fly ash). Document and report operating parameters for all relevant control devices to EPA and relevant state, territorial, or Tribal authorities.

Further details on suggested parameters and procedures are provided in Table 5-1 and Appendix A.

3.a.vi Treatment commercial availability

Section 3.a.i describes the commercial availability of thermal treatment devices. The United States has about 22 commercial hazardous waste combustion facilities[17] in operation; over a dozen large-scale, commercial carbon reactivation companies with about 17 furnaces; 193 MSW incineration units at 75 facilities; and 170 SSIs at 86 facilities.

3.a.vii Summary

PFAS-containing waste can potentially be treated in several types of thermal treatment devices, including HWCs, MWCs, SSIs, and activated carbon reactivation furnaces, but further research is needed to gain a better understanding of what may be possible in practice. These treatment devices operate differently and handle different types of PFAS-containing media with varying concentrations. Even within the same category of thermal treatment device, designs and operating conditions may vary across sources in a way that could affect PFAS treatment efficiency. As a general approach, EPA encourages decision-makers to prioritize the use of destruction and disposal technologies that have a lower potential for PFAS release to the environment, over destruction and disposal technology options with a greater potential for environmental release of PFAS. EPA acknowledges that each destruction and disposal technology has limitations. However, managing PFAS to minimize environmental releases during destruction and disposal activities supports protection of human health and the environment.

There are limited characterizations of potential PFAS emissions from thermal treatment devices that burn PFAS-containing media, and EPA is not aware of any full emission characterizations that have been conducted at HWCs, MWCs, SSIs, or activated carbon reactivation furnaces or any studies to evaluate

[17] This includes commercial incinerators, cement kilns, and LWAKs that are permitted to burn hazardous waste.

the formation of products of incomplete combustion resulting from inefficiency to convert PFAS into carbon dioxide and hydrogen fluoride. EPA is also not aware of any studies that have been conducted on the extent to which PFAS contaminants partition to air pollution control device residuals or bottom ash, which may also be a concern. This is likely (in part) because PFAS emission measurement methods and other analytical methodologies (e.g., for fly ash, other waste streams) are limited and continue to be developed. Data, however, from pilot-scale experiments conducted by EPA researchers suggest that temperatures above approximately 1,100°C / 2,012°F may result in high destruction efficiencies and few detectable fluorinated products of incomplete combustion.

Given the unique characteristics of fluorine combustion chemistry (particularly the strength of the carbon–fluorine bond), adequate thermal destruction of PFAS requires high temperatures and long residence times and likely benefits from direct flame contact. Hazardous waste combustion technologies (commercial incinerators, cement kilns, and LWAKs) can potentially achieve temperatures (~1,100°C / 2012°F) and residence times sufficient to break all carbon-fluorine bonds in the PFAS contained in the waste stream being thermally treated. Permitted hazardous waste facilities have stringent regulatory controls on temperatures and other important operating parameters to achieve a 99.99 percent destruction efficiency for other (non-PFAS) organic chemicals. Such facilities also have air pollution control devices to prevent certain gaseous and particulate pollutants from entering the atmosphere. However, information on the efficacy of PFAS destruction in these facilities is currently limited. EPA has limited data characterizing PIC emissions from these sources when they burn PFAS. EPA is working to develop measurement methodologies as well as to gather information to conclude whether PICs are adequately controlled. EPA recognizes that PICs are inevitable (even for nonfluorinated compounds); however, based on the unique characteristics of fluorine combustion chemistry, EPA believes it is important to determine whether thermal treatment devices and their associated post-combustion control devices are adequately controlling PICs, especially fluorinated PICs. Given all these factors, there is a current need to continue research activities investigating incineration of PFAS. After sufficient research has been completed to address the related knowledge and data gaps, EPA can make a more informed recommendation on disposal of PFAS compounds and PFAS-containing substances using incineration.

Similar conclusions can be drawn for activated carbon reactivation furnaces as for HWCs. Experimental data suggest that thermal destruction of PFAS will occur in two stages: first during reactivation of the GAC, and then when the off-gas is introduced into a high-temperature zone with temperatures as high as 1,000°C/1,832°F. As referenced in Section 3.a.i, an activated carbon reactivation furnace can be equipped with an afterburner to treat off-gases at high temperatures to achieve 99.99 percent DRE of VOC. In addition, scrubbers can be installed to remove acid gases. This is a promising treatment method, but more information is needed, including confirmation that PICs are controlled based on actual operations, establishment of standard operating conditions for activated carbon reactivation furnaces of various designs to ensure optimal destruction of PFAS, and an understanding of how thermal treatment influences the physical and chemical properties of GAC (in ways that can affect GAC's adsorption behavior and sorption capacity for PFAS).

Research and testing of PFAS destruction performance within MWCs is extremely limited, primarily comprising laboratory and pilot-scale studies (Aleksandrov et al., 2019; Taylor et al., 2014). For example, to assess whether PTFE is destroyed or reformed as PFAS, the Aleksandrov et al. study uses a pilot-scale rotary MWC with afterburner chamber combusting PTFE granules added to wood pellets (also firing natural gas). This study looked at a half-load scenario of 870°C (1,600°F) with a four-second residence time and a full-load scenario of 1,020°C (1,870°F) with a 2.7-second residence time. The study analyzed

for 31 PFAS compounds within the flue gas samples collected, assumed to represent a broad range of PFAS. While the laboratory and pilot-scale studies conclude that MSW incineration of PTFE is not a significant source of PFAS, the laboratory thermal reactor and the pilot incinerator used in these studies may not be representative of the design of MWC units currently operating in the United States. For example, the pilot-scale unit in the Aleksandrov et al. study is a rotary combustion chamber followed by an upflow afterburner. No MWC units operating in the United States have a similar configuration. In addition, while several PFAS species were analyzed for in these studies, it is important to note that there are far more PIC species possible, and no studies have thoroughly evaluated the types and quantities of PICs.

As noted earlier in this section, Wang et al. (2013) investigated PFAS interactions with CaO and $Ca(OH)_2$ at moderate temperatures (200°C to 900°C, or 390°F to 1,650°F), both with and without sewage sludge. These experiments were conducted in a laboratory (i.e., combustion in a crucible within a muffle furnace) and found that these calcium species exhibit a pseudo-catalytic effect promoting PFAS destruction and fluorine capture at relatively low temperatures. The study did not investigate the evolution of PICs during the thermal treatment process. While this study shows promising results for the use of catalysts to achieve PFAS destruction and fluorine capture at low temperatures, along with the potential for full-scale application (since lime is occasionally added to sewage sludge to control odor at SSIs), it is important to note that, as with the MWC studies described above, there are caveats for applying these results to the real-world design and operation of SSIs.

More research is needed to address these issues and develop reliable measurement techniques. Section 5 summarizes EPA's continuing PFAS research, as well as a general proposal to collaborate with stakeholders to address these uncertainties promptly. See Appendix D for a summary of costs and considerations.

3.b Landfills

RCRA regulations define a landfill as “an area of land or an excavation in which wastes are placed for permanent disposal, and that is not a land application unit, surface impoundment, injection well, or waste pile” (40 CFR 257.2). The goal of solid waste landfills is to contain waste, and thereby restrict the release of contaminants within the landfill from entering the environment. Landfills are commonly classified by the types of waste they accept and/or by their ownership status.

Landfills control waste and corresponding pollutants through containment. Because of their many and varied uses, PFAS enter landfills as part of the general MSW stream, in industrial waste, or in other PFAS-containing wastes, with a range of concentrations. Types of landfills include MSW, hazardous waste, industrial, C&D, and ash monofill.

Some landfills are available disposal options for PFAS and PFAS-containing materials. MSW landfills commonly receive large quantities of wastes with significant PFAS concentrations (e.g., biosolids, septage, soils excavated during remediation, and phytoremediation biomass). These concentrations are much lower than some industrial or commercial wastes with high PFAS content (e.g., leather tannery, chrome plating, and textile industry waste). Permitted hazardous waste landfills employ the most extensive set of environmental controls (e.g., double liner systems with leachate collection/treatment and leak detection) and practices (e.g., comprehensive record keeping) that are currently available for the containment of commercial and industrial wastes with high PFAS content (see Table 3-2). Hazardous waste landfills are more effective at minimizing PFAS release into the environment than other landfill types. Note that hazardous wastes that are typically landfilled are not usually biodegradable; thus, most hazardous waste landfills do not have LFG collection and control systems installed and, therefore, may not be appropriate for disposal of biodegradable PFAS-containing wastes (e.g., biosolids) that may produce LFG. It is also noted that leachate from hazardous waste landfills is designated as hazardous waste (F039) and must be managed in accordance with specific requirements for hazardous waste. Nonetheless, some leachate treatment or management options cannot treat or destroy PFAS.

Most modern MSW landfills, when constructed and operated with appropriate controls (e.g., a flexible membrane liner system and leachate and LFG collection and management systems), can also help contain PFAS. However, research indicates that although MSW landfills contain PFAS for the most part, up to 5 percent of the PFAS may be released in the LFG and, 11 percent may be released in the leachate annually (Tolaymat et al., 2023). Also, leachate may be sent to wastewater treatment plants that are not capable of treating or destroying PFAS; thus, the PFAS in landfill leachate may be released to the environment. While some information is available, EPA plans to research to understand the effects of PFAS on liner integrity, gaseous emissions from landfills, the effectiveness of leachate treatment for PFAS removal, and the levels and types of PFAS in landfill leachate (see Section 5). MSW landfills present a good opportunity to dispose of lower-concentration PFAS waste such as biosolids, phytoremediation biomass, and contaminated soils. However, there is a need for additional research regarding the effectiveness of emerging PFAS separation and destruction treatment technologies on a landfill leachate matrix.

While landfills might serve as long-term containment sites, it is unclear how effective they are at containing PFAS. Because landfills are a containment method and do not destroy PFAS, PFAS are anticipated to persist in landfills for the life of the compounds, which could be many centuries.

Section 3.b focuses on the viability of landfilling as a means of containing PFAS and PFAS-containing material, discussing:

- The types of PFAS waste and how they behave within a landfill.
- The types of landfills that receive PFAS-containing waste.
- The types of environmental controls and their ability to effectively contain PFAS.
- The potential for environmental releases of PFAS associated with landfilling.
- Recommendations for deciding what type of landfill is most appropriate for PFAS-containing waste.

- Methods to monitor PFAS at landfills and corresponding waste streams.
- Uncertainties and unknowns associated with landfilling PFAS-containing waste.

3.b.i Types of PFAS and PFAS-Containing Materials

As described in the Executive Summary and Section 2, "PFAS" is a broad term for a wide range of chemicals. When disposed of in a landfill, these different types of PFAS may behave differently from one another and may require different considerations for the types of landfills that are suitable for disposal and the types of emissions controls that are necessary to contain the PFAS over time.

PFAS Polymers. Stable polymeric PFAS (e.g., PTFE or Teflon™) are less likely to migrate within a landfill by partitioning to the gas or liquid (i.e., leachate) phase and should not be confused with side-chain fluorinated polymers; however, physical abrasion of the polymers can lead to the creation of fluorinated microplastics that may be suspended in landfill leachate. Although fluoropolymers are highly resistant to chemical and thermal degradation, they can still break down into microplastics due to weathering and physical strain, increasing their dispersion and bioavailability (Lohmann et al., 2020). Fluorinated microplastics have been measured in landfill leachate (He et al., 2019), but because UV radiation and resulting oxidation in landfills is negligible and the physical processes that lead to abrasion and the development of microplastics are expected to be relatively low in landfills, the bulk of stable fluoropolymers would be expected to be retained for a long duration. Additionally, soluble, and volatile PFAS have been identified in fluoropolymers as synthesis byproducts or incomplete reactants.

Soluble PFAS. Soluble PFAS and precursors that degrade to soluble PFAS, including perfluoroalkyl acids such as PFOA, PFOS, PFHxS, PFBA, and HFPO-DA, can more easily and quickly partition to the liquid phase and become part of the landfill leachate. Landfills without an appropriate liner and leachate collection system (see Section 3.b.iii) will allow this PFAS-containing leachate to enter and contaminate the groundwater. It is therefore not appropriate to dispose of soluble PFAS in landfills without these controls in place.

Volatile PFAS. Volatile PFAS and forms that degrade to volatile PFAS, including alcohols such as FTOHs and FASEs may be released through uncollected or fugitive LFG. These types of PFAS should therefore be disposed of in landfills with LFG collection and control systems in place and operating (see Section 3.b.iii.6). Furthermore, PFAS waste that is comingled or combined with other waste determined to be biodegradable (see EPA Test Methods for biodegradability listed at *https://www.epa.gov/pesticide-labels/criteria-biodegradability-claims-products-registered-under-fifra*) should only be disposed of at landfills with gas collection and control systems in place. The biodegradable fraction of waste will produce LFG as it decomposes and allow volatile PFAS to be emitted from the landfill.

Mechanisms and rates of transformation. The behavior of PFAS in landfills is a complex and multifaceted process that involves various abiotic and biotic transformation and partitioning pathways. While the exact mechanisms and rates of transformation are not fully understood, both aerobic and anaerobic conditions in landfills can facilitate the conversion of PFAS precursors into more persistent terminal PFAS species. It is notable that fluorotelomer carboxylic acids (FTCAs) are a soluble intermediate transformation product which has been well documented to accumulate in biologically active anaerobic landfill conditions and is considered a landfill leachate contamination indicator. FTCAs result from the degradation of volatile PFAS such as FTOHs. For this reason, volatile PFAS-containing wastes should be managed in landfill environments which are also appropriate for soluble PFAS disposal.

As the environmental and health risks of PFAS are the subject of emerging research, it is essential to consider PFAS management strategies that minimize their release and transformation in landfills and other waste management systems. For example, Subtitle D MSW landfills are required to install a low-permeability liner prior to waste disposal, and LFG at MSW landfills is collected and managed based on the landfill's permitted design capacity and emission rate of nonmethane organic compounds (NMOCs) (40 CFR part 60, subparts Cf and XXX). Given these potential pathways for release, Table 3-1 summarizes the recommended engineering controls at landfills accepting PFAS waste based on the type of PFAS and the biodegradability of any comingled waste. It is noted that non-biodegradable stable polymeric PFAS do not require specific controls since they are not anticipated to migrate or biodegrade and generate gas, can be disposed in any type of landfill, and are not included in the table below. Also note that soluble PFAS comingled with biodegradable waste should have both control liquid and gaseous emissions, i.e., leachate collection and gas control.

Table 3-1. Recommendations for Disposal of PFAS-Containing Waste by Type of PFAS, Waste Biodegradability, and Type of Landfill Controls to Reduce Risks of Environmental Release

Type of PFAS	Degradability of comingled waste	Landfills with liner and leachate collection	Landfills with gas collection and control
Stable polymeric PFAS (e.g., PTFE)	Biodegradable		✓
Soluble PFAS (e.g., PFAAs)	Biodegradable	✓	✓
	Non-biodegradable	✓	
Volatile PFAS (e.g., FTOHs)	Biodegradable		✓
	Non-biodegradable		✓

3.b.ii Types of landfills

Landfills are typically classified by ownership status and by the type of solid waste they are permitted to receive, which determines the types of environmental controls they must employ. Depending on the type of waste disposed, a landfill could be subject to regulation and permitting under RCRA, the CAA, and/or TSCA. RCRA regulates two types of landfills: Subtitle C facilities receive hazardous waste, while Subtitle D landfills are primarily intended for the management of non-hazardous waste and can include MSW landfills, industrial non-hazardous waste landfills, C&D waste landfills, and coal combustion residual landfills. The CAA regulates air emissions from MSW landfills and TSCA regulates landfills that contain PCBs. The requirements under RCRA, CAA, and TSCA determine how the landfill must be constructed, operated, controlled, maintained, monitored, and closed when it reaches its final capacity.

Although categories and environmental controls vary from state to state, the following categories of landfills exist in most states. Landfills tend to have similar environmental controls within each category:

- Hazardous waste
- MSW
- Ash monofill
- Industrial
- C&D debris

Table 3-2 identifies the environmental controls required by RCRA and CAA for the landfill types defined in RCRA Subtitles C and D. RCRA regulations focus on the containment of solid waste and leachate, while CAA regulations focus on collection and control (destruction) of components in LFG. The landfill types

differ in how they are constructed, operated, controlled, monitored, and closed, reflecting the different types of waste they are allowed to receive.

- Subtitle C hazardous waste landfills that meet the minimum technology requirements set under RCRA.
- Subtitle C hazardous waste landfills are permitted to receive hazardous wastes that pose potential risk to humans and the environment and therefore have the most stringent environmental controls.
- Subtitle D MSW landfills are allowed to receive MSW and are required to install a low-permeability liner prior to waste disposal. LFG must be collected and managed according to the requirements of the CAA standards of performance (40 CFR part 60 subparts Cc, Cf, WWW, and XXX) at landfills that meet the regulatory requirement thresholds. Subtitle D landfills that receive non-hazardous and non-biodegradable waste tend to have environmental controls commensurate with the waste they receive. These controls can vary from state to state; for example, bottom liner, leachate collection, and final cover requirements for industrial and C&D landfills range from none to rigorous.

Note that certain small MSW landfills in arid or remote locations are exempt from RCRA design and groundwater monitoring requirements (40 CFR 258.1). See Sections 3.b.ii.2 and 3.b.iii.1 for additional exemptions.

Table 3-2. Required Environmental Controls by Landfill Type

Landfill Type	Federally Regulated Under	Bottom Liner and Leachate Collection System	Gas Collection and Control System	Final Cover
Hazardous waste	RCRA Subtitle C	Yes (double liner or better)	No	Flexible membrane liner (FML) cap
MSW	RCRA Subtitle D 40 CFR part 258 CAA 40 CFR parts 60 and 63	Yes (composite liner or better)	Yes (when regulatory size and emission thresholds are triggered)	FML cap
Ash monofills	RCRA Subtitle D 40 CFR part 257	Yes (composite liner or better)	No	Clay cap
Industrial	RCRA Subtitle D 40 CFR part 257	Varies by state, from no liner requirement to composite liner	No	Varies by state, from no requirements to FML cap
C&D debris	RCRA Subtitle D 40 CFR part 257	Varies by state, from no liner requirement to composite liner	No	Varies by state, from no requirements to FML cap

PFAS concentrations have been detected in landfill leachates from various types of landfills, as shown in Table 3-3.

Table 3-3. Range of PFAS Concentrations in Different Types of Landfill Leachate Reported in Published Studies. Adapted from Tolaymat et al., 2023.

Matrix	Number of PFAS Detected (Number of PFAS in Method)	∑PFAS Range (ng L^{-1})	Country	Reference
MSW Leachate	25 (26)	300 – 58,000	USA	Chen et al. (2023)
	10 (11)	15,000 – 18,000	USA	Solo-Gabriele et al. (2020)
	24 (24)	2,700 – 7,400	USA	Huset et al. (2011)
	30 (70)	2,000 – 29,000	USA	Lang et al. (2017)
	2 (2)	330 – 2,600	USA	Clarke et al. (2015)
	28 (28)	230 – 29,000	USA	Helmer et al. (2022)
	2 (2)	47 – 3,400	USA	Michigan Waste & Recycling Association (2019)
	22 (25)	1,400 – 125,000	USA	NWRA (2020)
	31 (40)	BDL – 104,000	USA	California Water Boards (2023)
	14 (14)	33 – 15,000	Australia	Gallen et al. (2016)
	9 (9)	210 – 46,000	Australia	Gallen et al. (2017)
	15 (15)	Not reported	Australia	Simmons (2019)
	25 (43)	31 – 13,000	Germany	Busch et al. (2010)
	24 (24)	2,500 – 36,000	Canada	Benskin et al. (2012)
	16 (18)	700 – 6,400	Canada	Li (2009)
	2 (2)	50 – 2,300	Canada	Gewurtz et al.
	16 (27)	2,200 – 6,100	Norway	Eggen et al. (2010)
	7 (8)	200 – 1,500	Norway	Kallenborn et al. (2004)
	4 (4)	210 – 610	Finland	Perkola & Sainio (2013)
	7 (10)	14 – 17,500	Ireland	Harrad et al. (2019)
	8 (16)	640 – 1,400	Spain	Fuertes et al. (2017)
	28 (30)	320 – 11,000	Norway	Knutsen et al. (2019)
	17 (26)	0.3 – 1,300	Sweden	Gobelius et al. (2018)
	11 (14)	7,300 – 290,000	China	Yan et al. (2015)
	33 (57)	3,040 – 109,000	China	Liu et al. (2022)
	17 (17)	1,800 – 43,300	China	Huang et al. (2022)
	18 (18)	1,270 – 7,660	Singapore	Yin et al.
C&D Leachate	8 (9)	4,200 – 11,000	Australia	Gallen et al. (2017)
	24 (26)	270 – 30,500	USA	Chen et al. (2023)
	11 (11)	14,000 – 16,000	USA	Solo-Gabriele et al. (2020)
MSW Incineration Ash Leachate	9 (11)	2,800 – 3,400	USA	Solo-Gabriele et al. (2020)
	26 (26)	39 – 54,500	USA	Chen et al. (2023)
MSW Gas Condensate	26 (26)	199 – 80,900	USA	Chen et al. (2023)
	53 (92)	3,000 – 50,000	USA	Smallwood et al. (2023)
Hazardous Waste Leachate (Primary)	17 (28)	570 – 377,000	USA	California Water Boards (2023)
Hazardous Waste Leachate (Secondary)	13 (24)	25 – 3,700	USA	California Water Boards (2023)

BDL = below detection limit; ng/L = nanograms per liter

The following subsections describe the types of landfills that are expected to contain PFAS or PFAS-containing materials, with a focus on design and operation aspects that EPA considers important from a PFAS-treatment perspective.

3.b.ii.1 Hazardous waste landfills

Hazardous waste landfills are permitted to receive waste that is defined as "hazardous" under RCRA. This waste either is explicitly listed as hazardous or demonstrates at least one of certain characteristics (i.e., toxicity, corrosivity, reactivity, or ignitability) as defined by RCRA. Hazardous waste landfills (Subtitle C landfills) can be used for non-hazardous wastes like PFAS, when the generator wants a more controlled solution. These landfills are required to have a double liner system and must adhere to waste pretreatment standards prior to disposal (40 CFR part 268). Most hazardous waste landfills are not biologically active because they do not typically accept biodegradable wastes (e.g., biosolids, food scraps), and therefore typically do not need to have gas collection systems. Conditions in these landfills are not expected to cause PFAS emissions via LFG, although gas collection systems could be installed if a problem arises related to gas release or gas emissions. Any hazardous waste landfill must have a final cover consisting of an FML covered by soil.

PFAS-containing waste is and will likely continue to consume a fraction of hazardous waste landfill capacity. Although waste containing PFAS is currently not defined as hazardous waste under RCRA (unless the particular wastes are hazardous for some other reason), some waste generators, perhaps to be cautious, have been sending PFAS-containing wastes to hazardous waste facilities. To ensure hazardous waste landfill capacity is available in the future, EPA reviews and analyzes the Biennial Hazardous Waste Report and other data to develop and then publish an assessment of national capacity for hazardous waste management.[18] The last such capacity assessment indicated that there is adequate capacity nationwide through 2044, and a new assessment is currently underway to incorporate new information and extend the time horizon. EPA will continue to work with states to monitor hazardous waste treatment and disposal capacity and report on the status.

3.b.ii.2 Municipal solid waste landfills

EPA estimates that in 2018, 50 percent of the MSW generated was landfilled (U.S. EPA, 2024). An MSW landfill typically has at least a bottom liner and an extensive gas collection and control system (GCCS) to collect the LFG generated when the biodegradable waste, such as food scraps and office paper, degrades over time. Some MSW landfills have accepted PFAS manufacturing wastes, and as a result, PFAS concentrations in leachate are higher than the typical range expected in MSW landfill leachate (NWRA, 2020). Under RCRA, MSW landfills that received waste after 1993 must install a composite liner that meets design criteria (40 CFR 258.40). However, MSW landfills that receive less than 20 tons of waste per day are exempt from installing a liner and monitoring groundwater under RCRA (40 CFR 258.1(f)(1)). MSW landfills that exceed specified thresholds for size (based on design capacity) and emissions of NMOCs are required to install gas collection systems under current CAA regulations. Therefore, a subset of MSW landfills do not have gas collection and could release fugitive PFAS associated with LFG emissions. Similarly, unlined MSW landfills are ineffective at managing the release of mobile PFAS to groundwater (see Section 4.a). The fate of PFAS in LFG that is managed through on-site GCCS including on-site flares, engines, boilers, and turbines is unknown.

[18] Background information and links to related documents are available at *https://www.epa.gov/hwpermitting/assessment-national-capacity-hazardous-waste-management*.

3.b.ii.3 Ash monofills

Ash monofills are a subtype of MSW landfills that mainly receive ash from MSW incinerators but could also receive smaller volumes of other waste streams such as biosolids from WWTPs. Ash monofills typically have a bottom liner and final cover requirements similar to other MSW landfills. However, they usually do not require GCCSs due to the use of incineration to remove biodegradable waste. Solo-Gabriele et al., (2020) found that ash monofills have lower PFAS concentrations than other landfill types, as shown in Table 3-3. While some landfill wastes, such as MSW ash, may be low in PFAS concentrations, the inclusion of higher-PFAS waste types may increase PFAS release. With limited data on the presence of PFAS in ash monofill leachate, more research is needed to determine the PFAS and precursor content of ash from different incineration technologies and air pollution control systems.

3.b.ii.4 Industrial landfills

Industrial landfills receive solid waste from industrial operations (non-municipal). Industrial landfills are often designed to manage specific waste streams (e.g., furnace slag, fly ash, plastics). The designs of industrial landfills vary widely based on the characteristics of the waste they receive. Requirements for environmental controls at these landfills also vary from state to state. Depending on the waste types and size of the landfill, some states do not require a liner. If a liner is required, a membrane cap is often also required. Due to the variability in control technologies, industrial landfills may not be an effective disposal option for managing uncontrolled releases of PFAS. Landfills that have historically received PFAS manufacturing wastes have been associated with high concentrations in leachate and reported environmental impacts (MPART, 2020). Some waste types received at industrial landfills, including plastics and materials with polishes or coatings, are associated with high concentrations of PFAS (OECD, 2013). Specifically, industrial processes such as the leather tanning, chrome plating, and textile industries contribute to PFAS in the industrial solid waste stream (ITRC, 2022).

3.b.ii.5 Construction and demolition landfills

C&D landfills receive waste from construction, renovation, and demolition projects, as well as other inert materials that are generated in high volumes, comparable to MSW waste (U.S. EPA, 2020b). The requirements for environmental controls at these landfills vary widely from state to state, ranging from no liner to a required composite liner. C&D landfills receive some PFAS-containing wastes (e.g., building materials and carpeting with PFAS treatments) (OECD, 2013; Solo-Gabriele et al., 2020; Bečanová et al., 2016), and soluble PFAS have been noted in the leachate from C&D landfills that are equipped with a leachate collection system (Chen et al., 2023). If a liner is required, a membrane cap could also be required. GCCSs are not required in C&D landfills due to low levels of biodegradable waste received compared to MSW landfills. Therefore, PFAS-containing wastes that also include a biodegradable component should not be disposed of at C&D landfills. A GCCS may sometimes be necessary to remediate a specific issue, such as gases generated from the decay of drywall. C&D landfills that lack composite liners and leachate management systems are unlikely to prevent the migration of soluble or volatile PFAS types; however, longer chain PFAS polymers such as PTFE, which is found in some electrical insulation and membrane material, are less mobile and likely to be contained in the waste mass for a longer period.

3.b.iii Ability of engineered landfill components to contain PFAS

PFAS are emitted from landfills via two possible routes: landfill leachate and LFG. Landfill leachate is liquid that has come into contact with solid waste and is either derived from the waste itself or the result of rainwater intrusion into the waste mass. Leachate contains soluble, suspended, or miscible

materials removed from such waste. LFG is the result of the natural decomposition of organic material in landfills under anaerobic conditions. LFG is composed of roughly 50 percent methane, 50 percent carbon dioxide, and a small amount of NMOCs.

Existing efforts to manage contaminants in landfills focus on controlling leachate and LFG emissions. As shown in Figure 3-1, landfills constructed with environmental controls (e.g., bottom liner, leachate collection system, gas collection system, final cover system) manage the release of contaminants into the environment.

The uses of the engineered landfill controls shown in Figure 3-1 vary by landfill type due to differences in types of waste accepted, operating practices, site conditions, and federal and state regulations.

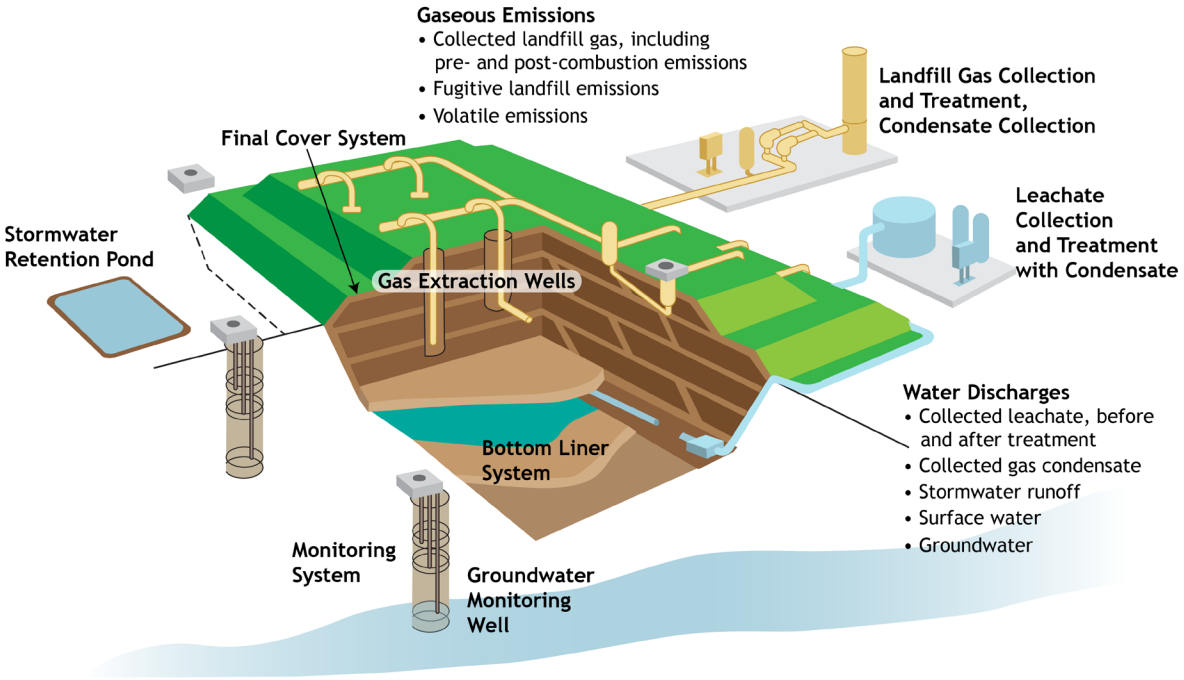

Figure 3-1. Engineered landfill components and potential PFAS release pathways.

3.b.iii.1 Bottom liner and leachate collection system

Under RCRA, any new landfill, replacement of an existing landfill, or lateral expansion of an existing landfill must have a double liner and leachate collection system if it receives hazardous waste, to limit leachate and gas release through the bottom of the landfill. Most landfills that are regulated under RCRA to receive non-hazardous waste are subject to design criteria that require either a composite liner and leachate collections system or a state-approved design that satisfies performance standards to ensure that regulated chemicals do not migrate beyond a specified distance from the landfill.

The variation of landfill requirements among states poses a challenge for the long-term containment of existing PFAS in landfills: state requirements for landfill liners vary, and some landfills are not required to have liners because of waste type or quantities received. Additionally, RCRA-exempt sites do not require liners (40 CFR 258.1). Because PFAS are not a RCRA-regulated hazardous waste, existing unlined

landfills could include PFAS-containing wastes that are easily emitted into the environment. Depending on their mobility, PFAS compounds could impact groundwater if disposed of in an unlined landfill.

A liner is built of layers of clay and/or polymers (i.e., FMLs) designed to withstand the weight of waste and soil. Leachate will collect on top of the liner, so its design must include a leachate collection system contoured to collect leachate through a network of pipes leading to a low point called a sump. The collected leachate is pumped from the landfill and managed as liquid wastes (see Section 2.f and Section 3.b.iii.5). Uncontrolled leachate could result in the release of PFAS into the environment.

PFAS interactions with landfill liner materials have been the subject of limited studies. The most common types of FML are made with polyethylene geomembranes. PFAS diffusion through linear low-density polyethylene is reported below detection diffusion rates (Di Battista et al., 2020), and diffusion through high-density polyethylene may be even slower due to differences in material structure. PFAS likely pass through clay liners, which are required to have low hydraulic conductivity on the order of 10^{-6} centimeters per second, at the same rate as leachate and other constituents such as chloride (Li et al., 2015).

The most significant pathway for leachate (and PFAS) transmission through geomembrane or composite liners is via imperfections (e.g., flaws or holes) (Di Battista et al., 2020). A review of landfill liner performance reported median leakage rates of 44 and 33 liters per hectare per day for geomembrane and composite liners, respectively, and overall liner collection efficiency of 98 percent (Jain et al., 2023). Even if liners successfully prevent leachate from reaching groundwater, very few data exist on whether concentrated PFAS waste interacts with the different types of geotextiles used for landfill liners, thus affecting the performance of the liner. While the performance of clay liners may not be affected drastically, there is currently no research on the long-term stability of FML in the presence of PFAS.

3.b.iii.2 Landfill gas collection system

Landfills use GCCSs to manage gas generated from decomposing organic waste. A GCCS consists of a network of perforated pipes sunken into the waste mass. These “gas wells” are connected to a central blower that pulls gas from the wells. Despite the presence of a GCCS, gas can still migrate both through the surface of the landfill and underground through the bottom of the landfill. The gas produced by MSW landfills contains about 50 percent methane that is usually collected and burned off at the site via flares or for energy recovery; however, those systems for LFG destruction (e.g., flares, engines, boilers) typically operate up to 85°C—below the minimum temperature required to destroy PFAS.

Not all landfills are required to collect LFG (see Table 3-2). As noted in Section 3.b.iii.6.1, research has found that soluble PFAS with relatively high vapor pressures can be emitted into the atmosphere via the gas generated at landfills (Ahrens et al., 2011; Hamid et al., 2018; Wang et al., 2020; Weinberg et al., 2011). Direct sampling methodologies are currently under development, and published concentrations of PFAS measured *in situ* are limited to a single study (Titaley et al., 2023). LFG flares generally operate at approximately 650°C to 850°C, lower than the 1,100°C necessary to achieve the mineralization of PFAS. Nonetheless, LFG collection and management systems (e.g., flares) must be present at MSW landfill sites that accept PFAS waste, especially biodegradable PFAS waste such as biosolids. The use of GAC prior to the flaring of LFG can be effective in removing PFAS from LFG. Data on the fate of PFAS in LFG that is managed through on-site GCCS, including on-site flares, are still limited. See Section 5 for potential research needs.

3.b.iii.3 Final cover system

After a regulated landfill has reached its designed and permitted capacity, it must be capped with a cover system. This system typically consists of some combination of soil and membrane materials and is primarily intended to reduce infiltration of rainwater into the landfill to minimize leachate generation. The cover system also helps increase the efficiency of the GCCS and reduce uncontrolled gas emissions. Synthetic membranes and caps are more effective at controlling release of PFAS than earthen covers. Earthen covers are more subject to wet/dry cycles and cracking and are more likely to result in uncontrolled LFG emissions, which could contain PFAS (Ahrens et al., 2011; Tian et al., 2018; Wang et al., 2020; Weinberg et al., 2011).

3.b.iii.4 Other environmental controls and monitoring systems

In addition to the major infrastructure discussed above, solid waste landfills implement other practices and systems to protect human health and the environment. In active landfill cells, daily application of a material such as soil or inert waste covers exposed solid waste. Daily cover reduces leachate generation, gas emissions, and direct exposure to humans and wildlife. Access control for a landfill site, such as a fence, is typically also required to reduce direct human and ecological exposure to waste. Extensive monitoring networks are generally required to measure the landfill's impact on surface water and groundwater. RCRA Subtitle C requires all hazardous waste landfills to install groundwater monitoring wells. See Section 3.b.iii.5 for leachate discharge controls.

3.b.iii.5 Leachate discharge controls

3.b.iii.5.1 Leachate characteristics

Leachate is the liquid effluent from landfills primarily generated through the percolation or infiltration of rainwater through waste. Leachate often contains high concentrations of biodegradable and non-biodegradable organic matter, dissolved and suspended solids, heavy metals, ammonia, and sulfur compounds (Mukherjee et al., 2015; Renou et al., 2008). The waste type, age, climate at the landfill site, and methods of landfill operation dictate the characteristics of leachate. These factors result in highly variable leachate characteristics across landfill types and on a site-by-site basis. Subtitle C hazardous waste landfills are required to use a leachate collection system during their active and post-closure care periods to mitigate adverse impact to human health and the environment. Since the use of leachate collection systems at Subtitle D landfills varies by landfill type and state requirements, the efficacy of leachate management and PFAS emissions depends on the controls implemented. PFAS containment in landfills is expected to be indefinite, so the generation of PFAS-containing leachates remains a probability during the post-closure care period and beyond. Ideally, the leachate collected at the bottom of the landfill is removed and managed to minimize impacts to human health and the environment. See Section 2 for more a more detailed discussion on the types of leachates and associated PFAS.

3.b.iii.5.2 Off- and on-site management of leachate

The most common method for non-hazardous waste leachate disposal is off-site treatment at municipal WWTPs, where leachate is mixed with wastewater and treated. The dynamic nature of leachate characteristics, the presence of non-biodegradable compounds and ammonia, and the presence of emerging contaminants (such as PFAS) in the leachate may make it difficult for WWTPs to effectively treat the influent water. In some cases, a landfill with elevated PFAS in its leachate may burden a WWTP's ability to treat, remove, or destroy these compounds before discharge to the environment (Masoner et al., 2020). As mentioned in Section 2.a.ii, wastewater treatment technologies used at most municipal WWTPs are generally ineffective at destroying or controlling PFAS (Schultz et al., 2006) and as

a result may also be ineffective at treating PFAS-containing landfill leachate. Furthermore, in WWTPs, PFAS may bind to and accumulate in biosolids, which can lead to PFAS entering the environment if biosolids are applied to land. Some WWTPs have requested that landfill operators pretreat leachate on site, and some WWTPs are implementing surcharges based on the leachate quality. Underground injection is another form of off-site leachate management (see Section 3.c).

Table 3-4 presents leachate management or treatment methods for the on-site management of leachate. Multiple technologies in the table are marked for further research—technologies for which, at the time of publishing, data do not exist to support or reject application for PFAS treatment. "Secondary treatment required" refers to the remaining concentrated or captured PFAS, which must be disposed of after treatment. "Potential secondary release" refers to the potential for PFAS release or breakthrough during the treatment process. Leachate characteristics are site-specific; therefore, the effectiveness of leachate technology should be evaluated on a site-by-site basis. (Table 3-3 lists average PFAS concentrations observed in different types of landfill leachate.)

Landfill operators should identify management or treatment methods that: (1) are suitable for the leachate at their specific sites and (2) meet the leachate discharge standards for chemicals and characteristics of leachate that are regulated. For example, leachate from a hazardous waste landfill is regulated as a listed hazardous waste (F039) and must be managed appropriately but that does not necessarily mean that treatment technologies are adequate to control the release of PFAS into the environment. For example, evaporation is often used to reduce leachate volume, which could lead to uncontrolled PFAS volatilization. The geography of the landfill site and cost-effectiveness of the methods play a crucial role in the identification of viable approaches to leachate management or treatment. For example, evaporation is often used to reduce dependence on treating a specific chemical(s) (e.g., ammonia). The use and effectiveness of leachate management strategies in removing or destroying PFAS during treatment varies (and, as noted in Section 3.b.vi, methods to quantify effectiveness are still under development). Leachate treatment technologies can be largely categorized into physiochemical processes, physical processes, biological processes, natural processes, and other management methods, as grouped in Table 3-4. Considering that leachate contains a variety of chemicals, a combination of physiochemical treatment processes can be used to narrowly target specific parameters for pre-treatment, or as part of a multi-step treatment strategy.

Table 3-4. Existing Landfill Leachate Treatment Technologies for PFAS Removal or Destruction

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Physiochemical Processes				
GAC	Adsorption	• Familiar technology • Effective for long-chain PFAS	• Secondary treatment required • Short-chain PFAS breakthrough • Potential secondary release • Cost	• McCleaf et al. (2017), Pan et al. (2016), Ross et al. (2018)
PAC with coagulation	Adsorption	• Effective for long-chain PFAS	• Secondary treatment required • Costly for high-volume leachate • Potential secondary release	• Bao (2014), Pan et al. (2016)
Polymeric adsorption	Adsorption	• Tailored for specific compounds	• Secondary treatment required • Potential secondary release	• Liu (2017)
Ion exchange resin	Ion exchange adsorption	• Specified for certain compounds • More effective than GAC for long-chain compounds	• Secondary treatment required • Less effective for short-chain PFAS • Potential secondary release	Dickenson & Higgins (2016), McCleaf et al. (2017), Ross et al. (2018)
Zeolite	Ion exchange adsorption	• Inexpensive	• Secondary treatment required • Low surface area compared to GAC • Unknown reaction with short-chain PFAS	Chiang et al. (2017), Ochoa-Herrera & Sierra-Alvarez (2008)
Ozonation/ ozofraction-ation	Oxidation	• Potentially effective multi-contaminant removal	• Potential side-product formation • Secondary treatment required	Franke et al. (2019), Lin et al. (2012), Rahman et al. (2014), Ross et al. (2018)
Fenton oxidation	Oxidation	*Limited data available*	*Limited data available*	*None identified*

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Photocatalytic advance oxidation process	Oxidation	• Permanent degradation	• Potential side-product formation • Cost	Lockwood (2018), Ross et al. (2018)
Coagulation-flocculation	Precipitation	*Limited data available*	*Limited data available*	Bao (2014), Dickenson & Higgins (2016), ITRC (2018), Rahman et al. (2014)
Chemical precipitation	Precipitation	*Limited data available*	*Limited data available*	*None identified*
Air stripping	Volatilization	*More research needed*	• Potential secondary emissions	*None identified*
Physical Processes				
RO	Physical separation	• Commonly used • Effective for short and long-chain PFAS	• Secondary treatment required for high-volume concentrate • Membrane fouling	Dickenson & Higgins (2016), Ross et al. (2018)
NF	Physical separation	• Uses less energy than RO • Effective for short- and long-chain PFAS	• Secondary treatment required	Boo et al. (2018), Dickenson & Higgins (2016)
Ultrafiltration (UF); microfiltration (MF)	Physical separation	*N/A*	• Not effective for PFAS	U.S. EPA (2020a)
Climatic evaporation; thermal evaporation; mist evaporation	Volume reduction	*Limited data available*	• Potential secondary emissions	*None identified*
Other On-Site Management Methods				
Recirculation	Containment	• Co-location with landfill	• Oversaturation • Potential surface water contamination • Dependent on climate	*None identified*
Underground injection	Containment	• Potential solution for PFAS concentrate	• Dependent on site geology • Regulatory approval	ITRC (2018)

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Incineration	Thermal destruction	• PFAS destruction	• Potential secondary emissions (incomplete destruction) • Regulatory approval	ITRC (2017), Yamada et al. (2005)
Solidification	Containment	• Co-location with landfill • Reduces PFAS mobility	• Consumes air space in landfill • Unrealistic for large leachate volume	*None identified*
Biological Processes				
Activated sludge process sequencing; batch reactor; anaerobic; digestor; membrane bioreactor	Biological processes	*Limited data available*	• Limited by high concentrations of non-biodegradable organic matter	Ross et al. (2018), Saez et al. (2008), U.S. EPA (2020a)
Natural Processes				
Constructed wetlands; aerated ponds; phytoremediation; land application	Environmental release	*N/A*	• Direct release of PFAS	U.S. EPA (2020a)

3.b.iii.5.3 Leachate management and treatment technologies

Membrane treatments separate compounds from the leachate using mechanical filtration and pressure. Leachate passes through selective membranes (such as RO, NF, UF, and MF membranes) that divide it into two parts: permeate (which has passed through the membrane) and concentrate (which has not). The permeate and concentrate can then be treated as independent streams. The primary difference between these membranes is the pore size, which in turn affects the operating pressure and removal efficiency for different types of contaminants. RO is the most commonly used type of membrane for leachate treatment, while NF, UF, and MF are generally used in combination with other treatment technologies including RO. RO and NF are known to be effective in concentrating some PFAS, but UF and MF have pores that are too large to limit the release of most water-bound PFAS across the filtration membrane. Membrane fouling and a large amount of concentrate generation are two of the major drawbacks observed in implementing the membrane treatment system for landfill leachate and may be further complicated by high concentrations of PFAS (Dickenson & Higgins, 2016; ITRC, 2018; Ross et al., 2018).

An adsorption process with activated carbon is used for targeted removal of organic matter at some landfill sites. Activated carbon is known to be effective at trapping some PFAS, but it may need to be combined with other treatment methods to manage the range of PFAS found in landfill leachate. Activated carbon is a non-selective treatment method, expected to be less effective in nutrient-laden effluents such as landfill leachate. Once saturated, activated carbon needs to be reactivated through a pyrolysis process (see Section 3.a), collected as solid waste, or otherwise treated, with consideration of

the PFAS concentration (ITRC, 2017). Leachate also may need to be pretreated before activated carbon treatment to avoid rapidly saturating the carbon.

Methods using ozone, Fenton's reagent, or advanced photocatalytic technologies are used to oxidize organic matter in the leachate. Ozone and hydrogen peroxide (H_2O_2) in combination with other oxidizing agents have been observed to remove up to 99 percent of chemical oxygen demand from leachate at different operating conditions (Renou et al., 2008) and may be effective at reducing or modifying certain PFAS in leachate (Ross et al., 2018). Ultraviolet photocatalytic advanced oxidation is known to be capable of destroying PFAS, but additional studies are needed to understand the subsequent products associated with this method (Lockwood, 2018; Ross et al., 2018).

Ion exchange processes using zeolite and magnetic ion exchange resin remove ammonia and organic matter, respectively. Ion exchange can be flexibly designed to address different compounds and may be effective at reducing PFAS in leachate; however, performance data are not currently available. As with activated carbon, the leachate may require pretreatment and the spent media would need to be handled as solid waste or otherwise treated.

Air stripping of landfill leachate is used for ammonia removal. While air stripping could be effective in the treatment pathway of leachate, if it is used before the removal of PFAS, it would likely lead to emissions of more volatile PFAS to air.

Recirculation of leachate within a landfill—a management strategy unique to MSW landfills—keeps the leachate within the landfill. Although recirculation can filter heavy metals and improve leachate quality, it is primarily used as a management option that may also help accelerate biodegradable waste decomposition. The recirculation of leachate in the landfill would return any PFAS to containment within the landfill. However, recirculation tends to increase the PFAS content of the landfill and may result in larger fugitive PFAS emissions since the waste will degrade faster.

Underground injection, specifically Class I injection, has also been used to manage landfill leachate in the United States (see Section 3.c).

Natural processes (such as constructed wetlands and phytoremediation) and biological processes (degradation, nitrification, and denitrification) are expected to be ineffective at treating and preventing release of many PFAS into the environment. Current biological treatment processes such as the activated sludge process and sequencing batch reactor have not been shown to be effective at treating many PFAS, but future research may show biological treatment can play a role in controlling some PFAS or converting them into other types of PFAS. Note that biological treatment does not necessarily result in PFAS releases directly into the environment, because the outputs can be further treated.

Leachate treatment through evaporation reduces the volume of leachate. Open-air evaporation methods may be effective at concentrating leachate but are a pathway for secondary PFAS releases to air. Commercial evaporators operated through the heat generated by the LFG combustion or other fuel sources are sometimes used at landfills. Exhaust gases emitted from the evaporators may be exposed to high temperatures, but those temperatures may not be high enough or last long enough to destroy PFAS (see Section 3.a).

3.b.iii.6 Landfill gas emission controls

3.b.iii.6.1 Landfill gas characteristics

Under the anaerobic conditions that dominate landfill environments, organic waste (e.g., food waste, paper, cardboard) decomposes and generates LFG. LFG in MSW landfills consists mostly of methane and carbon dioxide. In most landfills where gas is collected, it is burned for energy or to destroy the methane and other organic chemicals it contains. Even at sites that actively collect LFG, a fraction (EPA estimates 25% on average; AP-42, Vol.1, Chapter 2.4) of the LFG is emitted directly to the environment through the landfill surface and other routes. These uncontrolled emissions are referred to as fugitive losses.

Research has found that soluble PFAS with relatively high vapor pressures can be emitted into the atmosphere via the gas generated at landfills (Ahrens et al., 2011; Hamid et al., 2018; Wang et al., 2020; Weinberg et al., 2011). EPA is currently researching direct LFG sample evaluation for PFAS concentrations (see Section 5).

Unlike waste in MSW landfills, the C&D landfill waste that contributes most to LFG production is generally dominated by gypsum drywall (Yang et al., 2006). Gypsum drywall results in C&D LFG largely consisting of hydrogen sulfide, a highly pungent gas, with a smaller fraction of methane. Because C&D landfills generate a lower volume of gas than MSW landfills, LFG from C&D landfills is typically not collected and is often emitted to the environment without treatment.

3.b.iii.6.2 On- and off-site management of landfill gas

LFG collection and management are regulated under the CAA through New Source Performance Standards (NSPS) and National Emission Standards for Hazardous Air Pollutants (NESHAP) programs. After collection, LFG can be managed on site and burned using a flare. There are two basic types of flares common at MSW sites: open (candlestick) and enclosed flares. LFG can also be managed off site, where it is usually piped from the landfill to a nearby gas-fired system to generate heat or power.

On-site open flares must operate in accordance with key parameters for exit velocity and flare diameter for non-assisted flares (in 40 CFR 60.18). Additionally, a heat-sensing device must be installed to indicate continuous flame presence (but no specific temperature level). A landfill with an enclosed flare must reduce NMOCs to 20 parts per million by volume (ppmv) outlet or reduce NMOCs by 98 percent via a one-time performance test. Lowered emissions are maintained by following operating parameters set during the test for the requisite flare temperature and flow rate.

Combustion temperatures and duration may prove to be critical factors for destruction of PFAS in LFG. While on-site flare systems average 850°C (1,550°F) (U.S. EPA, 2008), power-generating engines and boiler systems may run even cooler. None of these systems operate at the temperature necessary to mineralize PFAS (1,100°C) as indicated in the EPA boiler database. See Section 3.a for a more complete discussion on conditions required for PFAS destruction.

Under the CAA regulations, if LFG is treated for sale or use in a beneficial energy recovery device, it must be treated according to a site-specific treatment plan before being utilized on site or piped out of the facility. Like liners, active gas collection systems are not required at all landfills, depending on the landfill size and level of NMOCs in the LFG. The presence or absence of an LFG collection and control system directly affects the release of PFAS via fugitive emissions.

LFG condensate is a liquid that has condensed in the LFG collection system piping during the extraction of gas from the landfill. In gases with high concentrations of water vapor, water condenses in pipes and

accumulates in traps staged throughout the collection network. This condensate contains volatile compounds and accounts for a relatively small percentage of flow from a landfill. Gas condensate is commonly collected and managed with the landfill leachate as liquid waste. PFAS has been detected in LFG condensate, with perfluorobutanesulfonic acid (PFBS) being the dominant species at a concentration of 1,000 nanograms per liter (Li, 2011).

3.b.iv Potential for releases during landfilling

Over time, there is increased potential for certain pollutants to move into the environment beyond the footprint of the landfill. As water passes through the landfill, it may leach pollutants from the waste—including PFAS—and move them deeper into the waste mass. Controlled landfill leachate is collected and either reinjected, treated on site, or sent for off-site treatment. In the absence of leachate management systems, uncontrolled leachate releases occur when water travels through the waste, out of the landfill, and into groundwater or surface water (see Section 4).

LFG can also contain heavy metals, organic chemicals, and greenhouse gases and can produce explosive mixtures of gas in the vicinity of the landfill if not properly controlled (ATSDR, 2001). LFG capture technologies are widely used to control gaseous emissions from landfills. However, not all landfills are required to install and operate LFG collection systems. Even when an LFG collection system is installed and properly operated, a fraction of LFG is emitted directly to the environment through the landfill surface and other routes as fugitive losses (see Section 4).

Even years after landfill closure, direct human and ecological exposure to PFAS is possible if PFAS are emitted through the air, groundwater, or surface water, or if remaining waste is disturbed. Because landfills contain PFAS but are not designed to destroy these compounds, they represent a potential source of PFAS release well beyond the period in which landfills receive waste and the post-closure care period. Ideally, landfill areas could be used for other beneficial purposes after closure; this requires that potential risks from landfill contents be adequately managed. Direct exposure to PFAS from landfilled waste is possible for people living or working near landfills due to gaseous or water releases from the site. Additionally, if PFAS-containing wastes are present on trucks and moved to active cells, landfill employees are directly exposed to PFAS on the job. Research has shown elevated concentrations of PFAS in landfill ambient air (Hamid et al., 2018).

Potential impacts to vulnerable communities from landfill releases should also be considered. Considerations should include which media may be affected by releases, and the potential exposure pathways resulting from releases. The characteristics of the potential exposed communities (e.g., demographics, socioeconomic status, ambient exposures, health conditions) provide information regarding the potential for disproportionate and adverse health and environmental effects, including cumulative impacts.

Ensuring that PFAS-containing waste is properly disposed of in lined landfills with active gas collection systems where volatile PFAS or MSW landfills are involved, is instrumental in reducing PFAS emissions into the environment. Care must also be taken to avoid disposal of PFAS wastes in landfills that are known to have compromised liners, as PFAS in the leachate will migrate and contaminate groundwater.

3.b.v Testing and monitoring

Currently, there are no federal requirements for the monitoring of PFAS in landfill waste, leachate, condensate, or LFG. EPA and others are conducting studies to evaluate the effectiveness of landfills in

containing or managing PFAS (see Section 3.b). Landfill operators should include PFAS measurements with the regular leachate monitoring parameters that are regularly evaluated. Analyzing PFAS in LFG may pose a challenge for comparison across destruction/control technologies and types of landfills due to the lack of standardized testing (see Section 5.a for research needs).

The lack of testing and monitoring limit effective risk communication and dialogue with adjacent communities. The importance of dialogue with communities, and in particular, communities that may be more vulnerable to PFAS exposures, cannot be overemphasized. Suggestions for risk communication are included in Section 4.

3.b.vi Uncertainties/unknowns

EPA plans to conduct further research on PFAS within landfills, including the potential for PFAS to migrate to leachate or LFG without adequate controls. As with thermal treatment, EPA lacks detailed information on the amounts and concentrations of PFAS and precursor compounds in wastes that are landfilled. Limited research is providing some information on PFAS fate and portioning in landfill environments. The bulk of PFAS seems to remain with the solid waste mass, with quantifiable percentages in LFG and leachate. However, there is high level of uncertainty in these values and more data are needed. Sampling and analytical methodologies must be developed to quantify potential PFAS flows out of landfills—an effort that may be complicated by the long lifespan of some PFAS. Additionally, the efficacy of treatment options for PFAS captured by leachate and LFG systems is not well understood and is in some cases intrinsically entwined with TWTDS and thermal treatment options. EPA continues to research these complex and important issues. Refer to Section 5 for a summary of EPA and DoD's planned research activities specific to landfill containment, wastewater treatment, and thermal treatment of PFAS.

When evaluating landfill options, decision-makers (e.g., managers of PFAS-containing materials and PFAS-containing waste) should consider potential impacts to communities, including vulnerable populations. Uncertainties regarding LFG or leachate releases could have consequences for communities that are exposed and may be disproportionately affected. EPA recommends that decision-makers screen communities located in the vicinity of potential releases from the destruction, disposal, and storage options (considering fate and transport) in order to consider the potential for adverse or disproportionate impacts (see Section 4) and to consider potential measures to prevent, reduce, or address such impacts. Depending on site-specific circumstances (e.g., PFAS concentrations, impacted media, and potential exposure pathways), the size and shape of this area (vicinity) will vary.

3.b.vii Summary

Due to widespread use and disposal through typical waste management pathways, many PFAS-containing wastes are currently managed through containment in landfills. Though landfills (except C&D landfills) are designed for permanent waste containment and management of liquid and gas production, it is currently unclear if all landfills used to dispose of PFAS and PFAS-containing materials have controls that are effective for managing PFAS discharges and emissions from waste streams. PFAS-containing waste should not be placed in C&D landfills that don't have liner systems to intercept and manage the leachate. Even with appropriate liners, research has shown an overall collection efficiency of 98 percent for geomembrane and composite liners. Given the chemical makeup of PFAS, some compounds are expected to persist in landfills for years.

As leachate passes through landfills, PFAS are released from degrading wastes. PFAS have been detected in the leachate for all types of landfills, and improper management of landfill leachate would result in PFAS releases. To date, research on the efficacy of wastewater treatment technologies in capturing or destroying PFAS in leachate is limited, as most landfills are not currently required to treat leachate for PFAS. The existing data suggest that adsorption and separation treatment mechanisms have been shown to concentrate or capture PFAS from landfill leachate (see Table 3-4). Other leachate management options can control the release of PFAS, including recirculation and solidification, which return PFAS to the landfill. Leachate treatment through natural processes such as constructed wetlands, land application, or ponds is ineffective for preventing the release of PFAS into the environment. More data are needed on the volatilization of PFAS during leachate handling and treatment.

PFAS can be emitted with LFG that is generated as waste decomposes over time. On-site and off-site LFG management commonly uses flares, engines, or boilers to combust LFG. Combustion temperature and duration could be critical factors for the destruction of PFAS in LFG, as discussed in Section 3.a.

To varying degrees, hazardous waste or MSW landfills are feasible and effective disposal options for PFAS and PFAS-containing materials. Permitted hazardous waste landfills employ the most extensive set of environmental controls (e.g., double liner systems with leachate collection and leak detection) and practices (e.g., extensive record keeping) that are currently available for the containment of PFAS waste (see Table 3-2) and as a result would be more effective at minimizing PFAS release into the environment than other landfill types. Hazardous waste landfills do not typically accept biodegradable wastes (e.g., biosolids, food scraps), and are not biologically active, so they do not generally need to be equipped to collect and control LFG. Therefore, hazardous waste landfills are not expected to cause PFAS emissions via LFG and may not be appropriate options for biodegradable PFAS-containing wastes.

Modern MSW landfills, when constructed with appropriate controls (e.g., liner system and leachate and gas collection and management systems), can also control the release of PFAS into the environment. Even with these controls in place, the proper management of landfill gaseous and liquid releases needs to be applied to minimize PFAS release into the environment (see Section 3.b.iii). Care must be taken to apply the leachate control technologies that are effective at containing (e.g., solidification, recirculation) or destroying PFAS (see Table 3-4).

Given the high level of uncertainty associated with PFAS behavior in landfills, the effects of PFAS on liner integrity, gaseous emissions from landfills, the effectiveness of leachate treatment for PFAS removal, and the levels and types of PFAS in landfill leachate—additional research will help to further evaluate this disposal method for PFAS and PFAS-containing wastes. See Figure 3-2 for a summary of recommended landfill disposal options for PFAS-containing wastes and considerations for selecting the best option based on both waste and landfill characteristics.

See Appendix D for a summary of costs and considerations.

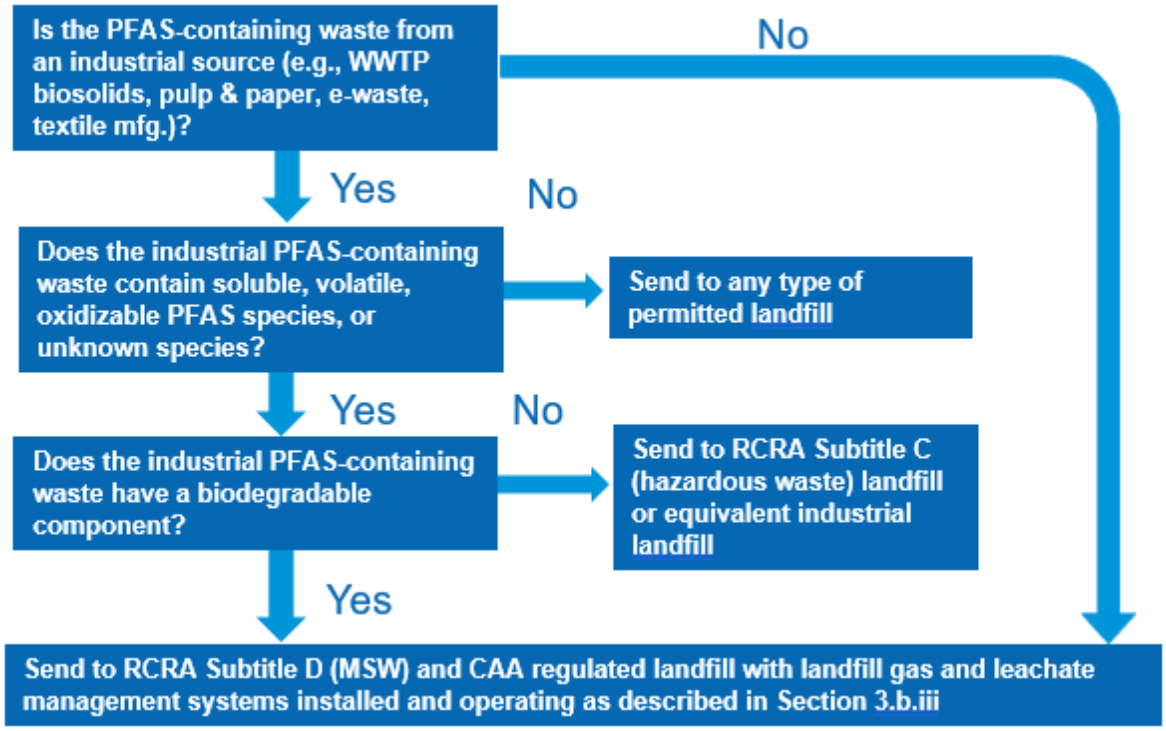

Figure 3-2. Decision framework for selection of landfill disposal for PFAS-containing industrial waste.

3.c Underground injection

Underground injection wells are a feasible and effective disposal option that normally should minimize release of PFAS into the environment. However, underground injection wells are only suited for the disposal of liquids and are restricted to locations with suitable geology. PFAS-containing fluids are currently handled similarly to other waste streams that are injected deep into geologic formations in Class I non-hazardous industrial and hazardous waste disposal wells, while shallow Class V wells would be inappropriate for the management of PFAS-containing fluids. The limited number of wells currently receiving PFAS and accepting off-site waste, well location, and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection.

3.c.i Types of wells

Underground injection is generally defined as the subsurface emplacement of fluids through a well. Under the Safe Drinking Water Act (SDWA), EPA is authorized to regulate the permitting of injection wells—including construction, operation, monitoring, and proper closure—for the purpose of protecting USDWs. Underground injection control (UIC) regulations are found in 40 CFR parts 144 to 148.

EPA's UIC program shares information for owners and operators of injection wells, regulators, and the public about safe injection well operations to prevent the contamination of USDWs. Under the UIC program, EPA regulates the permitting of the following well types:

- **Class I** wells inject into geologic formations below the lowermost USDW and are further subdivided into four categories: municipal wastewater, radioactive waste, hazardous waste, and non-hazardous industrial waste disposal wells (see Figure 3-3).
- **Class II** wells are used for injection activities associated with oil and gas production and hydrocarbon storage.
- **Class III** wells are solution mining wells used to inject fluids for the purposes of dissolving and extracting minerals.
- **Class IV** wells, with limited exceptions, have been banned by EPA since 1984 and were used to inject hazardous or radioactive waste into or above geologic formations containing USDWs.

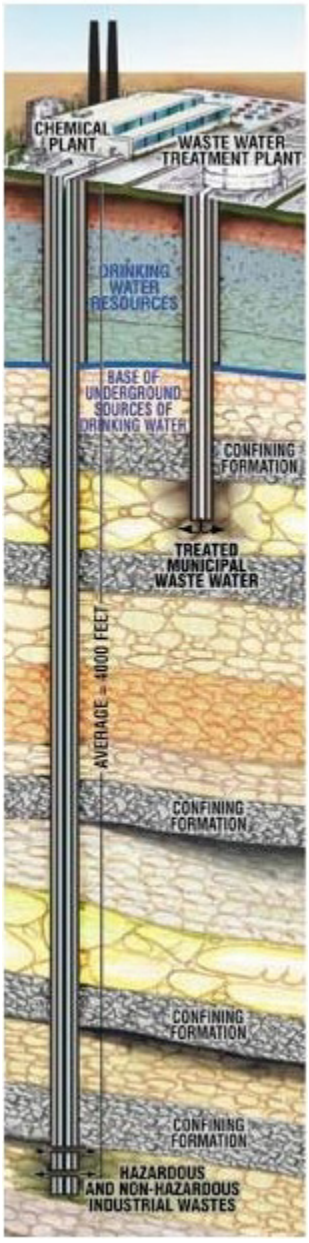

Figure 3-3. Class I wells.

- **Class V** wells include injection wells that are not included in Classes I, II, III, IV, or VI. EPA has identified multiple subtypes, including stormwater drainage wells, septic system leach fields, and agricultural drainage wells.
- **Class VI** wells are used to inject and geologically sequester carbon dioxide.

EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high concentration liquid PFAS waste has a lower potential for environmental release when compared to other PFAS destruction and disposal options, and there is relatively low uncertainty in this

determination. Class I underground injection wells are designed to dispose of and isolate liquid waste below the land surface and beneath USDWs. The standards associated with the construction, operation, and monitoring of Class I wells are designed to ensure protection of USDWs. These standards include at least one confining layer between the zone in which the fluid will be emplaced and the lowest USDW. While Class I wells are an option for managing PFAS-containing fluids, this technology may not be appropriate everywhere. The suitability of a site for injection is dependent on the geologic formations in the area. Sites need to be evaluated to ensure that there is an appropriate confining zone and that there are geologic formations that can receive fluids.

Class I wells for non-hazardous industrial and hazardous waste are currently being used for disposal of PFAS-containing fluids and are the focus of this section. PFAS-containing fluids that may be disposed of via Class I underground injection wells may originate from industrial activities such as chemical production (e.g., products and byproducts) and waste management operation (e.g., landfill leachate).

The standards associated with the permitting, construction, operation, and monitoring of Class I hazardous waste wells, which are regulated under RCRA and SDWA, are more stringent than for non-hazardous industrial waste disposal wells.

3.c.ii Siting, engineering, and operational controls

3.c.ii.1 Overview of the regulatory framework

Underground injection through Class I non-hazardous industrial and hazardous waste wells is a long-standing, well-regulated disposal technology. Underground injection has been used as a waste disposal practice in the United States since the 1930s, beginning with disposal of brines from oil production activities. Underground injection of wastewater from industrial facilities has been in practice since the 1950s. In response to concerns around underground injection activities and incidents of well failure, in 1974 (the same year the SDWA was enacted), “EPA issued a policy statement in which it opposed underground injection without strict control and clear demonstration that the wastes will not adversely affect groundwater supplies” (U.S. EPA, 2001).

Final UIC regulations were published six years later, and federal and state regulation and oversight has been informed by extensive reviews of injection practices and the associated risks over time (U.S. EPA, 2001). The requirements for Class I wells under 40 CFR part 146 and 40 CFR part 148 (which applies to hazardous waste wells only) are designed to ensure that injected fluids cannot migrate into USDWs through either of two potential pathways: loss of waste confinement or “improperly plugged or completed wells or other pathways near the well” (U.S. EPA, 2001). These requirements include, but are not limited to:

- Proper siting.
- Conducting geologic and hydrogeologic studies that demonstrate that injected fluids will not endanger USDWs.
- Implementing specific design, construction, and operation requirements.
- Implementing continuous monitoring and periodic monitoring and testing requirements.
- Performing appropriate well closure and plugging.

Specific components of these requirements are discussed further below.

3.c.ii.2 Class I non-hazardous industrial and hazardous waste wells

Underground injection to Class I non-hazardous industrial and hazardous waste wells reduces the potential risks of human exposure to injected materials, avoiding discharge to surface and shallow groundwater and generating little or no air emissions. When injected into non-hazardous industrial or hazardous waste Class I wells, fluids are placed below the lowermost USDW. The area into which waste is injected is referred to as the injection zone. Injection zones of Class I wells typically range from 1,700 to more than 10,000 feet in depth (U.S. EPA, 2001). Injection zones are porous and permeable geologic formations. They are separated from USDWs by one or more confining layers of impermeable rock. The confining layers prevent injected fluids from migrating vertically into a USDW.

Class I wells are sited in geological areas that are conducive to injection operations. Siting considerations include ensuring that injected fluids will not migrate through natural fractures and faults from the injection zone into USDWs. Likewise, well operators are required to demonstrate the absence of non-natural pathways (e.g., abandoned wells) or other nearby active wells that could allow for movement of injected fluids into USDWs, within a prescribed area surrounding the well (known as the area of review). In addition to the safeguards offered by siting, engineering, and operating requirements, well design and construction requirements incorporate redundant safety features, and construction materials are "corrosion-resistant and compatible with the wastewater and the formation rocks and fluids into which they come in contact" (U.S. EPA, 2001). Class I wells might also use multiple strings of well casing, inject through tubing set on a packer, and be constructed with adequate cement alongside the entire well string to protect any USDWs.

3.c.ii.3 Potential for Release

Permitted underground injection of fluids through Class I non-hazardous industrial and hazardous waste wells ensures that injected fluids are confined and cannot enter USDWs—the pathway of concern for this waste disposal technology. In its 2001 study of risks associated with Class I wells, EPA stated that the "probability of Class I well failures, both non-hazardous and hazardous, has been demonstrated to be low. In the unlikely event that a well would fail, the geology of the injection and confining zones serves as a final safety net against movement of wastewaters to USDWs" (U.S. EPA, 2001).

Injection well operators invest millions of dollars in the permitting, construction, and operation of wells. Development of Class I non-hazardous industrial and hazardous waste wells is a resource-intensive process, with the geologic limitations noted previously. In addition, siting requirements limit the areas in the country where Class I wells can be located (see Section 3.c.iii). Routine operation and maintenance include addressing requirements for extensive mechanical integrity testing, monitoring, and periodic submission of permit/no-migration petitions.

3.c.ii.4 Additional requirements for Class I hazardous waste wells

Class I hazardous waste wells are highly protective of USDWs and include additional requirements beyond those of Class I non-hazardous industrial waste wells. The 1984 Hazardous and Solid Waste Amendments to RCRA prohibited land disposal of hazardous waste, including via underground injection, with limited exceptions. Hazardous waste disposal via Class I injection wells is permitted if the operator can demonstrate that the waste will remain where it has been injected for as long as it remains hazardous (defined under regulation as a period of up to 10,000 years). To demonstrate this, Class I hazardous waste well operators must receive approvals of "no-migration petitions" from EPA.

No-migration petitions present information and modeling results using data on local and regional geology, waste characteristics, geochemical conditions of the well site, injection history, and many other factors, which EPA reviews to determine whether the petitioner has adequately demonstrated that the waste will not migrate from the disposal site for as long as it remains hazardous. Furthermore, Class I hazardous waste well facilities are subject to inspections and well operators must conduct annual testing and analysis to demonstrate they are meeting the conditions of the permit and that all assumptions, projections, and models are still appropriate and valid. This includes performing mechanical pressure tests and geophysical logging tests to assess well integrity both internally and externally to ensure injected fluids are being emplaced and are remaining within the injection zone.

3.c.iii Availability

The United States currently has 925 Class I wells. Slightly less than half (48 percent) are permitted for non-hazardous industrial waste injection. Approximately 15 percent are permitted for hazardous waste disposal. The remainder are permitted for municipal wastewater disposal. Currently, EPA is aware of both non-hazardous industrial and hazardous Class I wells that manage PFAS-containing fluids. However, there is currently no national information on the number and location of Class I non-hazardous industrial or hazardous waste wells that could accept PFAS-containing waste or are willing to accept waste not generated on site.

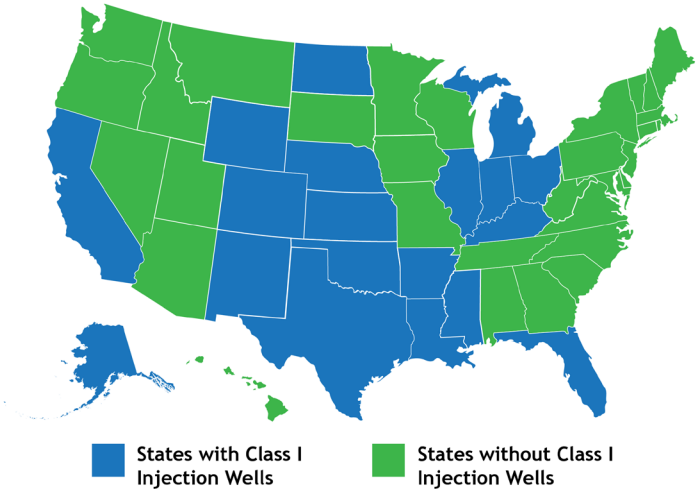

Figure 3-4. States with Class I non-hazardous or hazardous waste injection wells.

Figure 3-4 shows all states that currently have at least one permitted Class I injection well of any type (non-hazardous industrial or hazardous waste). Table 3-5 provides a more detailed breakdown of the number of permitted Class I wells by state.

Table 3-5. Inventory of Permitted Class I Non-Hazardous and Hazardous Waste Wells in the United States (FY 2022; Source: EPA)[19]

Location of Wells		Number of Wells	
EPA Region	**State/Tribe**	**Class I Non-Hazardous**	**Class I Hazardous**
4	Florida	343	-
	Kentucky	2	-
	Seminole Tribe	3	-
	Mississippi	4	4
5	Illinois	5	2

[19] EPA's inventory of Class I non-hazardous waste wells consists of all non-hazardous waste wells, including municipal and industrial waste wells. However, the municipal waste wells are located exclusively in Florida.

Location of Wells		Number of Wells	
EPA Region	**State/Tribe**	**Class I Non-Hazardous**	**Class I Hazardous**
	Indiana	13	4
	Michigan	40	7
	Ohio	7	11
6	Arkansas	8	4
	Louisiana	16	19
	New Mexico	6	-
	Oklahoma	6	-
	Osage Nation	1	-
	Texas	83	77
7	Kansas	58	7
	Nebraska	11	-
8	Colorado	13	-
	North Dakota	8	-
	Wyoming	89	-
9	California	52	-
10	Alaska	22	-
Total		**790**	**135**

3.c.iii.1 Class I non-hazardous industrial waste wells

Non-hazardous industrial waste wells are currently located across 19 states and two Tribal lands, though the majority are in five states—Wyoming, Texas, Kansas, California, and Michigan. There are currently no Class I non-hazardous waste wells in EPA Regions 1, 2, or 3 (see Figure 3-4 and Table 3-5). Disposal to this type of well requires well operators to apply for and receive a permit for specific waste streams. Current Class I injection wells may have limited capacity for PFAS-containing fluids, as many of them are used for specific purposes and disposal of waste generated on site. To begin accepting PFAS-containing fluids, existing well permits would have to be modified to recognize that the facility is accepting waste from other entities and authorize the facility to inject modified waste streams.

Well operators must also consider the well's capacity to accept additional volumes of waste and the compatibility of the PFAS-containing fluids with the well material, the geochemistry of the injection formation and formation fluids, and the properties of other injected wastes.

3.c.iii.2 Class I hazardous waste wells

Hazardous waste wells are currently located in nine states; however, most are in Texas and Louisiana. Most Class I hazardous waste wells are sited at industrial facilities and dispose of waste generated on site (U.S. EPA, 2016). There are currently no Class I hazardous waste wells in EPA Regions 1, 2, 3, 8, 9, or 10 (see Figure 3-4 and Table 3-5). Because of this geographic concentration of Class I hazardous waste wells, waste producers may face transportation and logistical challenges.

EPA anticipates the number of current Class I hazardous waste wells that would begin accepting new sources of PFAS-containing waste to be very limited due to the necessary modifications of Class I

hazardous waste well permits (e.g., increased injection volumes, changes to waste streams, no-migration petitions). These modifications would involve engineering and scientific evaluations, modeling, and public hearings.

3.c.iv Testing and monitoring

Class I non-hazardous industrial waste and hazardous waste disposal wells are subject to extensive testing and monitoring requirements established under federal regulations. Requirements for hazardous waste wells are more stringent than for non-hazardous industrial waste wells. Additionally, by law, states with primary enforcement authority for Class I wells may have more stringent testing and monitoring requirements. Class I monitoring and testing requirements are designed to ensure there are no leaks within or out of the well and that all injected fluid is contained in the injection zone.

Broadly, Class I well operators must:

- Analyze characteristics of injected fluids at a frequency that results in representative data.
- Continuously monitor and record injection pressure, annulus pressure, flow rate, and volume.
- Conduct internal and external mechanical integrity testing.
- Monitor for fluid release into the USDW within the area of review.

Class I hazardous waste wells operators must conduct mechanical integrity testing more often than Class I non-hazardous industrial waste operators. They also must establish and follow additional procedures for reporting and correcting mechanical integrity problems. Class I hazardous waste well operators must also develop and follow a waste analysis plan and conduct annual tests of cement at the base of the well (U.S. EPA, 2015).

Additional information on testing and monitoring requirements, including mechanical integrity testing, is included in EPA's summary document *Requirements for All Class I Wells and Class I Hazardous Waste Wells* and EPA Region 5's guidance on *Determination of the Mechanical Integrity of Injection Wells*.

Communicating testing and monitoring results with adjacent communities is particularly important given the high-profile nature of PFAS. The importance of encouraging dialogue with communities, especially communities that may be more vulnerable to PFAS exposures, cannot be overemphasized. Suggestions for risk communication are included in Section 4.

3.c.v Uncertainties/unknowns

The fate and transport of PFAS in the subsurface depends on the chemical and physical properties of specific PFAS and the geochemical properties of the injection zone. Understanding of the long-term fate and transport properties of PFAS (including precursors) in the injection zone is currently limited. Studies have shown wide ranges in PFAS properties, and these can be altered by mixture effects and interactions with co-contaminants. This creates uncertainty in predictions of PFAS contaminant release and longevity in the injection zone. These uncertainties need to be considered in the development of the required no-migration petition for disposal of PFAS in Class I hazardous waste wells.

When evaluating underground injection options, decision-makers (managers of PFAS-containing materials and PFAS-containing waste) should consider potential impacts to communities, including vulnerable populations. Underestimation of the potential for PFAS release could increase impacts to local communities, including vulnerable communities. EPA recommends that decision-makers screen

communities located in the vicinity of the destruction, disposal, and storage options in order to consider the potential for adverse, including any cumulative and disproportionate impacts (see Section 4), and potential measures to prevent, reduce, or address such impacts. Depending on site-specific circumstances (e.g., PFAS concentrations, impacted media, and potential exposure pathways), the size and shape of this area (vicinity) will vary.

3.c.vi Summary

EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high concentration liquid PFAS waste has a lower potential for environmental release when compared to other PFAS destruction and disposal options. Permitted underground injection of fluids through Class I non-hazardous industrial and hazardous waste wells ensures that injected fluids are confined and cannot enter USDWs—the pathway of concern for this waste disposal technology. Additional Class I wells may need to be constructed where geologically suitable, and existing well permits may need to be modified to meet the capacity needs for PFAS disposal. Research on the long-term fate and transport of PFAS (including precursors) to predict release potential in the injection zone could support future permits.

See Appendix D for a summary of costs and considerations.

4. Considerations for Potentially Vulnerable Populations Living Near Likely Destruction or Disposal Sites

The FY 2020 NDAA specifies that the interim guidance consider:

- The potential for releases of PFAS during destruction or disposal, including through volatilization, air dispersion, or leachate.
- Potentially vulnerable populations living near likely destruction or disposal sites.

This section describes potential releases and exposure pathways associated with destruction or disposal sites. It defines potentially vulnerable populations and provides interim guidance on considering vulnerable populations when assessing the potential impacts of releases. This section also suggests approaches to screen communities located in the vicinity of the destruction, disposal, and storage options in order to consider the potential for adverse and disproportionate impacts and potential measures to prevent, reduce, or address such impacts. Depending on site-specific circumstances (e.g., PFAS concentrations, impacted media, and potential exposure pathways), the size and shape of this area (vicinity) will vary. Focusing on impacts and potential ways to protect vulnerable populations, such as children who are more vulnerable than adults to chemicals like PFAS, will ensure the protection of all populations exposed to PFAS.

The primary audience of this interim guidance is managers of PFAS-containing materials and PFAS-containing waste and regulators who need to identify the most effective means for destroying or disposing of these materials, including to protect nearby communities who may include vulnerable populations. Others may find it useful, such as communities themselves, as well as community relations personnel, and the public. This section is not a primer on risk assessment and risk communication; rather, it contains pointers and references to existing information.

4.a Potential releases from destruction and disposal facilities

EPA develops regulations, guidance, and policies that ensure the safe management and cleanup of waste.[20] Nonetheless, it is possible for destruction or disposal activities to release PFAS.

For example, as described in Section 3.a.iii, thermal treatment activities could potentially release PFAS to the environment via stack emissions if adequate combustion conditions are not achieved or adequate pollution control devices are not used. Releases can also occur from the management of thermal treatment process residuals such as liquid discharges from acid gas scrubbers, air pollution control device media, and incinerator bottom ash. In addition, if uncontrolled, leachate can travel out of landfills (see Section 3.b.i) and into groundwater or surface water. Disposal of PFAS could also result in potential

[20] Information on EPA's actions to address PFAS can be found here: *https://www.epa.gov/pfas/key-epa-actions-address-pfas*

releases from increased transport, management, and handling of waste associated with all the available technologies.

Risk assessment and communication are important tools to help protect communities and the environment from potential releases of harmful substances. Tools from the risk assessment process may also be useful when considering whether a facility is an appropriate option for receiving PFAS-containing waste. Risk communication and community engagement are important for building trust and addressing concerns about potential releases. EPA has developed resources for assessing, managing, and communicating environmental risks, including interim guidance and tools available to stakeholders and the public. These resources are summarized in Section 4.c.

4.b Potentially vulnerable populations

To consider potential impacts on vulnerable populations in PFAS destruction and disposal decision contexts, it is helpful to keep in mind that vulnerability refers to characteristics of individuals or populations that place them at increased risk of an adverse health effect. Vulnerability includes the cumulative impacts of economic, demographic, social, cultural, psychological, and physical states of the individual person or population that influence patterns of exposure to environmental contaminants and alter the relationship between the exposure of the environmental agent and adverse health outcomes (U.S. EPA, 2019a).

Described in Guidelines for Exposure Assessment (U.S. EPA, 2019), EPA's Framework for Cumulative Risk Assessment (U.S. EPA 2003) describes four properties of vulnerability:

- Differential susceptibility: An increased likelihood of sustaining an adverse effect from exposure to an agent. For example, an individual, group, or population might be more likely to show a response to an agent at a lower dose than the general population because of a preexisting health condition (e.g., asthma, cardiovascular disease, disability), genetic variation, prior damage from exposure, concurrent exposures to other stressors or developmental or life stage [e.g., children, older adults, pregnant women]).
- Differential exposure: Differences in exposure (e.g., magnitude, duration, frequency, pathway, route) from a variety of factors, including life stage, socioeconomic status, and cultural characteristics. For example:
    - Children might have a higher exposure and proportionally higher body burden of pesticides than adults because of their behavior patterns or food consumption (Moya et al., 2004; NRC, 1993).
    - When neighborhoods are racially or economically segregated, low-income people and people of color might live in neighborhoods or conditions where pollution sources are more likely to be sited and concentrated and thus where they experience higher exposures to air pollution (Lopez, 2003).
    - Studies on fish consumption and subsistence fishing patterns have documented racial/ethnic differences that can increase exposure from persistent, bioaccumulative chemicals in fish or wildlife (Burger, 2000; Burger 2002a; Burger 2002b; Burger et al. 2001; Burger et al., 1999a; Burger et al., 1998; Burger et al., 1993; Burger et al., 1999b; Corburn, 2002).
    - Tribal Nations and Native Americans can be exposed differentially to toxicants when dietary patterns involve consumption of locally caught fish or game for traditional or religious reasons (Fitzgerald et al., 1999; Fitzgerald et al., 1995; Fitzgerald et al., 1998; Fitzgerald et al., 2001; Harper et al., 2002; Schell et al., 2003).

- Differential preparedness: The regulatory frameworks, protections, and resources that an individual, community or population uses or can access to withstand the insult of agents.
- Differential ability to recover: Refers to resources, repair, and resilience systems, such as income level, ability to move from an affected area or access to health care, which can affect recovery from the effects of an agent.

Communities with environmental justice concerns experience disproportionate and adverse human health or environmental burdens. These burdens may arise from a number of causes, including the cumulative impacts of inequitable access to clean water, clean air, natural places, and resources for other basic human health and environmental needs; the concentration of pollution, hazardous waste, and toxic exposures; and underinvestment in affordable housing that is safe and healthy and in basic infrastructure and services to support such housing, including safe drinking water and effective sewage management. The cumulative impacts of exposure to those types of burdens and other stressors, including those related to climate change and the environment, are also important indicators of vulnerable populations (Executive Order 14096, 2023).

The following sections provide examples of tools, methods, and approaches to identifying and considering vulnerable populations.

4.c Considering vulnerability

Executive Order (EO) 14096, "Revitalizing Our Nation's Commitment to Environmental Justice for All"" (issued by President Biden in April 2023), directs federal agencies to advance the goal of environmental justice, which means: "the just treatment and meaningful involvement of all people, regardless of income, race, color, national origin, Tribal affiliation, or disability, in agency decision-making and other federal activities that affect human health and the environment so that people:

(i) are fully protected from disproportionate and adverse human health and environmental effects (including risks) and hazards, including those related to climate change, the cumulative impacts of environmental and other burdens, and the legacy of racism or other structural or systemic barriers; and

(ii) have equitable access to a healthy, sustainable, and resilient environment in which to live, play, work, learn, grow, worship, and engage in cultural and subsistence practices."[21]

To advance this charge and apply the best available science on the vulnerability of exposure to children and other sensitive populations, EPA has developed tools, methods, and approaches to identify and assess the potential for adverse and disproportionate impacts, including risks, to potentially vulnerable populations, including communities with environmental justice concerns.

4.c.i Identifying potentially vulnerable populations

The consideration of potentially vulnerable populations living near likely PFAS destruction or disposal sites starts with identifying and characterizing adjacent and potentially exposed communities and populations. EPA provides the following tools to assist with this task:

[21] See EO 14096, section 2(b), 88 FR 25251 (2023). EO 14096 builds on and complements EO 12898, "Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations" (1994).

4.c.i.1 EJScreen

This EJ mapping and screening tool (*EJScreen*) provides EPA with a nationally consistent dataset and approach for combining environmental and demographic indicators. EJScreen users choose a geographic area; the tool then provides demographic and environmental information for that area. This is EPA's principal tool for characterizing and identifying communities with environmental justice concerns next to facilities or sources of pollution. Users can download reports that summarize search findings.

To summarize how environmental indicators and demographics come together in the same location, EJScreen 2.2 uses 13 EJ indexes that reflect the following 13 environmental indicators:

- Particulate Matter 2.5
- Ozone
- Diesel Particulate Matter
- Toxic Releases to Air
- Air Toxics Cancer Risk
- Air Toxics Respiratory Hazard Index
- Traffic Proximity
- Lead Paint
- Risk Management Plan (RMP) Facility Proximity
- Hazardous Waste Proximity
- Superfund Proximity
- Underground Storage Tanks (USTs) and Leaking USTs
- Wastewater Discharge.

The EJ Indexes combine environmental indicators with information about the low-income and racial and ethnic minority population in a Census block group. A Census block group is the smallest level of geography you can get basic demographic data for, such as total population by age, sex, and race (U.S. Census Bureau, 2023). For example, the EJ Index for traffic combines:

- The traffic indicator
- The low-income population
- The racial and ethnic minority population.

EJScreen presents results in terms of percentiles, allowing community comparisons with the rest of the state, an EPA Region, or the nation, and to identify which communities may be potentially overburdened.

Users can also look at the factors independently. In addition, EJScreen offers several more maps based on demographic and socioeconomic data (e.g., U.S. Census data, the American Community Survey) as well as indicators of other stressors, such as certain health indicators and access to medical care.

4.c.i.2 Enforcement Compliance and History Online (ECHO)

EPA's *Enforcement Compliance and History Online* (ECHO) website lets users search for facilities in communities to assess their compliance with environmental regulations that protect human health and the environment. Permit writers may consider susceptibility and vulnerability when establishing permit

conditions and ECHO is a useful tool to evaluate whether a facility is currently violating or has previously violated those conditions. Users access ECHO to:

- Search for facilities
- Investigate pollution sources
- Search for EPA enforcement cases
- Examine and create enforcement-related maps
- Analyze trends in compliance and enforcement data
- Identify facilities on or near Tribal land.

4.c.i.3 PFAS Analytic Tools

The *PFAS Analytic Tools* integrate 11 national datasets on PFAS into an interactive, web-based software. Users can filter data by PFAS or geographic area, explore application charts and maps, or download and open the files to explore the data. Information includes Clean Water Act discharges from permitted sources, a log of spills reported containing PFAS constituents, lists of facilities historically manufacturing and importing PFAS, federally owned locations where PFAS is being investigated, a history of known transfers of PFAS waste and how those wastes were managed, facilities that EPA knows is processing, releasing, and disposing of PFAS, PFAS detections in the environment (e.g., surface water, fish tissue), and drinking water testing results.[22] The data cover a broad list of PFAS and represent EPA's ongoing efforts to consolidate the growing amount of testing information that is available.

4.c.i.4 Private Domestic Well Map

EPA's *Private Drinking Water Wells* collection of online mapping tools provides information on drinking water providers and sources (including domestic [i.e., private] water wells and how many people are using them), as well as potential sources of contamination. Understanding the density and geospatial location of private domestic wells, and housing units relying on them, improves detection and response efforts.

EPA developed this mapping tool based on two methods to estimate private well density. The maps combine reported wells in 20 states with available well log data and the net housing unit method that is available in all 50 states for estimating domestic well use. The maps do not display the location of private wells. The value of this mapping tool is its identification of areas that may be vulnerable to groundwater contamination based on the presence of private wells. The source of contamination widget allows users to identify potential sources of contamination in defined locations.

[22] Information available to EPA is limited. For example, EPA has identified transfers of PFAS waste in EPA's eManifest system that tracks shipments of federally regulated hazardous wastes. Since PFAS are not currently regulated as hazardous waste, though, this information is not required to be reported – resulting in an incomplete picture of PFAS waste transfers in the United States. What EPA is able to identify in eManifest comes from querying free text fields where PFAS information is mentioned or a state has regulated PFAS as a hazardous waste and has established a state hazardous waste code. The tool also shows release and transfer information from the Toxics Release Inventory. However, the number of reporting facilities and reported recipient facilities has been low since the beginning of PFAS TRI Reporting likely associated with the *de minimis* exemption. A final rulemaking removing that exemption may lead to a more complete picture of releases and transfers in future reporting years. The PFAS Analytic Tools does not currently include information on PFAS destruction efficiency or efficacy.

4.c.i.5 Risk-Screening Environmental Indicators (RSEI) model

EPA's Risk-Screening Environmental Indicators (RSEI) model helps policy makers, researchers, and communities explore data on toxic chemicals being managed by industrial and federal facilities. RSEI incorporates information from the TRI on the amount of toxic chemicals released or transferred from facilities, together with factors such as the chemicals' fate and transport through the environment, each chemical's relative toxicity, and potential human exposure. RSEI model results can be used to help establish priorities for further investigation and to look at changes in potential human health impacts over time.

4.c.i.6 EnviroAtlas

EPA's *EnviroAtlas* highlights relationships between communities, land use, and environmental quality. The mapping functions help identify potential uses of land that, when combined with site contaminant data, may indicate possible exposure pathways. Such land use relationships can trigger deeper investigation into land uses to characterize relevant activities to inform site sampling and risk assessment.

The information gathered can be used to modify Conceptual Site Models, which are descriptions of contaminant sources, releases, transport pathways, and potential receptors. Accurate and complete Conceptual Site Models are required to ensure that samples are collected in appropriate media and risks are analyzed for potentially exposed receptors.

4.c.i.7 Climate and Economic Justice Screening Tool (CEJST)

The *Climate and Economic Justice Screening Tool* (CEJST) helps federal agencies identify disadvantaged communities geographically that are marginalized by underinvestment and overburdened by pollution. These communities are in Census tracts that are at or above the thresholds in one or more of eight categories of burden or are located on the lands of Federally Recognized Tribes.[23] The current version of the tool evaluates the likelihood of disadvantage based on climate change, energy, health, housing, legacy pollution, transportation, water and wastewater, and workforce development factors, each in combination with low-income or educational attainment status. The current version of the tool will be updated based on more feedback and research.

4.c.i.8 Centers for Disease Control and Prevention (CDC) EJ Dashboard

The Centers for Disease Control and Prevention (CDC) *EJ Dashboard* provides contextual public health messaging and allows users to evaluate several screening factors, including community characteristics, environmental exposures, health burden, and indexes. Assessments are based on ZIP code. and census tracts. Evaluating communities surrounding a facility may require the use of multiple ZIP codes and census tracts. Community characteristics include demographics and social vulnerability, as well as a description of the built environment (e.g., access to parks). The Social Vulnerability Index (SVI) uses U.S. Census data to determine the social vulnerability of every Census tract. Census tracts are subdivisions of counties for which the U.S. Census collects statistical data. The SVI ranks each tract across 15 social factors, including poverty, lack of vehicle access, and crowded housing, and groups them by theme.

[23] Census tracts that are completely surrounded by disadvantaged communities and are at or above the 50th percentile for low-income are also identified as disadvantaged by the CEJST.

The EJ Dashboard also provides more information on environmental exposures, health, and EJ. The Environmental Exposures tab presents environmental pollutant data, including water quality, age of housing, $PM_{2.5}$, and ozone. It also includes factors related to climate change. Under "Health Burden," users can examine health vulnerability based on access to health insurance and hospitals, disability, infant mortality, and percentage of low birth weights. The *Environmental Justice Index* is a calculation based on the combined rankings of the Environmental Burden Module, the Social Vulnerability Module, and the Health Vulnerability Module. The Environmental Justice Index represents a measure of cumulative impacts on human health and well-being.

4.c.i.9 Tribal Data

Tribal populations and Tribal lands can be identified in EJScreen, ECHO, PFAS Analytic Tools (U.S. EPA, 2023) or with Housing and Urban Development's Tribal Directory Assessment Tool (TDAT): *https://egis.hud.gov/TDAT/*. For example, by clicking on a specific state, the user can identify Bureau of Indian Affairs Tribal boundaries and areas along with environmental media and other mapping layers. In addition, all lands of Federally Recognized Tribes, including Alaska Native Villages, are identified as disadvantaged in the CEJST.

4.c.ii Screening strategies to support waste management decision-making

There is no singularly definitive way to screen for the presence of and potential impacts on vulnerable populations. However, combining information on demographics and environmental and enforcement compliance could provide a useful indication of already overburdened or potentially vulnerable populations to inform decision-making. To avoid adding to disproportionate impacts, decisions regarding the destruction/disposal of PFAS-containing materials should be supported by an evaluation of communities located in the vicinity of the destruction, disposal, and storage. For example, less preferred facilities could be identified as those having a history of significant Clean Air Act violations, in an area with poor air quality and a high percentage of low-income people with significant air-related health disparities (e.g., asthma, lung cancer). This type of screening-level analysis can be used to identify communities with adverse and disproportionate impacts so as not to further exacerbate those impacts. It could also trigger questions for the facility regarding additional strategies to reduce the release of PFAS and other substances into the surrounding environment, including additional health protection, mitigation, and monitoring measures needed.

EPA has created several tools that can be helpful for screening, as have other federal and state agencies. Each tool has strengths and limitations. Options and suggestions for conducting a screening are described below.

EPA's EJScreen (see Section 4.c.i.1) collates social and demographic information that provides insights into non-chemical stressors to communities and subpopulations. EJ screen provides data from the U.S. Census and the American Community Survey[24], as well as information on race, income, unemployment rate, limited English proficiency, educational attainment, and age. Users can drill down to learn about additional demographics, including population, health, housing, and other points of interest. These data can be particularly useful to characterize community resilience and limitations. EJScreen also has

[24] The American Community Survey is an ongoing survey that annually provides vital demographic information about the United States (*https://www.census.gov/programs-surveys/acs*). Data are updated annually as a 5-year average. EJScreen version 2.2 includes 2017-2021 ACS 5-year summary file data.

important information about existing pollution levels. It is most robust for air quality, although it does have information on releases to water via NPDES permits and other sources.

EJScreen also provides indicators on health disparities. Other sources on health include CDC's EJ Dashboard. States may include additional details on health burdens on their websites and tools.

Collectively, this information can provide a snapshot of communities with environmental justice concerns, allowing the user to flag communities that may be stressed due to multiple factors. Decision-makers, for example, could perform additional screening at destruction and disposal facilities with communities exceeding the 80th (or another appropriate) percentile in multiple indicators, and therefore more closely consider vulnerable populations while evaluating destruction, disposal, and storage facilities.

Regarding compliance, EPA's ECHO tool (see Section 4.c.i.1) provides enforcement and compliance data on specific candidate destruction and disposal facilities. A history of Clean Water Act violations, for example, could be an indicator of disproportionately exposed communities, particularly if they rely on public water systems using a surface water source downstream of the facility. In addition, communities using private wells for drinking water may be more vulnerable to releases regulated under RCRA or CERCLA.

4.c.iii Considerations for community engagement

In certain cases, community engagement is required under law. For example, facilities must hold public meetings before submitting part B RCRA permit applications (U.S. EPA, 2013a) and public hearings if they are requested for CAA Title V permits. In some cases, EPA's policy is to consult and coordinate with Tribes (U.S. EPA, 2013b). Community engagement is not merely a matter of meeting requirements, though. Advancing the goal of meaningful involvement is a core principle under EO 14096[25]. Reaching out to the community and providing notification, information, and an opportunity for input before deciding whether to accept PFAS-containing waste for destruction or disposal will help build trust and support for operations and can reduce the likelihood of negative reactions stemming from unresolved concerns.

In certain cases, community engagement is required under law. For example, facilities must hold public meetings before submitting part B RCRA permit applications (U.S. EPA, 2013a), where public hearings are requested for CAA Title V permits, and in some cases EPA's policy is to consult and coordinate with Tribes (U.S. EPA, 2013b). Community engagement is not merely a matter of meeting requirements, though. Advancing the goal of meaningful involvement is a core principle under EO 14096. Reaching out to the community and providing notification, information, and an opportunity for input before deciding whether to accept PFAS-containing waste for destruction or disposal will help build trust and support for operations and can reduce the likelihood of negative reactions stemming from unresolved concerns.

Meaningful community engagement typically includes two key elements:

- Public outreach to disseminate relevant and accessible information to the community, including in relevant local languages and in formats accessible to individuals with disabilities.

[25] *https://www.federalregister.gov/documents/2023/04/26/2023-08955/revitalizing-our-nations-commitment-to-environmental-justice-for-all*

- Public participation, which generally entails a dialogue with the community to ascertain information and viewpoints. This dialogue is particularly important because the community can provide local knowledge of health and existing conditions, identify concerns and issues that may not be readily apparent outside the community, and offer contextual/cultural perceptions and experience (U.S. EPA, 2016).

Although presenting highly technical information is always a challenge, involving vulnerable populations in a meaningful way may present different challenges and opportunities from those in a general public involvement effort. To foster meaningful participation of all community members, it may be important to address issues that could hinder a community's participation in the decision-making process. These may include time and resource constraints, language barriers, and lack of trust (U.S. EPA, 2016).

Examples of effective practices to engage diverse and vulnerable populations include the following:

- Early notification so that community input can be offered in a timely way and incorporated into the decision-making process.
- Conveying issues in ways that are tailored (for example, translation, timing, location) to each specific population.
- Bridging cultural and economic differences that affect participation.
- Developing trust between the government and potentially affected populations.
- Working closely with state and local partners, as well as other federal agencies, to present a unified, consistent message to communities.
- Developing stakeholder capacity or providing technical assistance to effectively participate in future decision-making processes (U.S. EPA, 2015b).

EPA has developed tools to assist the federal government, states, and private entities with community engagement and outreach. For example, the *Superfund Community Involvement Toolkit* (CI Toolkit, available at *https://www.epa.gov/superfund/superfund-community-involvement-tools-and-resources*) provides practical information to design and enhance community involvement activities. While the CI Toolkit is designed for users to quickly review and adapt a variety of community involvement tools to engage the community during all stages of the Superfund processes, the same tools can be adapted to engage communities adjacent to destruction and disposal facilities.

5. Research Needs and Data Gaps for Destruction and Disposal Technologies

EPA has a better understanding of potential PFAS releases from destruction and disposal activities, but more research is needed. This section identifies high-priority data gaps that researchers across government, academia, and industry need to address. This additional research will help EPA provide meaningful updates on effective destruction and disposal practices for PFAS-containing materials. This section outlines research needs to inform future guidance updates and provides an overview of existing research activities to address these gaps.

5.a Research needs to inform future guidance updates

EPA has translated the uncertainties and data gaps identified throughout this interim guidance into research needs, which are presented in Table 5-1. The research needs in Table 5-1 are focused on advancing our ability to measure PFAS in materials and releases from destruction and disposal technologies and improving our understanding of the performance of thermal treatment units, landfills, and underground injection control wells for managing PFAS and PFAS-containing materials. Individually, the research needs identified in Table 5-1 are complex to address because of the variety of substances within the PFAS class, the range of PFAS-containing materials discussed in this interim guidance, and the variability in technology designs and operating conditions. Collectively, some of the research needs identified in Table 5-1 are dependent upon other research needs. For example, fully characterizing PFAS releases from destruction and disposal technologies is dependent upon the availability of methods for measuring PFAS in air, water, and solids. Because of the complexity of the research needs and their inter-dependence, EPA anticipates that it will take years for the research needs in Table 5-1 to be fully addressed.

EPA has also prioritized the research needs in Table 5-1 as either *high*, *medium*, or *low* based on the potential for results to inform future versions of this interim guidance. In general, EPA designated the characterization of potential PFAS releases from thermal treatment units and landfills as high priority because these data are essential for determining whether communities surrounding destruction and disposal sites could be exposed to PFAS at unreasonable levels from these facilities. At the same time, EPA recognizes that current laboratory methods for identifying and quantifying PFAS are limited. As such, the agency also considers the development of sampling and analytical methods to be medium or high priority. The agency does not, however, believe that characterizing PFAS releases from PFAS destruction and disposal activities should wait until additional analytical methods are available. Rather, EPA expects that characterizing PFAS releases from destruction and disposal sites will be iterative and that future characterization efforts will be informed and guided by past efforts and the availability of new methods.

EPA designated research needs associated with the underground injection of PFAS and PFAS-containing materials via Class I wells as a low priority. The agency made this designation because the standards associated with the construction, operation, and monitoring of Class I wells are designed to isolate liquid wastes deep below the land surface and ensure protection of underground sources of drinking water. As

a result, EPA expects underground injection of liquid PFAS waste to have a lower potential for environmental release, compared to managing PFAS wastes through thermal treatment or landfills. While data on the performance of Class I wells for managing liquid PFAS waste would be informative, the highest priority continues to be on characterizing PFAS releases from thermal treatment units and landfills.

Table 5-1. Prioritized Research Needs to Inform Future Guidance Updates

Topic	Research Needs	Priority
Thermal Treatment	Methods for sampling and analyzing PFAS in solid-, liquid-, and gas-phase waste streams from thermal treatment units[a]	
	• Organic fluorine (all phases)	Low
	• Targeted methods for non-polar, semivolatile PFAS (gas-phase)	High
	• Targeted methods for cationic, zwitterionic, and nonionic PFAS (solid- and liquid-phase)	High
	Full-scale performance testing—following the parameters and procedures suggested in Appendix A—at:	
	• Hazardous waste combustors	
	○ Commercial hazardous waste incinerators	High
	○ Hazardous-waste-burning cement kilns	High
	○ Hazardous-waste-burning lightweight aggregate kilns	Medium
	• Carbon regeneration and reactivation units	High
	• Non-hazardous waste combustors	
	○ Sewage sludge incinerators	High
	○ Municipal waste combustors	Medium
	○ Thermal oxidizers	High
	Characterization of PFAS releases from thermal treatment units operating under different conditions/designs	
	• Gas-phase emissions	High
	• Air pollution control device discharges	High
	• Bottom ash	High
	• Biosolids, remediated soil	High
Landfills	Methods for sampling and analyzing PFAS in liquid- and gas-phase waste streams from landfills[a]	
	• Organic fluorine (liquid- and gas-phase)	Medium
	• Targeted methods for non-polar, semivolatile PFAS (gas-phase)	Medium
	• Targeted methods for cationic, zwitterionic, and nonionic PFAS (liquid-phase)	Medium
	Approaches for solidification and stabilization of PFAS-containing materials[a]	
	• Effectiveness of differing solidification and stabilization techniques	High
	• Performance over time	High
	Fate and transport of PFAS—including partitioning between solid-, liquid-, and gas-phases in:[a]	
	• Hazardous waste landfills	High
	• Industrial waste landfills	High
	• Municipal solid waste landfills	Medium
	• Ash monofill landfills	Low
	• Construction and demolition (C&D) landfills	High
	Full-scale performance testing of engineered landfill components	
	• Bottom liner and leachate collection systems	Low
	• On-site leachate treatment systems	High

Topic	Research Needs	Priority
	• Gas collection and emission control systems • Final cover systems	Low Low
	Characterization of PFAS releases from landfills operating in different regions and under different conditions/designs • Gas-phase emissions • Groundwater contamination	 High High
	Efficacy and potential release of PFAS during leachate treatment • Conventional technologies • Emerging technologies	 High Medium
Underground Injection (Class I)	Performance data from wells that are managing PFAS-containing liquids • Surface management practices • Effects on injection performance	 Low Low
	Long-term fate and transport of PFAS in injection zones of Class I wells • Mixture effects • Interactions with co-contaminants	 Low Low
	Data on the presence/absence of PFAS in groundwater near Class I wells receiving PFAS-containing liquids	Low
Emerging Technologies	Lab-, pilot-, and field-scale research to test the effectiveness of emerging technologies for different PFAS-containing materials and to characterize the outputs for PFAS and non-PFAS constituents.[b]	High

[a.] EPA is conducting research on this topic. See Section 5.b.ii for a high-level overview of EPA research and development activities.

[b.] See Section 6 for discussion of emerging technologies. EPA encourages technology developers to generate and publicly release data that can be used to answer the questions presented in the technology evaluation framework in Section 6.b.

5.b Current research efforts to address data gaps

Addressing the research and data gaps described in Section 5.a will require effort across government, academic, and private institutions. This section provides an overview of resources to learn more about prospective research activities.

5.b.i Governmental, academic, and industry research activities

In late 2021, the Office of Science and Technology Policy (OSTP) formed the interagency PFAS Strategy Team as part of the National Science and Technology Council (NSTC) to coordinate federal research on PFAS. In early 2023, the PFAS Strategy Team published the *Per- and Polyfluoroalkyl Substances (PFAS) Report*. The PFAS Report provides a high-level overview of research on PFAS as a chemical class by addressing the following strategic areas: removal and destruction; safer alternatives; sources and pathways of exposure; and toxicity. This document is a state-of-the-science report that includes research activities, gaps, and opportunities for the federal government. Following release of the PFAS Report, the PFAS Strategy Team initiated efforts to develop a federal strategic plan to address data gaps

identified in the PFAS Report. Additional information is available in the *CEQ Report on Biden-Harris Administration Progress on PFAS* (March 2023).[26]

While this interim guidance only outlines major DoD and EPA research programs, a more complete overview of existing federal PFAS research activities is available in Appendix A of the OSTP PFAS Report. DoD is the largest federal funder of PFAS destruction and disposal research (see Appendix B, OSTP 2023). Within DoD, the Strategic Environmental Research and Development Program (SERDP) and the Environmental Security Technology Certification Program (ESTCP) have been funding significant research on PFAS for several years. The goals of this research include:

- Improving PFAS analytical methods and AFFF site characterization
- Understanding PFAS ecotoxicological effects
- Developing tools for assessing the fate of PFAS in the subsurface
- Developing and validating *in situ* and *ex situ* PFAS treatment technologies.

In 2022, SERDP-ESTCP published its *Summary Report: Strategic Workshop on Management of PFAS in the Environment* (Leeson et al., 2022). This report identifies research and demonstration needs for PFAS fate and transport, sampling and analysis, thermal treatment, non-thermal destructive treatments, and concentration technologies. To address these research needs, SERDP and ESTCP fund a robust research program, with annual solicitations for proposals. Descriptions of all PFAS-related statements of need and funded projects are available at *https://www.serdp-estcp.org/Featured-Initiatives/Per-and-Polyfluoroalkyl-Substances-PFASs*. Additionally, the Defense Innovation Unit has begun funding opportunities for innovation in technology for on-site PFAS destruction and remediation.

Colleges and universities, who are the recipients of federal and other research funding, conduct cutting-edge research related to PFAS destruction and disposal. These institutions often bring together expertise from many disciplines. This collaboration enables the rapid development of innovative approaches for managing the constantly changing set of PFAS-containing materials.

Other entities have strong interests in expanding into the area of PFAS material management, disposal, and destruction. These entities include private industry, the operators of waste disposal operations and technologies, municipal water utilities, professional and trade associations, and relevant research foundations. These organizations are actively developing and marketing solutions to address PFAS material management, disposal, and destruction.

5.b.ii EPA research and development activities

As described above, EPA is one of many governmental, academic, and industry organizations engaged in research on PFAS destruction and disposal. EPA's ORD is conducting research to characterize PFAS-contaminated sites and sources, and to understand the fundamental mechanisms of PFAS destruction and disposal technologies. This section provides a high-level overview of EPA research activities to support future interim guidance updates.

[26] See also White House Fact Sheet: Biden-Harris Administration Takes New Action to Protect Communities from PFAS Pollution (March 14, 2023): *https://www.whitehouse.gov/briefing-room/statements-releases/2023/03/14/fact-sheet-biden-harris-administration-takes-new-action-to-protect-communities-from-pfas-pollution/*.

5.b.ii.1 Characterizing PFAS-containing materials

EPA is developing laboratory-based aqueous leaching methods to characterize leaching behavior of organic constituents, including PFAS, from solid materials under a range of environmental conditions. These methods are based on existing SW-846 Leaching Environmental Assessment Framework (LEAF) methods for inorganic constituents of potential concern (U.S. EPA, 2023). The methods produce a source term (i.e., as a concentration or release rate). Screening-level or scenario-based assessments can use the source term to model transport in the subsurface environment (Garrabrants et al., 2021a and 2021b).

EPA is continuing to develop and validate robust analytical methods to detect and measure PFAS in aqueous, solid, and gas-phase samples. The data generated with these methods will improve the understanding of environmental fate and transport and help evaluate the effectiveness of various treatment and destruction technologies. The suite of PFAS analytical methods under development includes targeted methods validated for quantitative analysis of a wider range of target analytes and matrices; class-specific methods, such as adsorbable organic fluorine and the total oxidizable precursors assay, to screen for a range of PFAS precursors; and non-targeted analytical methods to identify novel PFAS.

5.b.ii.2 Thermal treatment

ORD continues to conduct laboratory- and pilot-scale research to describe the behavior and mechanisms of destruction of PFAS-containing materials subject to thermal treatment. ORD facilities include a pilot-scale incinerator (the Rainbow furnace) and rotary kiln. This research examines the operating conditions (time, temperature, and combustion parameters) necessary for adequate PFAS destruction using conventional thermal treatment. The goal is to develop a mechanistic understanding of PFAS behavior and help interpret results from full-scale field studies. This includes measuring the generation of PICs from different PFAS-containing materials.

ORD is also interested in opportunities to partner with thermal treatment facilities to conduct field-scale research. The goals of this research would be to determine if representative field conditions achieve adequate thermal destruction of PFAS as defined by conventional DRE; characterize potential PICs/PIDs; and evaluate alternate indicators of destruction performance. The details of this thermal treatment field testing request are outlined in Appendix A.

5.b.ii.3 Landfills

ORD is developing novel sampling and modeling approaches to identify PFAS and characterize fate and transport at contaminated sites and source areas, including landfills. ORD is also evaluating solidification and stabilization techniques for PFAS applications.

5.b.ii.4 Extramural research

EPA supports PFAS research and development efforts through several programs, including *research grants*, the *Small Business Innovation Research* (SBIR) program, *challenges and prizes*, and the *P3 Student Design Competition*. For example:

- In 2019, *EPA awarded grants to eight universities* to better understand the environmental risks posed by PFAS and identify practical approaches to manage their potential environmental impacts. Several of these projects focused on characterizing PFAS in landfills. Research

completed under these projects contributed to EPA's improved understanding of the potential for PFAS releases from landfills.

- In 2021, EPA collaborated on the *Innovative Ways to Destroy PFAS* challenge. Partners included SERDP-ESTCP, the Environmental Council of States and the Environmental Research Institute of the States, the Michigan Department of Environment, Great Lakes and Energy, and the Colorado Department of Public Health and Environment. The goal of the challenge was to discover new technologies and approaches that have the potential to remove at least 99 percent of PFAS in unused AFFF without creating harmful byproducts.
- EPA's SBIR program has funded many small businesses developing technologies to test and treat PFAS. These companies are developing products to destroy PFAS in a range of media using technologies including plasma reactors, electrochemical processes, sonolysis, hydrothermal alkaline treatment, and mechanochemical destruction. More information on technologies funded by EPA's SBIR program is available at *https://www.epa.gov/sbir/test-and-treat-pfas-epa-sbir-technologies*.

Information on open solicitations can be found at *https://www.epa.gov/chemical-research/pfas-research-extramural-funding-opportunities*.

6. Emerging Technologies for PFAS Destruction and Disposal

Because of their chemical and physical properties, PFAS can pose unique challenges for end-of-life materials management. As described in Section 3, the effectiveness of commonly used waste management technologies, such as thermal treatment and landfilling, for managing PFAS materials can vary. Additionally, current operating conditions and practices at some thermal treatment facilities and landfills may not be sufficient to limit releases of PFAS to the environment. Concerns about the effectiveness of widely-used technologies for managing PFAS materials call for innovative research and development efforts toward new technologies as well as testing to apply existing destruction technologies to PFAS materials at various scales.

Development of new technologies typically involves the following stages:

- Technology development often starts with exploring and understanding the basic scientific principles and processes that underly the technology. At this early stage, the primary focus is on gaining understanding of how the process works and whether it shows promise for a particular application (e.g., PFAS destruction).
- If the results of early experiments are promising, the next stage of development generally focuses on prototype development and testing under controlled conditions. This stage allows developers to better understand whether the technology is practical and effective at larger scales. It also provides developers with information on costs associated with manufacturing and operating units.
- In the final stage of development, the focus generally shifts to field-scale demonstration projects that allow developers to test the technology under a variety of real-world conditions and to develop better cost estimates for operation and maintenance. During this stage, developers may identify the best and most cost-effective applications for the technology. In the case of PFAS destruction and disposal, this may include identifying the types of PFAS materials best suited for the technology (e.g., high-concentration materials versus low-concentration materials).

At any stage of the technology development process, developers may determine that the technology is not effective or is not cost-effective and development can stop.

In addition to research to identify and develop novel technologies for PFAS destruction, efforts are underway to apply existing destruction technologies—other than thermal treatment—to PFAS materials. In these cases, the scientific principles and processes underlying a technology may already be understood, but there is little information on the performance of the technology or its applicability to PFAS materials. Evaluating the applicability of an existing technology to PFAS materials can occur at various scales:

- Laboratory- and pilot-scale studies can be used to evaluate the effectiveness of a technology under controlled conditions and to determine how operating conditions can affect PFAS destruction.
- Field studies can provide data from full-scale applications that reflect the variability seen in real-world operating conditions.

The purpose of this section is to: (1) provide an overview of EPA efforts to identify and test emerging technologies for PFAS destruction and (2) introduce the PFAS destruction and disposal technology evaluation framework, which provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS materials.

6.a EPA's PFAS Innovative Treatment Team

EPA's ORD initiated the PFAS Innovative Treatment Team (PITT) in 2020 as a short-term dedicated, cross-ORD effort to identify, review, and conduct preliminary research on potential treatment technologies. Over six months, the multi-disciplinary PITT conducted state-of-the-science reviews of proposed methods to dispose and/or destroy PFAS in media and wastes. Several criteria were evaluated using available information, including efficacy, feasibility, performance, and costs of each technology, while also considering potentially hazardous byproducts. The PITT partnered with other agencies and states to conduct a competitive public challenge to identify solutions that were potentially overlooked and to encourage further development of potential technologies.

The PITT chose to focus on the effectiveness of four technologies: mechanochemical degradation, electrochemical oxidation, gasification and pyrolysis, and supercritical water oxidation. These four technologies showed theoretical promise of the sought-after criteria: PFAS destruction, production of few to no hazardous residuals or byproducts, commercial availability, and cost effectiveness for various contaminated matrices. References and discussion for each technology can be accessed in the four PITT Research Briefs at *https://www.epa.gov/chemical-research/pfas-innovative-treatment-team-pitt*. The identification of these technologies by the PITT should not be considered an endorsement or recommendation to use these technologies to destroy PFAS. Additional research is needed to determine the effectiveness of these technologies for different PFAS-containing materials and to characterize the outputs for PFAS and non-PFAS constituents. An overview of the results of the PITT's state-of-the-science review is available in *Developing Innovative Treatment Technologies for PFAS-Containing Wastes* (Berg et al., 2022).

After the state-of-the-science reviews, the PITT selectively encouraged development and research of the four chosen emerging technologies to better understand the potential for PFAS destruction, specifically AFFF, while avoiding creation or transfer of environmental hazards. The PITT conducted in-house research and partnered with industry and academia to collect data regarding the technologies and to encourage further development of the methods required to ascertain PFAS destruction efficacy. Although the effort originally was allotted six months in 2020, the work initiated by the PITT continues to produce journal articles, fact sheets, and ORD reports. Some of the results from this continued work are described below. When considering the timeline, including navigating the initial restrictions of the COVID-19 pandemic, note there were several hurdles to obtaining necessary data, such as limited access to industrial field sites, analytical methods development, and availability of standards.

6.a.i PITT-investigated emerging technologies

To further explore the potential for mechanochemical degradation of PFAS, ORD scientists partnered with colleagues in New Zealand to conduct a proof-of-concept case study using a benchtop ball mill, AFFF-spiked sand, and AFFF-contaminated soil (Gobindlal et al., 2023). Mechanochemical degradation is a treatment technology that uses a high-energy ball-milling device, with the option of co-milling reagents, to produce highly reactive conditions to degrade contaminants. Results from the AFFF-spiked sand showed a 99.99% destruction efficiency for the sum of all measured PFAS after 960 min, and results from the AFFF-contaminated soil indicate that measured PFAS were below the limit of detection

after 1440 min. Because this study analyzed PFAS in the solids after different ball milling time intervals, from 15 to 1440 min, the authors were able to identify increases in some of the measured PFAS before concentrations decreased, indicating the transformation of PFAS during ball milling. An extractable organic fluorine method was also used to determine the reduction in extractable organic fluorine before and after ball milling. In the case of AFFF-spiked sand, the authors reported a 97.8% reduction in extractable organic fluorine. A 53.5% reduction in extractable organic fluorine was reported for the AFFF-contaminated soil. Air emissions were not characterized as part of this study, making it difficult to determine whether full mineralization of PFAS occurred, and more work is needed in this regard. As noted in the study, more work is also needed to identify primary operations variables to inform the scalability of mechanochemical destruction.

In 2020, ORD conducted a pilot study at a biosolids treatment facility using pyrolysis (Thoma et al., 2022). Pyrolysis is a process that decomposes materials at moderately elevated temperatures in an oxygen-free environment. During the pilot study, dried biosolids were fed into a pyrolysis reactor operating at approximately 610 °C (1100 °F). The dried biosolids and the resulting biochar were sampled and tested for 41 target PFAS. Twenty-one PFAS were detected in the input biosolids, and none of the target PFAS were detected in the biochar. The pyrolysis system's target PFAS removal efficiencies were estimated to range between >81.3% and >99.9%. The pilot study also included limited analysis of the air emission control system, with results indicating no transmission of the target PFAS to the air. It is important to note, however, that full characterization of PFAS using non-targeted methods was not performed and more work is needed to understand PFAS transformations and the destruction mechanism.

ORD also completed studies to test the effectiveness of supercritical water oxidation for treating AFFF. Supercritical water oxidation is a process that occurs when the temperature and pressure of water is above the critical point. Above the critical point, oxidation processes are accelerated. In 2020, ORD partnered with three companies to perform tests of their supercritical water oxidation systems on dilute, PFOS-based AFFF (Krause et al., 2022). During these demonstration tests, each system was operated under slightly different conditions, and each company analyzed samples of the influent and effluent for slightly different PFAS. The overall destruction efficiency of each system was calculated by summing the concentrations of the measured PFAS. In all cases, the overall destruction efficiency was found to be greater than 99%. It is important to note, however, that the sum of the PFAS measured in the effluent ranged from approximately 10 µg/L to approximately 100 µg/L, suggesting that further treatment of the effluent may be necessary. It is also important to note that non-targeted analysis was not conducted, and air emissions were not monitored, making it difficult to assess the fate, transport, and transformation of PFAS with the supercritical water oxidation systems.

In 2021, ORD also partnered with a company to conduct tests at industrial-scale supercritical water oxidation system (Sahle-Demessie et al., 2022). These tests used a dilute, FTS-based AFFF. The primary objective of the study was to determine the destruction efficacy of the PFAS in the input material. Analysis of the influent and effluent showed greater than 99.99% destruction of the total PFAS measured. The average sum of the targeted PFAS in the effluent was approximately 55 µg/L, but PFAS were also detected in the tap water used as quench water in the system, suggesting that the overall performance of the system could be improved if non-PFAS-contaminated water is used in the system. A secondary objective of the study was to characterize degradation products using non-targeted analysis and stack sampling for nonpolar volatile fluorochemicals. Non-targeted analysis of the effluent tentatively identified the shorter carbon-chain PFAS on the targeted analyte list, and the authors suggested a possible destruction mechanism that would be consistent with this result. Further work is

needed, however, to determine the destruction mechanism. The air emissions sampling did not detect targeted PFAS in air emissions above background levels; further work with finalized air methods (e.g., OTM-50) is needed to confirm this observation.

At this time, EPA is neither recommending nor discouraging the use of any emerging technology for managing PFAS-containing materials, including the technologies studied by the PITT. While the PITT studies generally indicated potential for PFAS destruction, further work using newly available methods is needed to more fully characterize the outputs of these processes and to evaluate their performance for PFAS-containing materials beyond AFFF.

6.b PFAS Destruction and Disposal Technology Evaluation Framework

Researchers have proposed metrics to evaluate PFAS destruction and disposal technologies, including technology readiness levels (TRLs), DREs of target compounds, fluorine mass balances, and others (Berg et al., 2022; Deeb et al., 2021; Krause et al., 2021). When used individually, these metrics fail to accurately capture comprehensive system performance or provide a holistic understanding of the potential for PFAS transformation and/or release to the environment. For example, DREs calculated from targeted analyses using existing methods can result in underreporting of the total PFAS in a matrix. That's because existing detection methods can only measure a fraction (e.g., 50 individual PFAS) of the total number of PFAS that may be present in a sample. Similarly, TRLs can fail to accurately reflect the current development stage of a technology by either reporting the overall maturity of the technology, instead of its specific PFAS application, or by relying on a niche, small-scale application to justify an overall readiness level.

These limitations drive the need for a comprehensive framework for evaluating a technology and its application to PFAS-containing materials. Such a framework should allow the user to prioritize the collection and consideration of different pieces of information. To meet these needs, EPA developed a technology evaluation framework that uses a multiple-lines-of-evidence approach to evaluate a technology/PFAS material combination (Table 6-1). The framework provides a transparent approach for evaluating and selecting a technology to reduce PFAS releases to the environment. EPA recommends that managers of PFAS-containing materials use the framework to evaluate emerging technologies, and to inform decisions about destruction and disposal of PFAS-containing materials.[27] EPA encourages technology developers to generate and publicly release data that can be used to answer the questions presented in the framework.

The framework comprises several topical sections: technology, material, analytical methods, disposal/destruction efficacy, community considerations, and regulatory requirements. Within each section, EPA has identified key pieces of information that, when considered together, provide a more holistic evaluation of a technology and its applicability for PFAS disposal or destruction.

The framework is intended to be an adaptable tool that allows the user to prioritize the collection and consideration of different pieces of information via the "priority" column in the framework. This allows users to address questions most relevant to their priorities and with respect to their decision context

[27] The Interstate Technology and Regulatory Council (ITRC) PFAS Team developed the *PFAS Technical and Regulatory Guidance Document* (available at *https://pfas-1.itrcweb.org/*) to support state and federal environmental staff, as well as others, to gain a working knowledge of the current state of PFAS science and practice. Section 12 of the guidance document provides information on PFAS treatment technologies, including destruction technologies. Managers of PFAS-containing materials may find this resource useful when completing Table 6-1.

and the shared priority of preventing and mitigating potential exposures. Users may also choose to prioritize addressing certain questions before others to streamline their evaluation of a technology/material combination. For example, if a user of the framework is evaluating the performance of a destruction technology, the questions in the disposal efficacy section of the framework are not needed and could be removed from the framework. As another example, a user may prioritize answering questions under the technology section of the framework because those questions may rule out a technology for a particular application (e.g., the technology may not be available at the scale needed to process the PFAS-containing material of interest). Once a technology is ruled out, lower priority questions do not need to be answered. While users may not answer each question in the framework, EPA encourages users of the framework to address as many questions as possible to inform decisions about the destruction and disposal of PFAS materials.

Table 6-1 shows this approach, followed by more detailed considerations for each question.

Table 6-1. Framework for Evaluating Destruction/Disposal Technologies for PFAS-Containing Materials

Category of Information	Key Questions	Priority[a]	Answer and Associated Notes for PFAS Material of Interest
Technology	If available, what is the TRL for the technology/material combination of interest?		
	Is the technology of interest available at the scale needed for the intended application?		
	Is a treatment train needed to meet the desired destruction/disposal outcome?		
Material	What PFAS-containing material has been used to test the performance of the technology of interest?		
	Which PFAS, and at what concentration ranges, have been used to test the performance of the technology of interest?		
	Are there non-PFAS constituents that may affect the performance of the technology of interest?		
Analytical methods	Which targeted analytical methods (e.g., OTM-45, draft EPA Method 1633) have been used to characterize the performance of the technology for the PFAS-containing material of interest?		
	Has non-targeted analysis been performed on waste streams from the technology/material combination of interest?		
	What other analytical approaches have been used to characterize the performance of the technology for the PFAS-containing material of interest?		
	Are there any concerns about the quality of the data generated during testing?		
Disposal efficacy	Have potential transformation and partitioning pathways been identified for the technology/material combination of interest?		
	Are engineering controls in place to prevent or minimize release of PFAS to the environment?		

Category of Information	Key Questions	Priority[a]	Answer and Associated Notes for PFAS Material of Interest
	What is the longevity of the disposal technology?		
	Has a fluorine mass balance been determined?		
	Does the disposal of the PFAS-containing material contribute to the potential release of non-PFAS constituents to the environment?		
Destruction efficacy	Is the mechanism of destruction understood?		
	Have all process inputs and outputs been characterized for PFAS to the extent possible given current analytical methods?		
	What is the reported destruction efficiency?		
	Have any PIDs (or PICs) been identified?		
	Has a fluorine mass balance been determined?		
	Have all process outputs been characterized for non-PFAS constituents to the extent possible given current analytical methods and understanding of the composition of the PFAS-containing material?		
Community Considerations	Has a destruction/disposal site been identified?		
	What are the characteristics of the surrounding community?		
	Are there potentially vulnerable populations and/or communities with environmental justice concerns near the destruction/disposal site?		
	Are PFAS releases anticipated from the technology/material combination of interest?		
	Has the surrounding community been engaged?		
Regulatory requirements	Are there state or federal regulations that control emissions or releases from the technology of interest?		
	Are there state or federal regulations that control the management of the PFAS-containing material of interest?		

[a] Users can prioritize key questions using a variety of approaches. For example, questions could be labeled as *high, medium*, or *low* priority. Questions could also be prioritized using a numerical ranking system with *1* indicating questions to answer first, *2* indicating questions to answer second, and so forth.

6.b.i Key questions for technology evaluation

Technology. The first section of the framework focuses on the destruction or disposal technology. Key questions include:

- **If available, what is the TRL for the technology/material combination of interest?** TRLs are generally assigned using the *definitions developed by NASA* (NASA, 2023), where level 1 corresponds to observation and reporting of basic scientific principles and level 9 corresponds to "flight proven"

technologies. TRLs may be determined through technology readiness assessments[28] or through other methods. If other methods are used, EPA recommends that users consider the source of reported TRLs and prioritize TRLs determined through independent technology readiness assessments over TRLs assigned by the technology developer.

- **Is the technology of interest available at the scale needed for the intended application?** Some technologies may only be available as mobile, containerized units, which may be suitable for high-concentration, low-volume materials. These units may not be appropriate for low-concentration, high-volume materials, where a stationary treatment unit with greater capacity is needed.
- **Is a treatment train needed to meet the desired destruction/disposal outcome?** If so, describe the treatment train needed and whether such technology is available and effective for the PFAS-containing material of interest. Note that treatment trains may produce materials that will also need to be managed.

Material. The second section of the framework focuses on the PFAS-containing material of interest. The six types of PFAS-containing materials discussed in this interim guidance vary in terms of phase, PFAS composition and concentration, physical and chemical properties, and overall composition (e.g., the presence of other contaminants). To understand technology performance across the range of variations within a material type, the following key questions should be addressed:

- **What PFAS-containing material has been used to test the performance of the technology of interest?** The description of the material(s) used to evaluate a technology/material combination of interest should be specific as possible (e.g., 3M Litewater versus AFFF), and links to bulk material characterization should be included, if available. If the material evaluated is artificially contaminated (i.e., spiked with known PFAS species and concentrations), that should be noted because it may not be an accurate reflection of the performance of the technology for the intended application.
- **Which PFAS, and at what concentration ranges, have been used to test the performance of the technology of interest?** To best inform decisions on technology use, the PFAS and concentrations used to test performance should match the PFAS and concentrations anticipated for the intended application.
- **Are there non-PFAS constituents that may affect the performance of the technology of interest?** This could include constituents in the original PFAS-containing material or constituents that may be created or introduced during a treatment train or by the technology of interest. For example, hydrofluoric gas may be produced during PFAS destruction, which may cause corrosion.

Analytical methods. PFAS are a large class of substances, and there are various approaches for identifying and measuring PFAS. EPA recommends using a combination of approaches to characterize the performance of the technology for the PFAS-containing material of interest, including characterizing PFAS in emissions or waste streams from the technology of interest. Key questions to be addressed under this section include:

- **Which targeted analytical methods (e.g., OTM-45, draft EPA Method 1633) have been used to characterize the performance of the technology for the PFAS-containing material of interest?** When possible, EPA recommends the use of standardized and/or validated methods for targeted analysis.

[28] See the *Technology Readiness Assessment Guide* for best practices for evaluating technology maturity. The guide, developed by the U.S. Government Accountability Office and released in January 2020, provides organizations with best practices for conducting high-quality assessments.

- **Has non-targeted analysis been performed on waste streams from the technology/material combination of interest?** Non-targeted analysis is an important tool for characterizing PFAS in waste streams from a technology/material combination of interest because it can tentatively identify PFAS beyond those measured using targeted analytical methods.
- **What other analytical approaches have been used to characterize the performance of the technology for the PFAS-containing material of interest**? Other analytical approaches may include total oxidizable precursor assays and total organic fluorine assays for PFAS and analysis for non-PFAS substances (e.g., HF).
- **Are there any concerns about the quality of the data generated during testing?** For any quality assurance/quality control concerns identified, the user should determine whether it is appropriate to use the data to inform decisions about destruction and disposal of the PFAS-containing material using the technology of interest.

Disposal efficacy. Effective disposal of PFAS-containing material should prevent or minimize re-release of PFAS to the environment. Key questions for evaluating the efficacy of a disposal technology for a particular PFAS-containing material are identified below. (Questions included in this section should be skipped when evaluating a destruction technology.)

- **Have potential transformation and partitioning pathways been identified for the technology/material combination of interest?** The fate and transport of PFAS within a disposal technology can help inform whether PFAS may be present in emissions or releases from the technology. Note that the characteristics of the receiving matrix and environmental conditions can affect the fate and transport of PFAS within the disposal technology.
- **Are engineering controls in place to prevent or minimize release of PFAS to the environment?** If so, is there a monitoring system in place to evaluate the performance of the engineering controls?
- **What is the longevity of the disposal technology?** Because of the strength of the carbon–fluorine bond, PFAS are persistent. It is important to consider the lifespan of the disposal technology and whether the technology can contain PFAS for very long timeframes.
- **Has a fluorine mass balance been determined?** If so, is there fluorine that is unaccounted for? In some cases, a fluorine mass balance may be impractical.
- **Does the disposal of the PFAS-containing material contribute to the potential release of non-PFAS constituents to the environment?** PFAS-containing materials may contain other, non-PFAS constituents. Depending on the identity of those constituents and their potential to impact human health and the environment, it may be important to consider whether appropriate engineering controls are in place to prevent or minimize releases of non-PFAS constituents.

Destruction efficacy. Destruction of PFAS should result in breaking carbon–fluorine bonds without reforming PFAS and releasing PFAS to the environment. Key questions for evaluating the efficacy of a destruction technology for a particular PFAS-containing material are identified below. (Questions included in this section should be skipped when evaluating a disposal technology.)

- **Is the mechanism of destruction understood?** If so, has the destruction mechanism been experimentally confirmed, and have the reaction kinetics been determined? A thorough understanding of the destruction mechanism improves confidence in the performance of the technology of interest for PFAS.
- **Have all process inputs and outputs been characterized for PFAS to the extent possible given current analytical methods?** If not, what information may be missing?

- **What is the reported destruction efficiency?** Destruction efficiencies (or DREs) are generally reported for specific PFAS (e.g., PFOA or PFOS). As noted earlier, the destruction efficiency (or DRE) alone may not be sufficient to determine whether other PFAS may be released to the environment during the destruction process.
- **Have any PIDs (or PICs) been identified?** If so, which PFAS have been detected and at what levels? Are those PFAS regularly detected for this technology/material combination?
- **Has a fluorine mass balance been determined?** If so, is there fluorine that is unaccounted for? In some cases, a fluorine mass balance may be impractical.
- **Have all process outputs been characterized for non-PFAS constituents to the extent possible given current analytical methods and understanding of the composition of the PFAS-containing material?** The destruction of PFAS-containing materials is expected to result in non-PFAS products. Depending on the identify of those products and their potential to impact human health and the environment, it may be important to consider whether appropriate engineering controls are in place to prevent or minimize releases of non-PFAS constituents. It may also be important to consider the effect of the destruction process on non-PFAS constituents in the PFAS-containing material of interest. Thus, the characterization of process outputs beyond PFAS may be warranted.

Community considerations. When considering destruction and disposal technologies for PFAS-containing materials, it is important to consider the community that may be exposed to potential PFAS releases from intended destruction or disposal. Key questions to consider include:

- **Has a destruction/disposal site been identified?** Some destruction technologies may be mobile, allowing for treatment and destruction to occur where PFAS-containing materials are generated or stored. Other technologies may be stationary, requiring PFAS-containing materials to be brought on site for destruction or disposal. The use of mobile technologies may allow flexibility in siting to avoid potential impacts on overburdened and vulnerable communities.
- **What are the characteristics of the surrounding community?** See Section 4 for tools and approaches that can be used to characterize communities near destruction/disposal sites.
- **Are there potentially vulnerable populations and/or communities with environmental justice concerns near the destruction/disposal site?** Section 4 provides tools and strategies that can be used to screen nearby communities for potentially vulnerable populations and/or communities with environmental justice concerns.
- **Are PFAS releases anticipated from the technology/material combination of interest?** If so, describe which PFAS may be released, at what levels, and over what duration. Also note whether there are controls in place to mitigate releases to avoid or minimize potential impacts to surrounding communities.
- **Has the surrounding community been engaged**? Sharing information about planned destruction or disposal activities for PFAS-containing materials allows community members to take actions to address concerns they may have. There may also be opportunities to collaborate with government officials and community leaders on engagement activities.

Regulatory requirements. Regulations regarding the destruction or disposal of PFAS-containing materials can vary from state to state and may change over time. Key questions to consider include:

- **Are there state or federal regulations that control emissions or releases from the technology of interest?** Such regulations may limit the amount of PFAS or other pollutants present in emissions or other releases from the technology of interest.

- **Are there state or federal regulations that control the management of the PFAS-containing material of interest?** Such regulations may specify or restrict destruction or disposal options for the PFAS-containing material of interest.

Appendix A: EPA Guidance to Conduct PFAS Emissions Field Testing at Commercial Thermal Destruction Sources

The U.S. Environmental Protection Agency (EPA) Office of Research and Development (ORD) is conducting per- and polyfluoroalkyl substances (PFAS) thermal destruction emissions characterization research to improve our understanding of the behavior of PFAS with respect to waste incineration and thermal treatment (e.g., hazardous waste, municipal waste, biosolids, contaminated soils, spent media), as well as thermal destruction emissions control technologies (e.g., afterburners, thermal and catalytic oxidizers). The following could be used by any entity evaluating thermal treatment of PFAS-containing materials either in collaboration with EPA or independently.

Overall goals of the field tests are as follows:

- Confirm/determine if thermal treatment under representative conditions can result in the thermal destruction of PFAS as defined by conventional destruction and removal efficiency (DRE) testing.
- Characterize potential products of incomplete combustion/destruction (PICs/PIDs) and evaluate the use of alternative, or surrogate, indicators of destruction performance.
- Confirm that any treated material is appropriate for any defined beneficial reuse (e.g., treated soils, reactivated granular activated carbon [GAC]).

To achieve these goals, it is necessary to determine the specific conditions (i.e., temperature, residence time, and turbulence) required to maximize DREs, minimize PICs/PIDs, and produce products appropriate for beneficial reuse. Because bench- and pilot-scale testing have limitations, actual test data under full-scale thermal treatment conditions are necessary to determine if representative thermal processes can achieve these goals.

Sampling Details:

- EPA is available to collaborate with the host site on the technical approach for source characterization. Testing would require multiple stack sampling methodologies performed by commercial stack testing companies, including the host's regular tester, if desired.
- All gas, liquid, and solid inlet, intermediate, and outlet streams will be collected and analyzed. This includes:
    - At the stack and including all air pollution control devices
    - All inlet streams (e.g., materials to be thermally treated, air or gas inlets, water), including samples taken prior to testing
    - All residual streams (e.g., bottom ash, baghouse and/or electrostatic precipitator [ESP] solids, scrubber effluent, spent carbon)
    - All final products (e.g., reactivated carbon, soils), if applicable
- A comprehensive air emission source characterization would include:
    - Samples would be collected for semivolatile PFAS, using method OTM-45 targeted (known) PFAS, or method established endpoints. Samples would be collected for volatile PFAS, using

method OTM-50 and analyzed for targeted (known) PFAS in samples and the identification of unknown detected volatile fluorocarbons.

- Samples would be collected for other semivolatile target compounds using methods SW-846 Methods 0010/3542/8270 with the inclusion of the Method 8270 procedure. Carbon hexafluoride (C_2F_6) and carbon tetrafluoride (CF_4) could be injected during one day of testing, ideally at multiple injection locations, as a surrogate measure of destruction efficiency if appropriate and permitted.
- Tests would be run under a single, representative process condition including the waste that would be co-fired with PFAS-containing material.
- EPA would prioritize testing several PFAS-containing materials, including but not limited to:
  - Incineration of aqueous film forming foam (AFFF)
  - Incineration of wastewater sludges
  - Reactivation of spent GAC
  - Incineration of municipal solid waste
  - Thermal treatment of contaminated soils
  - Incineration of spent ion exchange resins and their concentrated regeneration liquids
- All sampling would be conducted under a well-documented sampling plan and quality assurance project plan.
- Final testing results would be shared with EPA, the state, local authorities.

Additional details on emission testing approaches can be provided upon request.

Supplemental Information

Emissions sampling and analytical approaches

Emissions samples would be collected for polar, nonpolar, volatile, and semivolatile PFAS compounds and analyzed for both targeted PFAS compounds, or method established endpoints.

EPA's Other Test Method (OTM) 45 would be used to collect polar semivolatile PFAS compounds for targeted analyses. The method's 50+ target analytes include many PFAS commonly found in AFFF. This would enable DE, DRE, and emission rate determination as appropriate for a known list of PFAS compounds.

The OTM-50 canister sampling method would be used to collect nonpolar volatile PFAS compounds for targeted compound analyses. The current target list includes CF_4 and C_2F_6 as well as a procedure to identify unknown volatile fluorocarbons.

Non-targeted analyses (NTA) are an optional analytical tool for characterizing potential PICs/PIDs. High resolution mass spectrometry, combined with chromatographic separation and multiple ionization techniques, is used to identify compounds present in collected samples. NTA could be performed on the OTM-45 samples. Fourier transform infrared (FTIR) spectroscopy would be used to measure a variety of compounds in real-time, including hydrogen fluoride (HF), hydrogen chloride (HCl), carbon dioxide (CO_2), and water (H_2O); multiple PFAS compounds including CF_4 and C_2F_6; and multiple known PICs/PIDs. FTIR is particularly critical during surrogate compound injection.

ORD research questions

The following section describes detailed elements of the research questions ORD will ultimately work to address, as well as the input information that is needed. ORD requests an opportunity to engage with the host facility prior to developing a full sampling plan to better understand site-specific conditions and requirements.

Process characterization

- **Question:** How does the process operation affect the destruction and removal of PFAS compounds present in the feed?
- Requires understanding of waste feed (e.g., description, concentration, other wastes), feed approach (e.g., liquid feed, through flame/post flame, co-fired, drums/barrels), and feed rate
- Requires data on combustor operations and conditions (e.g., temperature, residence time)
- Requires data on air pollution control devices (APCD) and their operation: configuration, operating parameters (e.g., temperature, pressure drop, pH of scrubbing liquid, gas velocity)

Determine destruction removal efficiency (DRE)

- **Question:** What is the DRE and emission rate of the specific PFAS compounds present in the feed
- material?
- Requires known input rate and identity of PFAS compounds in waste
- Requires evaluation of the extent of PFAS mineralization
- Requires replicate sampling of polar semivolatile organics using OTM-45 for quantitative measurement of feed PFAS compounds in emissions
- Requires sampling across multiple APCDs

Products of incomplete combustion/destruction (PICs/PIDs)

- **Question:** Are PICs/PIDs formed during thermal treatment and measured by OTM-50 present and, if so, what are they and under what conditions?
- Requires replicate sampling of polar, nonpolar, semivolatile, and volatile organics for non-targeted compound analysis using OTM-45, OTM-50, and Method 0010/3542/8270.
- Requires sampling across multiple APCDs.

Alternative indicators of destruction performance

Question: Can easily measured/monitored, hard-to-destroy compounds serve as alternative (surrogate) indicators for PFAS adequate destruction or PID formation conditions?

- Requires injection of known concentrations/masses of CF_4 and C_2F_6 (approximately 10 parts per million by volume stack equivalent) at representative waste injection locations
- Requires on-line FTIR monitoring of the surrogate compounds, PICs, HF, HCl and other compounds of interest
- Requires initial background signal baseline
- Requires concurrent OTM-50 sampling for analysis of surrogate compounds and known PICs

Analysis of fluorinated compounds in waste/effluent streams

Question: What is the fate of PFAS compounds across the entire thermal system?

- Requires sampling of all discharges
    - Gas sampling prior to and after APCDs (e.g., spray dryer, wet scrubber, baghouse and/or ESP, activated carbon injection)
    - Sampling of solid and liquid discharges (e.g., bottom ash, baghouse and/or ESP solids, scrubber effluent analyses, spent carbon)

Analysis of fluorinated compounds in final product materials, where applicable

Question: What PFAS remain in the material treated, such as reactivated GAC or treated soils?

- Requires sampling of influent and effluent materials
    - Sampling of solid materials (e.g., spent carbon and reactivated carbon)

Appendix B: Summary of the Clean Harbors Test Data

Summary

Two testing campaigns were conducted at Clean Harbors Environmental Services' (CHES) hazardous waste combustor (HWC) located in Aragonite, Utah. Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented Per- and Polyfluorinated Alkyl Substances (PFAS) Feed (Condition 2, where known amounts of four or five target PFAS were fed to the incinerator), and Post-spiking Normal Operations (Condition 3, where aqueous film-forming foam [AFFF] was included in the incinerator feed). Clean Harbors used the *Other Test Method 45 (OTM-45) Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources* (OTM-45) from the U.S. Environmental Protection Agency (EPA) for stack gas samples. The 49 targeted PFAS analytes were measured using liquid chromatography/tandem mass spectrometry (LC/MS/MS) with isotope dilution. The tests appear to demonstrate that the primary objective, "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," was achieved for the five selected PFAS compounds that were subjects of these studies.

Introduction

Two testing campaigns were conducted at CHES HWC located in Aragonite, Utah. The first campaign was conducted from June 17 to 19, 2021 and the second from February 17 to 19, 2022. The stated principal objective of the test program was to "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," with secondary objectives of conducting a mass balance of PFAS in process streams and demonstrating high hydrogen fluoride (HF) removal that would be associated with a high destruction of PFAS. This summary presents a high-level overview of both tests' final reports as well as a third-party review of the 2021 test performed by Dr. Philip H. Taylor under contract to CHES.

General Process Description

The HWC tested at the CHES Aragonite facility consists of a slagging rotary kiln incinerator followed by an afterburner. Solid waste materials and containerized wastes are fed into the rotary kiln only, while liquid wastes may be injected directly into rotary kiln or the afterburner. The air pollution control device system for the HWC as tested[29] consists of a spray dryer/gas quench followed by activated carbon injection upstream of a fabric filter (particulates, dioxin/furan, and mercury control). Following the fabric filter, the gases enter a sodium carbonate saturator/wet scrubber (sulfur dioxide, hydrogen chloride, hydrogen fluoride control) with TMT-15 (1,3,5-triazine2,4,6(1H,3H, 5H)-trithione, trisodium salt, used for additional mercury and metals control) injection.

[29] Stack testing was performed in the exit duct of the wet scrubber instead of at the stack for safety reasons (lack of scaffolding). The HWC is equipped with a wet electrostatic precipitator (WESP) following the wet scrubber and prior to the stack, but the WESP was decommissioned in 2004 and is no longer in service. These tests were conducted prior to the WESP although the stack location is the test location for compliance performance tests for the facility.

Operational Description

Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented PFAS Feed (Condition 2), and Post-Spiking Normal Operations (Condition 3), with the waste feed matrices as follows:

1. **Condition 1.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes). Following the 2021 testing, CHES determined that the sludge stream fed to the kiln during all three conditions included some AFFF. During the first run of the 2022 testing, CHES determined that AFFF was inadvertently being fed into the afterburner's corrosive waste port. The testing team decided to be consistent with runs 2 and 3 and continued the AFFF feed, with additional amounts of AFFF fed during Condition 3.
2. **Condition 2.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes), with the addition of augmented feed rates of four (2021) or five (2022) PFAS (or their equivalent potassium salt). The four PFAS are perfluorooctanioic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS), hexafluoropropylene oxide-dimer acid (HFPO-DA), and perfluorobutanesulfonate (PFBS, 2022 only). The target feed rate of the PFAS was estimated to be .0816 pounds per hour or around 0.62 grams per minute in 2021 for all PFAS, but the HFPO-DA was increased to 2.2 grams per minute in the 2022 testing to reflect the method detection limit (MDL) for this compound. Similarly, the PFBS feed rate was 0.33 grams per minute on average to reflect the MDL. The PFAS were fed in boxed containers to the rotary kiln via the containerized solid conveyor in approximately 10-gram portions of all PFAS compounds about every 15 minutes for the duration of these test runs.
3. **Condition 3.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes). For this test condition, AFFF concentrate was also fed (neat) to the incinerator. In 2021, the AFFF was fed via the containerized solids in 5-gallon buckets at a rate of 176 pounds per hour. During the 2022 test, the AFFF was labeled as Ansulite and was fed through the educt station to the incinerator directly from a tote bin. The AFFF feed rate ranged from 244 pounds per hour to 316 pounds per hour during the 2022 test.

The rotary kiln was operated in a temperature range between 1,893°F and 2,008°F for the 2021 test and between 1,949°F and 2,219°F for the 2022 test. The afterburner was operated at 2,052°F to 2,110°F during the 2021 test and 2,048°F to 2,075°F for the 2022 test. Oxygen content (free) at the exit of the rotary kiln was maintained between 8 and 9 percent and ranged from 6 to 7 percent for the afterburner for both test campaigns. Clean Harbors estimates that non-combustible material is retained within the combustor for approximately 60 minutes, while combustion gas residence time of the afterburner is two to three seconds.

For the 2021 test, the temperature of the flue gas was reported as 369°F following the spray dryer; between 341°F and 343°F following the fabric filter; between 166°F and 168°F at the saturator outlet; and 148°F to 153°F at the stack. For the 2022 test, the temperature of the flue gas was reported as

363°F following the spray dryer; between 168°F and 170°F at the saturator outlet; and 149°F to 151°F at the stack. The following table lists the air pollution control device operational parameters during the testing campaigns.

Test Campaign	Stack gas flow (acfm)	Soda Ash Flow (lb/hr)	Carbon Injection (lb/hr)	TMT-15 flow (lb/hr)
2021	66,793–68,761	452–789	30.7–31.5	3.95–4.48
2022	51,053–53,640	411–1594	32.0–33.1	3.64–4.00

Test Methods and Scope

During both testing campaigns, samples of stack gases and process streams were taken and analyzed for 49 PFAS target compounds, with the stated analytical objective of characterizing as many streams entering or exiting the incinerator as possible. Clean Harbors used EPA's *Other Test Method 45 (OTM-45) Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources* (OTM-45) for stack gas samples (as noted earlier, "stack" meaning the exit duct from the wet scrubber as it was deemed a safer sampling location than the actual stack). The 49 targeted PFAS analytes were measured using LC/MS/MS with isotope dilution.

Process streams sampled included waste fuels, clean fuels, waste feeds, process water, and residuals (liquids and solids), as well as some pre-test sampling of chemical inputs (soda ash, activated carbon, and TMT-15). As noted in the reports, however, due to the waste profile matrix complexity and the heterogeneity of all three solid waste streams, they were not sampled or analyzed for PFAS. Absent any final EPA-approved methods for media other than drinking water, LC/MS/MS analysis was used to measure the targeted PFAS compounds in the process stream samples.

In addition to the 49 PFAS analytes, the HF concentration of the stack gas was measured using EPA Method 26A. The AFFF-containing material in the 2021 test was analyzed for the 49 target PFAS both before and after chemical oxidation as a total oxidizable precursor assay (TOPA). During the 2022 test, a TOPA and total organic fluorine assay (TOFA) were performed on the AFFF-containing materials. The objective of performing TOPA is to "reveal perfluoroalkyl acid (PFAA), fluorotelomer sulfonate (FTS), and possibly other precursors that are not identifiable with targeted PFAS analysis." TOFA, as described in the 2022 report, identifies the mass of compounds containing carbon-fluorine bonds, and was performed using combustion ion chromatography following a laboratory in-house method for adsorbable organo-fluorine.

Results

According to the tests and third-party review, the primary objective of determining the destruction and removal efficiency (DRE) of each of the spiked (augmented feed) PFAS was achieved. The calculated DREs for each test (triplicate test run average) and PFAS compound are as follows:

PFAS Analyte	2021 Test DRE (%)	2022 Test DRE (%)
PFOA (perfluorooctanioic acid)	99.999943	99.99990
PFOS (perfluorooctanesulfonic acid)	99.999955	99.99977
PFHxS (perfluorohexane sulfonic acid)	99.999977	99.99996

PFAS Analyte	2021 Test DRE (%)	2022 Test DRE (%)
HFPO-DA (hexafluoropropylene oxide – dimer acid)	99.999979	99.99984
PFBS (perfluorobutanesulfonate)	n/a	99.99997

Both test reports note that none of the other 45 (or 44, in 2022) target PFAS analytes were present in the waste feed at levels sufficient to demonstrate 99.9999 percent DRE without spiking, even though stack gas concentrations were non-detect in many cases. According to the 2021 test report, there were three other PFAS present in the waste feeds at sufficient mass feed rate without spiking to enable demonstration of DRE's exceeding 99.999 percent. These included PFOS, 6:2 fluorotelomer sulfonate (FTS), and 8:2 FTS. The report stated that the FTS compounds are common constituents of AFFF.

As for the secondary objectives, the results are, as stated within Dr. Taylor's review, "most difficult to achieve as they involve more complex sampling issues." With respect to the secondary PFAS mass balance objective, he notes that "some of the PFAS that was not sampled in the infeed may have been more difficult to gasify and burn, contrary to the assertions in the report." However, he concurs with the report statements that the PFAS DRE is conservative.

The objective of demonstrating high HF removal that would be associated with a high destruction of PFAS is seemingly not achieved, primarily due to analytical issues. Dr. Taylor notes that "the sinks for the HF were not accurately quantitated leading to some questions about the validity of the reported HF removal efficiency." He further notes that the assumption that all fluorine in the waste if converted to HF is challenged, as there would be a required excess of hydrogen to fluorine to be demonstrated, which are not provided for in the data. Further, he stated that there is a "demonstrated lack of accuracy of the analytical methods for measuring inorganic fluorine in the residual streams," which, in his opinion, leads to a very low fluorine recovery mass balance. He concluded that, "development of better analysis methods for complex matrices for inorganic fluorine are needed before high HF removal efficiencies can be reported at full scale."[30]

Conclusions

The tests appear to demonstrate that the primary objective, "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," was achieved for the five selected PFAS compounds that were subjects of these studies. However, this study did not evaluate the formation of PICs due to previous methodology limitations. Dr. Taylor, in his review, noted this as well: "The larger question from an environmental viewpoint is the complete mineralization of these substances and prevention of emission of highly stable C_1-C_2 PFCs (perfluorocarbons)." Dr. Taylor concludes that CHES' results, although promising and demonstrating reduction of a limited selection of specific PFAS compounds, did not support complete mineralization.

[30] Although not stated by Dr. Taylor in his assessment, another possible reason for lack of finding inorganic fluorine (HF) could be the result of poor conversion (mineralization) of PFAS to HF and carbon dioxide during incineration. This may indicate formation of non-target PFAS or fluorocarbons during incineration that were not measured by these tests.

Appendix C: Summary of the Chemours Thermal Oxidizer Test Data

Introduction

Chemours Company FC, LLC, located in Fayetteville, North Carolina, manufactures chemicals and plastics and was required to install a thermal oxidizer to control per- and polyfluoroalkyl substances (PFAS) emissions. After installation, tests were conducted in March 2020 and March 2022. The objective of the tests was to determine how "the Thermal Oxidizer and 4-stage Scrubber system will achieve the emission reduction [of 99.99 percent], including the use of a surrogate for all PFAS, such as the hexafluoropropylene oxide (HFPO)." This summary presents a high-level review of the two tests' reports.

General Process Description

The thermal oxidizer at the Chemours facility operates at 10 million BTU per hour and is powered by natural gas. Waste gases from both polymer and monomer production are fed into the thermal oxidizer. The gaseous emissions from the oxidizer are fed into the four-stage packed bed column scrubber system while solid calcium fluoride (CaF_2) is removed, collected, and disposed of off site. The scrubber has three water scrubbing stages and one caustic scrubbing stage and is stated to remove hydrogen fluoride (HF) from the final emissions.

Operational Description

Test Methods and Scope

The tests done on the thermal oxidizer focused on five PFAS compounds: HFPO, hexafluoropropylene oxide-dimer acid (HFPO-DA), hexafluoropropylene oxide-dimer acid fluoride (HFPO-DAF), carbonyl fluoride (COF_2), and Flouroether E-1. These compounds were selected because they are handled and used at the Fayetteville facility. The compounds have varying chemical structures and properties and cannot be sampled and tested in the same manner.

Modified Method 18 sampling was used to capture the PFAS compounds. This method uses six fluoropolymer (PFA) impingers charged with methanol arranged in a series and captures the compounds using chemical reactions and condensation.

To capture HFPO-A, the facility needed to use Modified Method 0010 sampling with a heated probe and filter, condenser coil, XAD-2 resin cartridge, deionized water impingers, and a silica gel impinger. In addition to the normal Modified Method 0010 sampling process, this test added a second XAD-2 resin cartridge to monitor possible target PFAS breakthrough.

Three compounds, HFPO, HFPO-DAF, and COF_2, were sampled by chemical reaction. The sample gas was passed through the series of methanol impingers. The compounds then react with the methanol, and each produced unique ether compounds that were monitored and quantified using SW-846 Method 8260.

The strategy used to sample Flouroether E-1 and HFPO-DA was to capture the compounds through condensation and dissolution in the same methanol impingers. The volatile organic compound, Flouroether E-1, was then quantified using SW-846 Method 8260b. The semivolatile organic compound HFPO-DA was quantified using EPA Method 537.

Samples were taken from the polymer production and monomer production waste gas feed lines to capture the initial amount of PFAS compounds they produced as waste and give them a baseline concentration of PFAS prior to treatment. The other sampling location was in the stack after the thermal oxidizer and scrubber. This location would show how effective the process was at destroying the targeted PFAS compounds.

The sampling and testing methods only captured the amount of target PFAS compounds and did not measure any products of incomplete combustion. Although the four-stage scrubber was implemented to reduce the possible HF emissions, there was no sampling of HF.

Results

The results of the tests showed that the mandated 99.99 percent destruction of targeted PFAS compounds had been achieved. In both testing years the average PFAS destruction and removal efficiency (DRE) was above 99.999 percent with no result being lower than 99.999 percent. Results were presented as a total FPAS destruction efficiency with the amount of each target PFAS compound summed to provide an aggregate destruction efficiency. The total PFAS destruction efficiencies for each run and each year are as follows:

Year	Run 1	Run 2	Run 3	Average
2020	99.99982%	99.99974%	99.99986%	99.99981%
2022	99.99951%	99.99966%	99.99967%	99.99961%

Conclusions

The test reports demonstrate a PFAS destruction efficiency above the 99.99 percent that was mandated for the Chemours facility for the specific compounds that were tested. HFPO was tested as a surrogate for all species of PFAS, but there are no concrete data showing the performance of the thermal oxidation process for PFAS species outside of the compounds tested. There was also no discussion of possible products of incomplete combustion in the reports. The thermal oxidizer at the Chemours facility appropriately destroys the five PFAS compounds of interest that have been identified at the facility. However, removal processes for products of incomplete combustion or of destruction of potential compounds not studied but potentially found in the facility waste streams are still unclear.

Appendix D: Summary of Costs and Considerations

Introduction

This appendix provides some estimates of costs for end-of-life management of PFAS materials by thermal treatment, landfilling, and underground injection. The cost information presented is relatively uncertain and is likely most suitable to make comparisons between techniques.

The cost to destroy or dispose of PFAS and PFAS-containing materials can vary widely depending on a number of factors. Waste management infrastructure's design and operation are heavily influenced by regional needs, local regulations, and technological advancements. As a result, waste management costs vary by the type of waste and by location due to factors like availability and transportation costs. In addition, technological advances specifically related to the management of PFAS-containing materials can potentially reshape the cost and operational landscape of PFAS waste management. Multiple factors and limitations contribute to cost variability and should be considered when using the information in this appendix.

- Market conditions such as supply and demand change frequently, resulting in fluctuating costs.
- Location of destruction and disposal options and transportation affect case-by-case costs.
- Transportation costs or any special handling costs for accepting and treating additional waste are not included in most of these estimates, thus actual costs would vary.
- Costs may be affected by permitting and state/local requirements for PFAS-containing material, which vary depending on state/local regulations, public input, and possible environmental justice concerns.

Thermal Treatment

Hazardous Waste

Table D-1. Estimated Costs to Incinerate Different Types of Hazardous Waste (U.S. EPA, 2005a)

Hazardous Waste Type	Estimated Thermal Treatment Cost per Ton[a]
Liquids, sludges, solids (halogenated)	$1,300-1,889
Liquids, sludges, solids (non-halogenated)	$381-1,040
Lab packs	$6,448
Containerized gases	$3,120

[a] Costs were developed for hazardous waste combustors (HWC) that were affected by the 2005 National Emission Standards for Hazardous Waste Pollutants (NESHAP), including commercial incinerators, cement kilns, lightweight aggregate kilns, and commercial HWC boilers. Cost per ton is assumed to be in 2002 dollars, the same year basis of the regulation from which these costs were obtained. Costs were normalized to 2022 dollars using the Bureau of Economic Analysis (BEA) gross domestic product (GDP) deflator (U.S. BEA, 2023) for waste management and remediation services using a base year of 2002. Note that applying the BEA GDP deflator for this industry sector is a top-down approach. For regulatory purposes, a bottom-up approach is typically used, accounting for capital costs based on the Chemical Engineering Plant Cost Index (CEPCI), energy prices typically based on Energy Information Administration (EIA) data, and labor costs based on industry segment indices using Bureau of Labor Statistics (BLS) data.

Limitations:

- Costs have likely changed since 2002 and scaling costs to 2022 contributes to uncertainty.

- Does not include transportation costs or any special handling costs for accepting and treating additional waste materials.

Table D-2. Example Disposal/Reactivation Costs for Drinking Water Treatment Residuals (Derived from U.S. EPA, 2020a)

Method	Cost of Disposal ($/Pound of Media)	Estimated Cost of Disposal Plus Replacement Media ($/Pound of Media)[a]
Reactivated GAC—off-site	$0	$1.74
Disposal via landfill	$0.06	$2.35
Disposal via incineration	$1.28	$3.57

[a] Cost per pound is in 2022 dollars. For GAC, on-site reactivation is possible. However, the utility or site would have to have ample workforce, managerial, and financial (both capital and operating) resources to justify this choice. It is likely to be cost-effective only for very large facilities and would require consideration of other factors including availability of land and public opinion. Due to the complex analysis needed, a full comparison of off-site versus on-site is beyond the scope of this document.

Limitations:

- These estimates are presented as examples only to illustrate tradeoffs. Actual site-specific costs are likely to vary based on factors including the quantity of media reactivated/replaced and are used as an example of trends. In this example, reactivated GAC and virgin GAC are estimated to be $1.51 per pound and $2.29 per pound, respectively.
- All unit costs assume 21,000 lbs of GAC reactivated/replaced.
- For reactivated GAC, it is assumed that the "replacement" media is the returned reactivated media plus the replacement of the GAC lost during reactivation with virgin media (assumed to be 30 percent).
- Disposal costs assume 10 miles of transportation to the disposal site.
- Incineration costs are based on incineration of ion exchange resin media. Incineration of GAC could be somewhat more expensive, depending on the relative fuel value of the spent media.
- The analysis is complex and a number of issues need to be considered at the site level, such as those that affect costs (cost of energy, shipping, labor, construction, operation, sampling, etc.) and those that affect other matters (practicality, public versus private ownership, contract availability, regional reactivation availability, off-gas permitting, public opinion, etc.).

Landfills

Hazardous Waste

Table D-3. Estimated Costs to Landfill A Representative Type of PFAS-Containing Material (Defense Logistics Agency (DLA), 2023)

Hazardous Waste Type	Estimated Cost per Ton of Waste
Aqueous film-forming foam (AFFF) and other PFAS-related Solids/Debris, Non-RCRA, >100 parts per million (ppm) PFAS for direct disposal at RCRA Subtitle C Landfill (e.g., contract line item number (CLIN) PF06B1)	$1,300-3,660 ($0.65-1.83/lb)

Limitations:

- The DLA pricing web application lists current government contracts for destroying or disposing of PFAS and PFAS-containing materials and may be useful for government contract cost estimates. The estimated cost per ton (lb) of waste appears to include removal and disposal costs for the specific material, although a portion of transportation costs may be attributed to other cost elements of each respective contract so transportation costs may not be fully reflected in these costs.
    - **Per the DLA pricing web application:** The prices contained in the database were awarded based on contract terms and conditions, procurement requirements, and price reasonableness determinations. The prices and contract information in the database are for reference only.
- Users of the DLA pricing web application are cautioned that each contract was developed to meet specific requirements for specific geographic regions or military installations. There are multiple variables that result in the pricing information displayed, including contract award date, proximity to DLA-approved disposal facilities, quantities of PFAS material estimated for disposal in proportion to other hazardous waste on the contract, reoccurring need for services, and whether PFAS material is disposed of in bulk or whether there are small, limited quantities.
- Pricing is provided here for bulk waste types for disposal at a Subtitle C hazardous waste landfill. Pricing for multiple waste types with varying units of measure for disposal, including containerized waste, are provided in the DLA pricing web application.
- The estimated cost in the table above only applies to a limited number of military installations and only considered bulk pricing from 600 to 10,000 pounds. Pricing is expected to differ for containerized waste and should be considered when relying on this cost information.

Non-Hazardous Waste (Municipal solid waste)

Table D-4. Average MSW Tipping Fees per Ton by U.S. Region (EREF, 2022)

Region	Average Tipping Fee ($/ton)	Region	Average Tipping Fee ($/ton)
Pacific	$69.02	Northeast	$75.92
Mountains/Plains	$50.84	Southeast	$48.70
Midwest	$62.02	South Central	$50.84

Limitations:

- MSW landfills emit more PFAS than originally thought in 2020. Research estimates that although MSW landfills contain PFAS for the most part, up to 5 percent of the PFAS may be released in the landfill gas and, 11 percent may be released in the leachate annually (Tolaymat et al., 2023). Thus, MSW tipping fees may not be a relevant data point for cost information.

Non-Hazardous Waste (Liquid waste)

Table D-6. Average Industrial Wastewater Rates by U.S. Region (Unger et al, 2023)

Region	$/1,000 gal	Region	$/1,000 gal
Pacific	$11.90	Northeast	$4.82
Mountains/Plains	$3.12	Southeast	$7.52
Midwest	$4.77	South Central	$5.20

[a] Data are consolidated by region and the number of data points varies by region. American Water Works Association (AWWA) water and wastewater rate surveys were used to gather historical rate data for water and wastewater utilities in the United States. These datasets were compiled and assessed to produce a single dataset of time series rate data for 112 water utilities and 76 wastewater utilities located throughout the United States.

Limitations:

- These data do not include specific information on extra treatment considerations that may be required by a national pollutant discharge elimination system (NPDES) permit or by an industrial user permit for a discharge into a POTW to control the release of PFAS. Thus, similar to the cost of landfilling PFAS waste, the associated treatment of PFAS-laden leachate is difficult to assess because the available data are associated with typical industrial wastewater generators or typical landfill leachate.

One report examined the cost to manage landfill leachate on site (U.S. EPA, 2021). Based on review of the treatment processes and technologies that are currently used, the cost to manage leachate on site is highly variable but generally ranges between $10-150/1,000 gallons ($0.01-0.15/gallon). Capital costs can range from hundreds of thousands to several million dollars. The report lists multiple limitations and does not specify treatment for PFAS.

Underground Injection

Class I Wells (hazardous and non-hazardous)

Table D-6. Estimated Costs for Class I Wells

Underground Injection Cost	$/1,000 gal[a]
Deep well injection	$190-270 (deSilva, 2019)
Trucking costs	$10-200 (McCurdy, 2011)

[a] Costs were normalized to 2022 dollars using the Bureau of Economic Analysis (BEA) gross domestic product (GDP) deflator (U.S. BEA, 2023) for waste management and remediation services using a base year of 2019.

Limitations:

- Class I well capacity is limited, which may affect the costs associated with deep well injection.
- Because of the geographic concentration of Class I wells, waste producers may face transportation and logistical challenges.
- To begin accepting PFAS-containing fluids, owners/operators of existing Class I wells may incur costs to modify their permits to accept waste from other entities or new waste streams.

Another source includes costs for disposing of sewage sludge and indicates that among fees and transportation costs is a $37.50 per ton fee for deep well injection of leachate (CDM Smith, 2020).

VFC	volatile fluorinated compounds
VOC	volatile organic compound
WESP	wet electrostatic precipitator
WWTP	wastewater treatment plant
XPS	X-ray photo-electron spectroscopy
µg	microgram
$	United States dollar

Executive Summary

This 2026 update of the U.S. Environmental Protection Agency (EPA) interim guidance presents currently available information on the destruction and disposal of perfluoroalkyl and polyfluoroalkyl substances (PFAS) and PFAS-containing materials. This guidance focuses on updates to the current state of science and associated uncertainties for three large-scale capacity technologies that can destroy PFAS or control PFAS release into the environment: thermal treatment, landfills, and underground injection. This guidance document also discusses emerging technologies and provides a framework for evaluating these technologies for PFAS destruction or disposal. This guidance is non-binding and does not have the force and effect of law.

EPA published the first edition of this guidance on December 18, 2020, as required by the National Defense Authorization Act (NDAA) of 2020, and the second edition of this guidance on April 16, 2024. The NDAA directs EPA to address the destruction and disposal of PFAS and specific PFAS-containing materials, including aqueous film-forming foam (AFFF), contaminated media, textiles (other than consumer goods), and various wastes from water treatment. The NDAA also requires EPA to review and update the guidance as appropriate, but no less frequently than every three years. On April 28, 2025, the EPA Administrator committed to providing more frequent updates to the interim guidance—changing from every three years to annually—as EPA continues to assess the effectiveness of available treatment technologies.

The primary audience of this guidance are decision-makers (e.g., managers of PFAS and PFAS-containing materials making decisions about destruction and disposal) who need to identify effective means for destroying or disposing of PFAS-containing materials and wastes. The audience may also include regulators, waste managers, and the public, including affected communities. While this document highlights a few emerging approaches for PFAS destruction and disposal, EPA acknowledges that alternatives not discussed in this document may also be appropriate. EPA is recommending that managers of PFAS wastes consider the nature of the waste, location, potential for environmental release, and other factors to determine the most appropriate destruction, disposal, or storage method. As a general approach, EPA recommends that decision-makers prioritize the use of destruction and disposal technologies that have a lower potential for PFAS release to the environment over destruction and disposal technology options with a greater potential for environmental release of PFAS given similar costs or other considerations. EPA acknowledges that each destruction and disposal technology has limitations. This guidance is intended to assist with managing PFAS to minimize environmental releases during destruction and disposal activities supports protection of human health and the environment.

This guidance highlights effective PFAS destruction and disposal technologies to prevent or minimize environmental releases, while acknowledging the important distinction between a potential environmental release and human exposure and risk.

EPA has developed a fact sheet for the public, which provides a more concise and less technical presentation of key materials (see Appendix E).

Key Updates

EPA evaluated recent information pertaining to destruction and disposal options based on each technology's potential to destroy PFAS or control PFAS release into the environment. This approach is

consistent with EPA's mission to protect human health and the environment. This guidance describes several different types of technologies that are widely used and commercially available for PFAS treatment and disposal, and their potential to destroy PFAS or control PFAS releases is described herein (see Sections 1 and 3). The following technologies (listed in no relative order) generally have a lower potential for environmental release of PFAS compared to other technologies:

- **Underground Injection - Permitted Class I non-hazardous industrial or hazardous waste injection wells** are one of the regulatory waste management approaches that can provide reasonable assurance that injected fluids will remain isolated and not migrate into underground sources of drinking water (USDWs). However, over long timescales, uncertainties remain, including the long-term fate and transport properties of PFAS in the injection zone. These wells may help ensure that injected fluids are confined and cannot enter underground sources of drinking water. However, the limited number of wells currently receiving off-site PFAS and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection.
- **Landfills - Permitted RCRA Subtitle C hazardous waste landfills** incorporate the most stringent engineering controls and practices for containment and are expected to be more effective at minimizing PFAS release into the environment than other landfill types. EPA recommends landfills subject to Subtitle C of the Resource Conservation and Recovery Act (RCRA) when PFAS levels of the waste are relatively high, and landfill disposal is the selected option. However, for all landfill types, new information demonstrates that landfilling could result in higher PFAS releases to the environment than previously thought in 2024 (see Section 3.b).
- **Thermal Treatment - Permitted hazardous waste combustors** (HWCs) such as commercial incinerators, cement kilns, and lightweight aggregate kilns (LWAKs) and granular activated carbon (GAC) reactivation units with thermal oxidizers may operate under conditions more conducive to destroying PFAS and controlling related products of incomplete combustion (PICs). Research available since release of the 2024 Interim Guidance suggests that the use of higher temperatures, well mixed combustion environments, and longer residence times may be more conducive to destroying PFAS and controlling related PICs. Although newer, limited data have been obtained since the 2024 version of the interim guidance, uncertainties remain about the effectiveness of thermal treatment to adequately destroy PFAS or control release to the environment. EPA encourages additional testing with EPA-approved or EPA-evaluated methods by waste managers of thermal treatment operations (including testing for PICs present at the treatment device outlet and the presence of PFAS in all associated process and waste streams) to evaluate whether thermal treatment technologies are minimizing potential environmental releases. EPA's new analytical methods for a targeted list of polar semivolatile PFAS (Other Test Method 45 [OTM-45]) and volatile fluorinated compounds (OTM-50), as well as additional EPA methods under development for evaluating treatment of hard-to-destroy PFAS will allow better characterization of PICs which will help to address some of these uncertainties when additional data are collected as recommended in this guidance (Appendix A).

This list includes the three technology categories described in Section 3 and does not preclude the use of other new or emerging technologies. When considering the bullets above, it is important to note that real-world performance and testing data are generally limited. Additional performance and testing data—including data on destruction and removal of PFAS in thermal treatment devices, ongoing research activities, and long-term performance data for landfills and underground injection—may

change EPA's understanding of the ability of each technology to control PFAS. Section 4 of this updated guidance summarizes the data needs and priorities for research to inform future updates.

EPA continues to seek collaboration with thermal treatment facilities to conduct air emission testing during thermal treatment of PFAS and PFAS-containing materials (see Appendix A). In addition to performance and testing data, the 2026 guidance continues to identify other, high-priority data gaps that need to be addressed by researchers across government, academia, and industry for EPA to provide meaningful updates on effective destruction and disposal practices.

EPA partnered with industry and academia to collect data on emerging technologies for PFAS destruction, such as mechanochemical degradation, gasification and pyrolysis, and supercritical water oxidation. While the results from these studies show promise for PFAS destruction, further work using newly available methods is needed to more fully characterize the outputs of these processes and to evaluate their performance for a wider range of PFAS-containing materials. Managers of PFAS and PFAS-containing materials may consider these or other emerging technologies for PFAS disposal or destruction. To assist PFAS material managers with evaluating whether an emerging destruction (or disposal) technology is suitable for a particular PFAS-containing material, EPA developed a technology evaluation framework. The framework provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS and PFAS-containing material and includes considerations for communities. EPA recommends that managers of PFAS-containing materials use the technology evaluation framework to evaluate emerging destruction and disposal technologies and to inform their decisions about managing PFAS-containing materials. EPA also encourages technology developers to generate and publicly release data that can be used to complete the framework (see Section 5).

Public Feedback and Next Steps

EPA and other government, academic, and private institutions will continue to conduct research to better understand PFAS destruction and disposal (see Section 4). EPA will consider public comments it receives on this version of the guidance, as well as additional advancements in PFAS research and science to publish annual updates.[1] This guidance will be published with a 60-day comment period. EPA will publish a Federal Register Notice with Instructions on how to submit comments. During the public comment period, EPA encourages the public to submit studies and data related to management of the PFAS-containing waste described in Section 2. Additionally, continued collaboration with industry researchers is encouraged to conduct emissions testing of PFAS treatment devices, including evaluation of PICs and products of incomplete destruction (PIDs).

[1] On April 28, 2025, the EPA Administrator committed to providing more frequent updates to the interim guidance—changing from at least every three years as required by the NDAA to annually.

1. Introduction

This 2026 version of the interim guidance provides information on technologies that may be feasible and appropriate for the destruction or disposal of perfluoroalkyl and polyfluoroalkyl substances (PFAS) and PFAS-containing materials. This guidance is non-binding and represents the current state of science and the associated uncertainties for large-capacity technologies that can destroy PFAS or control PFAS release into the environment. This is an update to the interim guidance the EPA issued in 2024 and utilizes information and data reviewed up until September 2025.

EPA published the second version of this interim guidance and made it available for public comment.[2] This updated version incorporates the feedback EPA received from the 37 unique comments on the interim guidance submitted by states, Tribes, industries, trade organizations, environmental organizations, and members of the public.

The 2026 interim guidance contains the following new information:

Section 1: Introduction

- Updated review of PFAS destruction and disposal technologies.

Section 2: Description of PFAS-Containing Materials Identified in the FY 2020 NDAA

- Provided information regarding updates and planned revisions to the PFAS 8(a)(7) reporting rule under the Toxic Substances Control Act (TSCA [88 FR 70516, October 11, 2023]).
- Updated biosolids generation and management information.
- Updated information on the PFAS National Primary Drinking Water Regulations.

Section 3: Technologies for the Destruction and Disposal of PFAS and PFAS-Containing Materials

- Incorporated information from 2024 tests evaluating the PFAS destruction at hazardous waste incinerators in Aragonite, Utah and Port Arthur, Texas in Section 3.a.
- Added information from recent studies on thermal destruction of HFPO-DA into Section 3.a.i.1, laboratory- and facility-scale investigations of PFAS thermal treatment in sewage sludge incinerators (SSIs) into Section 3.a.i.3.1, and the efficacy of thermal oxidizers and carbon adsorption beds as PFAS control technologies at a fluoropolymer manufacturing facility into Sections 3.a.i.4 and 3.a.ii.
- Included published data evaluating landfill liner permeability and implications for PFAS transport and transformation in Section 3.b.ii.1, and added newly available published data on gas collection systems and implications for PFAS transport and transformation to Section 3.b.ii.2.
- Incorporated published ranges of PFAS concentrations measured in leachate samples from different types of landfills and municipal solid waste (MSW) landfill gas (LFG) condensate to Table 3-3 and data and information regarding PFAS concentrations in LFG samples from Subtitle D landfills to Section 3.b.ii.3.
- Updated Section 3.b.iii.6.2 regarding on- and off-site treatment technologies for landfill leachate that remove PFAS, and added new information on non-targeted analysis, uncertainties, and unknowns in Section 3.b.vi.
- Updated the information showing the locations of Class I wells in the United States using 2023 data in Section 3.c.iii.

[2] Interim PFAS Destruction and Disposal Guidance; Notice of Availability for Public Comment. U.S. EPA. 89 Federal Register 26879. April 16, 2024.

Section 4: Research Needs and Data Gaps for Destruction and Disposal Technologies

- Revised the table in Section 4.a based on new information presented in this document and public comments received on the 2024 interim guidance.
- Replaced discussion of current research efforts with links to ongoing, relevant federal research activities.

Section 5: Emerging Technologies for PFAS Destruction and Disposal

- Added information on the remaining PFAS Innovative Treatment Team (PITT) outputs in Section 5.a.
- Revised information on the technology evaluation framework in Section 5.b to incorporate suggestions from public comments received on the 2024 interim guidance.

Appendix A: EPA Guidance to Conduct PFAS Emissions Field Testing at Commercial Thermal Destruction Sources

- Expanded the list of inlet, intermediate, and outlet streams for sample collection and analysis to include process materials.
- Clarified the target analytes to include in an air emission source characterization.

Appendix B: Summary of the 2021 and 2022 Clean Harbors Test Data

- Added the test years (2021 and 2022) for the two source test campaigns conducted at an HWC to the appendix title.

Appendix C: Summary of the Chemours Thermal Oxidizer Test Data

- Expanded the table of destruction and removal efficiency (DRE) values to include the results for 2021, 2023, and 2024 from the test campaign conducted at a chemical manufacturer.

Appendix D: Summary of Costs and Considerations

- Updated the cost estimates for end-of-life management of PFAS materials by thermal treatment, landfilling, and underground injection from 2022 to 2024 dollars.

Appendix E: Fact Sheet for the 2026 Interim Guidance on the Destruction and Disposal of PFAS

- Added the fact sheet for the 2026 interim guidance document.

1.a Purpose and audience of this interim guidance

The purpose of this interim guidance is to describe technologies for managing the destruction and disposal of PFAS-containing materials and to recommend practices associated with these technologies that minimize PFAS releases to the environment. This purpose is consistent with EPA's mission to protect human health and the environment and the NDAA for Fiscal Year 2020, Public Law No: 116-92 (hereafter, "FY 2020 NDAA"), signed into law on December 19, 2019.

Section 7361 of the FY 2020 NDAA (see Figure 1-1) directs EPA to publish interim guidance on the destruction and disposal of PFAS and PFAS-containing materials no later than one year from the date of enactment of the FY 2020 NDAA. EPA published the initial interim guidance on December 18, 2020. The FY 2020 NDAA also requires EPA to review and revise the interim guidance at least every three years, if appropriate. The previous update was published in April 2024. On April 28, 2025, the EPA Administrator committed to changing the frequency of the interim guidance updates from every three years to annually as EPA continues to assess the effectiveness of available treatment technologies. This 2026 update fulfills that commitment.

The primary audience of this guidance are decision-makers who need to identify effective means for destroying or disposing of PFAS-containing materials and wastes based on their site-specific conditions, costs and other considerations. The audience may also include regulators, waste managers, and

technology developers who can use the technology evaluation framework in Section 5 to evaluate the applicability of emerging technologies to PFAS destruction or disposal. This guidance may also interest the general public, particularly communities near PFAS destruction and disposal sites. EPA has developed a fact sheet for the public that provides a more concise and less technical presentation of this guidance (see Appendix E).

SEC. 7361. PFAS DESTRUCTION AND DISPOSAL GUIDANCE.

(a) IN GENERAL.—Not later than 1 year after the date of enactment of this Act, the Administrator shall publish interim guidance on the destruction and disposal of perfluoroalkyl and polyfluoroalkyl substances and materials containing perfluoroalkyl and polyfluoroalkyl substances, including—

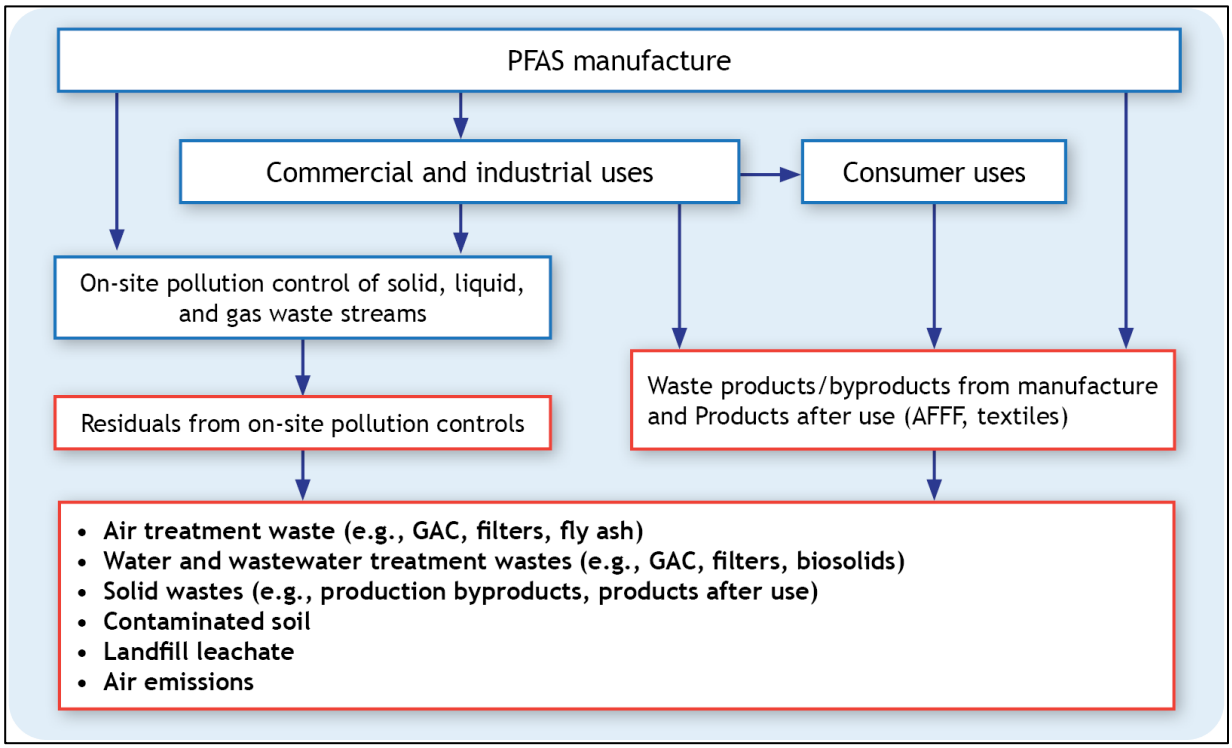
(1) aqueous film-forming foam;
(2) soil and biosolids;
(3) textiles, other than consumer goods, treated with perfluoroalkyl and polyfluoroalkyl substances;
(4) spent filters, membranes, resins, granular carbon, and other waste from water treatment;
(5) landfill leachate containing perfluoroalkyl and polyfluoroalkyl substances; and
(6) solid, liquid, or gas waste streams containing perfluoroalkyl and polyfluoroalkyl substances from facilities manufacturing or using perfluoroalkyl and polyfluoroalkyl substances.

(b) CONSIDERATIONS; INCLUSIONS.—The interim guidance under subsection (a) shall—

(1) take into consideration—
(A) the potential for releases of perfluoroalkyl and polyfluoroalkyl substances during destruction or disposal, including through volatilization, air dispersion, or leachate; and
(B) potentially vulnerable populations living near likely destruction or disposal sites; and
(2) provide guidance on testing and monitoring air, effluent, and soil near potential destruction or disposal sites for releases described in paragraph (1)(A).

(c) REVISIONS.—The Administrator shall publish revisions to the interim guidance under subsection (a) as the Administrator determines to be appropriate, but not less frequently than once every 3 years.

Figure 1-1. FY 2020 NDAA Section 7361.



1.b Scope and use of interim guidance

1.b.i PFAS and PFAS-containing materials in this interim guidance

Section 7361 of the FY 2020 NDAA (see Figure 1-1) lists six types of PFAS-containing materials and wastes[3]. Although the information included in this interim guidance is likely to be suitable for other types of PFAS and PFAS-containing materials, this interim guidance addresses destruction and disposal centering on these six material types, which are described in more detail in Section 2. In this document, the PFAS-containing materials covered by the FY 2020 NDAA that will be destroyed or disposed of are referred to as "waste."

Figure 1-2 shows conceptually how manufacturing activities could result in material streams that are within the intended scope of this interim guidance, including GAC and AFFF.

[3] While there is no current EPA consensus definition of PFAS, perfluoroalkyl and polyfluoroalkyl substances can be generally characterized as a very large group of synthetic chemicals that due to their strong carbon-fluorine bonds, can be very persistent in the environment. EPA's ***CompTox Chemicals Dashboard*** maintains a master list of more than 12,000 chemicals that are potential PFAS, including 10,200 chemicals containing a specific defined structure and an additional 1,300 without explicit structures (polymers and other chemical substances of unknown or variable composition).

Note: The red-outlined portions show where the FY 2020 NDAA material types occur during manufacture, use, and disposal of PFAS and PFAS-containing materials that are within the scope of this interim guidance.

Figure 1-2. Generation of PFAS materials identified in the FY 2020 NDAA.

1.b.ii Destruction and disposal technologies addressed in this interim guidance

This interim guidance presents three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS and PFAS-containing materials. Advances in scientific understanding allow EPA to make some recommendations; however, filling information gaps and addressing uncertainties will improve the scientific understanding and could lead to additional guidance in the future.

This interim guidance describes technologies with the potential to destroy PFAS or control releases of PFAS into the environment. Other waste management options are not discussed, because they are not within the intended scope of this interim guidance. For example, land application of biosolids containing PFAS does not control releases of PFAS into the environment.

Current technologies. In developing this third version of the interim guidance, EPA focused on the three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS wastes: thermal treatment, landfills, and underground injection. EPA also focused on reviewing recent data and information about the ability of each of these technologies to manage PFAS-containing materials through containment or destruction (i.e., breaking carbon–fluorine bonds and mineralization) while limiting releases of PFAS to the environment. In doing so, EPA prioritized addressing the scientific issues and uncertainties highlighted in the 2024 interim guidance and, when possible, relied on publicly available, peer-reviewed data and information (see Section 3).

Emerging technologies. Concerns about the effectiveness, availability, capacity, or cost of current, widely-used technologies for managing PFAS and PFAS-containing materials have motivated efforts to develop new technologies and apply existing technologies to PFAS materials. EPA is aware of and, in some cases, has participated in efforts to identify, develop, and test non-thermal destruction technologies for PFAS-containing materials (see Section 5).

Note that EPA is aware of additional information and technologies that were not considered for evaluation and are not mentioned in this guidance. EPA encourages continued collaboration with other government, academic, and private institutions to continue conducting research to better understand destruction and disposal of waste containing PFAS, and to be potentially included in future iterations of this guidance. EPA encourages technology developers to generate and publicly release data that can be reviewed, and to ensure the data are consistent with the tenets of gold standard science established in Executive Order 14303 (*Restoring Gold Standard Science*[4]).

In some cases, managers of PFAS and PFAS-containing materials may consider emerging technologies for PFAS destruction. When considering the use of emerging technologies, managers of PFAS-containing materials should work with state, territorial, or Tribal government agencies. To assist PFAS material managers with evaluating whether an emerging destruction (or disposal) technology is suitable for a particular PFAS-containing material, EPA developed a technology evaluation framework (see Section 5). The framework provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS materials.

In 2026, EPA is neither recommending nor discouraging the use of any emerging technology for managing the PFAS-containing materials specified in the FY 2020 NDAA. Instead, the Agency recommends that managers of PFAS-containing materials use the technology evaluation framework to evaluate emerging destruction and disposal technologies and to inform their decisions about managing PFAS-containing materials. EPA also encourages technology developers to generate and publicly release data that can be used to complete the framework (see Section 5).

Generally, destruction and disposal activities for PFAS-containing materials are currently not federally regulated. PFAS-containing materials may be managed in non-hazardous and hazardous waste treatment and disposal systems. Some exceptions exist, such as risk management requirements in cases where permits for production of new chemicals specify destruction or disposal methods following the review of a new chemicals notice under TSCA. Unless governing regulations require specific actions to the contrary, this guidance recommends selecting an approach that minimizes the potential for releases of PFAS into the environment.

Table 1-1 presents examples of the PFAS destruction and disposal technologies discussed in this guidance document for materials in solid, liquid, and gas phases.

4 Available at: https://www.govinfo.gov/content/pkg/FR-2025-05-29/pdf/2025-09802.pdf.

Table 1-1. Destruction and Disposal Technologies Discussed in This Interim Guidance, with Examples of PFAS-Containing Materials

Destruction and Disposal Technology, by Physical Phase of Materials	Examples of PFAS-Containing Materials (within the Scope of the FY 2020 NDAA) That Could Be Managed Using These Technologies

Solid phase:
Landfill disposal.
Thermal treatment.
	• Drinking water, groundwater, and wastewater treatment residuals:
	  ○ Biosolids/sewage sludge.
	  ○ Spent GAC.
	  ○ Ion exchange resins.
	• Air waste stream treatment residuals:
	  ○ Spent GAC.
	  ○ Fly ash.
	• Contaminated soil.
	• End-of-life products (e.g., textiles).
	• Solidified liquid wastes.

Liquid phase: Underground injection. Thermal treatment.	• Sewage sludge (liquid). • Landfill leachate. • AFFF (spent or concentrate). • End-of-life products (e.g., spent cleaning solvents). • Pollution control residuals (e.g., concentrates) from PFAS production and use.
Gas phase: Thermal treatment.	• LFG. • Emissions from manufacture, use, or destruction of PFAS.

1.b.iii Use of this interim guidance

This interim guidance provides information and suggested considerations for evaluating destruction and disposal options. This third version of the interim guidance is based on recent research and information available in 2025 and is responsive to the scope of the FY 2020 NDAA. This interim guidance presents background information on the manufacture and uses of PFAS, as well as solid, liquid, and gas waste streams containing PFAS, including those materials identified in the FY 2020 NDAA: AFFF, soils and biosolids, textiles, spent water treatment materials, landfill leachate, and PFAS waste streams from facilities manufacturing or using PFAS (see Section 2). Most significantly, it provides up-to-date information on potential releases during the destruction and disposal of PFAS and PFAS-containing materials (see Section 3) and identifies data gaps to be filled that can inform future EPA guidance (see Section 4). This version also incorporates information received during the public comment period for the 2024 interim guidance document.

This version of the interim guidance:

- Is based on currently available information on technology performance and capabilities for destruction and disposal of the PFAS and PFAS-containing materials specified in the FY 2020 NDAA (see Section 1.b.i).

- Focuses on three widely-used, commercially available destruction and disposal technologies that may be effective for managing PFAS wastes (i.e., thermal treatment, landfills, underground injection) (see Section 3).
- Identifies research needs to inform future updates to this interim guidance (see Section 4).
- Discusses the development of emerging technologies and includes a framework for evaluating technology/PFAS material combinations (see Section 5).
- Does *not* establish what concentrations of PFAS in wastes, spent products, or other materials or media would necessitate destruction or disposal. Regulatory mechanisms are more appropriate for establishing such concentrations.
- Provides references to destruction and disposal facility locators that decision-makers can use to request cost estimates. EPA recommends obtaining cost estimates from applicable destruction and disposal facilities as described in Section 1.c.ii. In addition, Appendix D provides some cost information that PFAS material managers may want to consider when evaluating different techniques to destroy or dispose of PFAS and PFAS-containing materials. Note that cost information presented in this appendix is associated with a relatively high level of uncertainty. Moreover, the cost of PFAS destruction and disposal may change based on demand and evolution of available technologies. Additionally, overall costs may vary widely based on the type of materials or the distance to a facility.

This interim guidance is not a regulation, is non-binding, and does not pose any specific requirements on users. Discussion in this guidance of EPA's regulatory authorities is for the purpose of describing controls relevant to the destruction or disposal of PFAS and should not be considered a description of the applicability of those authorities or affect EPA's or any other agency's ability to enforce under these authorities in the future.

1.c Considerations for managing PFAS and PFAS-containing materials

The information presented in this interim guidance can help managers of PFAS or PFAS-containing materials make informed decisions regarding destruction and disposal. To assist decision-makers, EPA reviews destruction and disposal options for thermal treatment, landfills, and underground injection based on the relative potential for releasing PFAS to the environment. This approach highlights destruction and disposal options with lower potential for PFAS releases to the environment compared to other options. Also, this approach is consistent with EPA's mission to protect human health and the environment and is designed to facilitate decisions that protect human health and the environment as much as possible.

EPA recognizes that the potential to control PFAS releases to the environment is one of several factors to consider when selecting among options for destroying or disposing of PFAS and PFAS-containing materials in a way that is consistent with maximizing protection to public health and the environment. Other factors include whether it is imperative to destroy or dispose of the waste immediately, the availability of interim storage or destruction and disposal options, the type and volume of waste materials, the concentrations of PFAS in the waste, and the presence of and potential impacts to nearby communities. In the following sections, EPA provides guidance for these decisions in terms of technology considerations and infrastructure considerations.

1.c.i Technology considerations - Relative potential for PFAS releases to the environment

Using the information presented in Section 3, and considering the significant uncertainties that remain, EPA listed destruction and disposal options in terms of relative potential for releasing PFAS to the environment. When considering the data and information presented in Section 3, EPA considered the type of data available (e.g., laboratory-, pilot-, or field-scale studies), the amount of data available (e.g., data from different operating conditions), and the quality of the data.

When considering the order, it is important to note that available performance and testing data are still generally limited. Additional performance and testing data—including data on destruction and removal of PFAS in thermal treatment devices, and long-term performance data for landfills and underground injection—are needed to support more specific guidance. When these data and information become available, EPA may reconsider and revise the order presented below.

EPA is not endorsing any technology, but it is presenting the technologies' relative potential to minimize PFAS release; EPA encourages those that minimize PFAS release; managers should choose based on site specific conditions. As a general approach, EPA encourages managers of PFAS and PFAS-containing materials to prioritize destruction and disposal options with a lower potential for releasing PFAS to the environment over the use of destruction and disposal technology options with a higher potential for environmental release of PFAS given similar costs or other considerations. EPA also encourages testing with EPA-approved methods of thermal treatment operations, including PICs and the presence of PFAS in all associated waste streams (see Appendix A), to evaluate whether site-specific conditions are minimizing potential environmental releases.

While the purpose of an effective destruction and disposal technology is to prevent or minimize environmental releases, it is also important to distinguish between a potential environmental release and direct human exposure and risk.

EPA encourages managers of PFAS and PFAS-containing materials to consider the factors discussed in this guidance and select current or future disposal or destruction technologies that protect human health and the environment as much as possible. Based on currently available information cited in this guidance, EPA has listed the following disposal and destruction options from lowest to highest based on their relative potential to release PFAS to the environment:

- **Interim storage with controls.** While not a destruction or disposal method, interim storage may be a short-term option, if the destruction or disposal of PFAS and PFAS-containing materials is not imperative, on-site storage capacity is readily available, and interim storage has proper controls in place to reduce releases into the environment. Storage may be more appropriate for some PFAS materials than others. For example, EPA recommends interim storage of low volumes of containerized or high PFAS-concentration materials. In contrast, some materials may be less appropriate for storage because they are continuously generated or are typically high volume. With proper engineering controls in place, interim storage can control PFAS releases in the short term.

- **Underground injection (Class I non-hazardous industrial and hazardous waste wells).** EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high-concentration liquid PFAS waste has a lower potential for environmental release when

compared to other PFAS destruction and disposal options, and there is relatively low uncertainty in this determination. The standards associated with the construction, operation, and monitoring of these Class I wells are designed to isolate liquid wastes deep below the land surface and ensure protection of USDWs. Operators of Class I hazardous waste wells must conduct mechanical integrity testing more often than Class I non-hazardous industrial waste operators. They also must establish and follow additional procedures for reporting and correcting mechanical integrity problems. Class I hazardous waste well operators must also develop and follow a waste analysis plan and conduct annual tests of the cement in place at the base of the well. While the standards associated with Class I hazardous wells are more stringent than for non-hazardous industrial wells, EPA has determined that the probability of failures for both has been demonstrated to be low. While Class I wells are an option for managing PFAS-containing fluids, this technology may not be appropriate everywhere. The limited number of wells currently receiving PFAS, well location, and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection. Additional Class I wells may need to be constructed where geologically suitable, and existing well permits may need to be modified to meet the capacity needs for PFAS disposal (see Section 3.c.v).

- GAC reactivation units with thermal oxidizers operating under certain conditions (applies only to GAC used for PFAS removal from drinking water treatment systems). GAC reactivation systems, with the associated use of off-gas thermal oxidizers (i.e., afterburners operating at temperatures greater than 1,100°C[5]) and gas scrubbing units, can potentially destroy PFAS without significant environmental releases, or without significant PFAS remaining on the reactivated carbon. However, as discussed in Section 3.a.i, more data are needed for confirmation, particularly regarding reactor operating conditions, differing GACs, evaluating GAC used for industrial processes and site remediation, and further characterization of PICs and PIDs. There is uncertainty associated with this option because it is based on limited research. While recent studies have improved understanding, additional research is needed to resolve uncertainties on PFAS emissions from full-scale reactivation facilities (see Section 3.a.v).
- **Thermal treatment units operating under certain conditions.** HWCs, including commercial incinerators, cement kilns, LWAKs, and thermal oxidizers, that operate under certain conditions (i.e., feeding liquid PFAS-containing materials, higher temperatures greater than 1,100°C[4], well mixed, and adequate residence time) may be more effective at adequately destroying (mineralizing) PFAS and minimizing PICs. There is uncertainty associated with this option because it is based on limited research and observations, there are limited data for the treatment of solid materials or containerized wastes, and there are limited emissions data (e.g., few test reports containing data for PIC formation and the presence of PFAS in air pollution control device [APCD] residuals) at full-scale facilities (see Section 3.a.v) due to previous methodology limitations. Site-specific considerations impact the ability of any thermal treatment unit to destroy PFAS; therefore, EPA encourages site-specific testing (see Appendix A) to determine if a particulate thermal treatment unit is suitable.
- **Hazardous waste landfills (RCRA Subtitle C).** This class of landfills has the most stringent environmental controls in place for minimizing environmental releases and migration of some

[5] Maximum PIC destruction was observed at and above 1,090°C as described by Shields et al., 2023.

PFAS from disposed waste. EPA recommends Subtitle C landfills when PFAS levels of the waste are relatively high and landfill disposal is the selected option. Permitted hazardous waste landfills have relatively low quantities of landfill leachate[6], which lessens the probability of mobilizing PFAS that is reversibly bound to the waste. These landfills are required to handle and treat leachate as listed hazardous waste (hazardous waste number F039 per 40 Code of Federal Regulations [CFR] 261.31), lessening the likelihood of environmental release. Because hazardous waste landfills generally do not receive organic wastes that decompose, PFAS migration via LFG is anticipated to be relatively low but LFG collection and destruction equipment could be installed if anaerobic decomposition is demonstrated (see Section 3.b). While recent studies have improved understanding of PFAS migration, additional research is needed to resolve uncertainties (see Section 3.b.vi).

- **Landfill disposal of stable polymeric PFAS (all landfill types)**. Stable polymeric PFAS, such as polytetrafluoroethylene (Teflon™) and fluorinated ethylene propylene (FEP), are large molecules that are not susceptible to hydrolysis or oxidation. They are neither volatile nor water soluble and, as a result, they are expected to remain within the waste mass for long periods of time. This PFAS category tends not to migrate with the leachate and is unlikely to volatilize with the LFG; therefore, permitted hazardous and MSW landfills may provide a good disposal option. Some data are available to support this assessment, but more data are needed to resolve uncertainties (see Sections 3.b.i and 3.b.vi).

- Disposal of volatile or water soluble PFAS in MSW landfills that have composite liners and leachate and gas collection and treatment systems. MSW landfills receive non-hazardous waste and most have composite liners and gas collection systems. Soluble PFAS in these landfills are likely to be released over time in landfill leachate, if they are not adequately bound or sequestered in immobile solids. Further research is needed on the ability of various solidification techniques to retain soluble PFAS for extended periods under the environmental conditions found in MSW landfills. Although MSW landfills generally have leachate collection and management processes in place, the typical practices employed are not expected to prevent further PFAS migration. In addition, MSW landfills generally receive significant quantities of organic wastes (e.g., food scraps) that decompose and thereby can cause PFAS migration via LFG. Multiple studies have reported elevated levels of PFAS in leachate and LFG. Studies estimate that up to 15 percent of mobile PFAS disposed in MSW landfills is emitted to the environment over time. EPA does not recommend MSW landfill disposal of media containing relatively high concentrations of soluble or volatile PFAS. While recent studies have improved understanding of PFAS migration in MSW landfills, additional research is needed to resolve uncertainties (see Section 3.b).

- **Thermal treatment at lower temperatures** including municipal waste combustors (MWCs), SSIs, or HWCs operating at lower temperatures or feeding solid or containerized PFAS materials. Some HWCs operate at temperatures near or below 1,100°C, while MWCs typically operate between 850 and 1,000°C, and SSIs typically operate at even lower temperatures. There is uncertainty associated with this option because it is based on very limited research. Limited data indicate the possibility of air emissions of some PFAS and PICs above the detection limits at

[6] EPA defines landfill leachate as the liquid formed when rainwater filters through wastes placed in a landfill. When this liquid contacts buried wastes, it leaches, or draws out, chemicals or constituents from those wastes (*https://www.epa.gov/landfills/municipal-solid-waste-landfills*).

lower temperatures (Shields et al., 2023). No data are available regarding the treatment of PFAS-containing solid materials or containerized wastes at lower temperatures. There are currently insufficient data and information to conclude anything about PIC formation or PFAS air emissions from full-scale combustion units operating at these lower temperatures or when feeding solid materials or containerized wastes. Because insufficient data are available, there is low confidence in the reliability of this technology to control PFAS releases (see Section 3.a).

- **Disposal of volatile, water soluble, or oxidizable PFAS in construction and demolition (C&D) landfills.** This class of landfills may not have a composite liner or leachate collection system. Because of the potential for environmental releases, EPA does not recommend that PFAS waste, other than wastes containing stable polymeric PFAS, be disposed of in this type of landfill. While few studies have documented emissions of PFAS from C&D landfills, the known mobility of PFAS in landfills and lack of engineered controls at C&D landfills make them unsuitable for PFAS disposal. For these reasons, EPA does not expect that C&D landfills will minimize PFAS releases to the environment (see Section 3.b).

1.c.ii Infrastructure considerations – Communities, costs, and capacity

Waste management infrastructure in the United States is a complex and varied system, crucial for managing the vast amounts of waste generated, including PFAS-containing waste. Therefore, in addition to considering potential for environmental release, decision-makers should consider site- or project-specific factors that may influence decisions about managing PFAS-contaminated wastes. Specific factors include, but are not limited to, the composition of the waste, the types and concentrations of PFAS, transportation costs, destruction and disposal costs, and potential impacts to communities.

EPA emphasizes the importance for decision-makers (managers of PFAS-containing materials making decisions about destruction and disposal) to consider potential impacts to nearby communities when evaluating destruction, disposal, and storage options. In deciding how to address PFAS waste, site-specific considerations and waste characteristics should factor into the decision.

The waste management infrastructure's design and operation are heavily influenced by regional needs, local regulations, and technological advancements. As a result, waste management options vary by the type of waste and by location due to factors like availability, feasibility, and transportation requirements. For instance, urban areas may incur higher disposal costs due to limited space while rural areas may face higher transportation costs due to distant disposal facilities. Furthermore, technological advances specifically related to the management of PFAS-containing materials can potentially reshape the cost and operational landscape of PFAS waste management. EPA recommends that decision-makers request cost estimates directly from potentially applicable destruction and disposal facilities. In addition, decision-makers can refer to Appendix D, which summarizes the estimated costs and factors to consider when evaluating technologies for destroying or disposing of PFAS and PFAS-containing materials.

Decision-makers seeking lists of waste management sites in the United States can access various resources depending on the type of waste and location. It is important to note that often the most direct source is local government websites, such as county or city environmental services or public works departments. These websites typically provide comprehensive lists and maps of local facilities, along with their types, hours of operation, and accepted waste materials. For specialized waste like hazardous or medical waste, state environmental protection agencies or EPA are valuable resources.

EPA websites, in particular, offer databases and tools such as *RCRAInfo*[7], which provides detailed information about facilities managing hazardous waste.

A general yet incomplete list of potential treatment and disposal facilities may also be available through the EPA Incident Waste Decision Support Tool (*I-WASTE DST*[8]). This list includes landfills (hazardous waste, MSW, industrial, and C&D), HWCs, and nonhazardous combustors (sewage sludge and municipal waste), but does not include all technologies available for PFAS destruction and disposal (e.g., cement kilns, carbon reactivation facilities, and underground injection facilities). *I-WASTE DST* is updated periodically and is limited to information available online.

Similar to cost estimation, developing management capacity estimates can also be challenging. Facilities that can potentially manage PFAS-containing waste are not evenly distributed and their number and capacity vary by region. Some areas across the United States face challenges due to limited available landfill space or capacity limits. Incineration and underground injection capacities can also be greatly influenced by technological capabilities and local regulations.

2. Description of PFAS-Containing Materials Identified in the FY 2020 NDAA

The FY 2020 NDAA identifies six types of materials that commonly contain PFAS (see Figure 1-1 and the Executive Summary). This section discusses each FY 2020 NDAA material type, its origin, potential sources of PFAS, current disposal and treatment methods, and potential releases to the environment.

What's New in Section 2 of the 2026 Guidance Document?

- Information on updates and planned revisions to the PFAS 8(a)(7) reporting rule under TSCA (88 FR 70516, October 11, 2023).
- Updated biosolids generation and management information.
- Updated information on the PFAS National Primary Drinking Water Regulations.

Data on FY 2020 NDAA-relevant material types come from a variety of sources, and more PFAS data will be available from EPA-managed datasets in the near future. For example, EPA's Chemical Data Reporting (CDR) dataset includes production volumes for manufactured and imported amounts and conveys certain industrial processing and use activities. One CDR data element distinguishes the amounts that are recycled instead of discharged or released to a waste stream. In the 2020 CDR reporting cycle, submitters began using Organization for Economic Cooperation and Development (OECD)-based industrial processing and use codes to better harmonize those data (U.S. EPA, 2020a).

Additionally, EPA's *Toxics Release Inventory (TRI) program*[9] collects data related to industrial releases and waste management of certain chemicals. The TRI program covers many, but not all, industry sectors and chemicals. Additionally, some facilities with a covered sector may not meet TRI reporting criteria. The TRI dataset includes, among other information, quantities of environmental releases to all media above certain thresholds (including on-site disposals and land application), as well as quantities transferred to off-site waste management facilities, including POTW. Under Section 7321 of the FY 2020 NDAA, certain PFAS were added to the TRI list beginning with Reporting Year 2020 (U.S. EPA, 2020b). As of Reporting Year 2023 (reporting forms due by July 1, 2024), a total of 189 PFAS are on the TRI list. TRI reporting data can be accessed at the *TRI Toolbox*[10].

In October 2023, EPA finalized the PFAS 8(a)(7) reporting rule under TSCA (88 FR 70516, October 11, 2023). In accordance with obligations under TSCA, as amended by the FY 2020 NDAA, the PFAS 8(a)(7) reporting rule requires any person that manufactures (including imports) or has manufactured (including imported) PFAS or PFAS-containing articles in any year since January 1, 2011, to electronically report information regarding PFAS uses, production volumes, disposal, exposures, and hazards. The PFAS 8(a)(7) rule will help EPA better understand and develop the most comprehensive dataset of PFAS sources and quantities manufactured in the United States. In May 2025, EPA announced an interim final rule which extended the dates of the reporting period for data submissions to April 13, 2026,

[9] Available at: *https://www.epa.gov/toxics-release-inventory-tri-program/what-toxics-release-inventory*.

[10] Available at: *https://www.epa.gov/toxics-release-inventory-tri-program/tri-data-and-tools*.

through October 13, 2026. On November 13, 2025, EPA proposed revisions and exemptions to the PFAS 8(a)(7) reporting rule and also proposed to amend the start date of the submission period to 60 days after the effective date of a future final rule. On April 13, 2026, EPA published a final rule that amended the submission period for the PFAS 8(a)(7) reporting rule to begin on January 31, 2027, or 60 days following the effective date of a forthcoming final action, whichever date is earlier. This final rule solely amends the start date of the data submission period; the proposed revisions in the November 2025 proposed rule will be addressed in a future final rule.

2.a Solid, liquid, or gas waste streams containing PFAS from facilities manufacturing or using PFAS

PFAS do not occur naturally. They are synthesized for use in a diverse array of industrial and commercial applications and may be released into the environment at every step in the production process, including during synthesis, polymerization, application, transport, usage, waste stream management, and disposal (3M Company, 2000b). Industrial waste streams containing PFAS stem from two main sources: (1) primary manufacturing facilities of PFAS, and (2) secondary industries that use PFAS or manufacture finished products that contain PFAS. A 2009 survey by OECD identified 27 primary manufacturers and processors of PFAS globally (OECD, 2011). At the time of that survey, more than 90 percent of the global annual production of PFAS was generated by eight manufacturers (Posner et al., 2009), all of which participated in EPA's 2010/2015 Perfluorooctanoic Acid (PFOA) Stewardship Program (U.S. EPA, 2006).

The goal of the PFOA Stewardship Program was to reduce PFOA facility emissions and their use in products by 95 percent by 2010, compared with 2006 baseline levels, and to eliminate PFOA from all facility emissions and products by 2015 (U.S. EPA, 2006). Companies that did not participate in the PFOA Stewardship Program likely continue to use these chemical substances. Long-chain PFAS and their precursors may still be produced as unintentional byproducts and may persist in facility emissions and as product impurities in small quantities (3M Company, 1999; Boucher et al., 2019; Lehmler, 2009; Kissa, 2001). Perfluoroalkyl sulfonic acids containing six or more carbons and perfluoroalkyl carboxylic acids with seven or more carbons are generally considered to be long-chain PFAS. PFOA and PFOS are examples of long-chain PFAS, and perfluorobutanesulfonic acid (PFBS) and PFHxA are examples of short-chain PFAS. Furthermore, information on the toxicity and environmental fate and transport of alternative PFAS chemistries is limited (Sun et al., 2016; Wang et al., 2014).

For the 2020 CDR reporting cycle, 52 sites reported a total domestic manufacture and import production volume of 339,000 tons for PFAS in 2019. This represents the aggregate production volume for PFAS produced and imported into the United States across all industries. Although the aggregate production volume might not include all PFAS sources (for instance, a specific chemical or site may not meet reporting obligations), it provides a proxy quantity of all PFAS domestically produced and imported.

Table 2-1 lists examples of PFAS uses and the resulting solid, liquid, and gas waste streams for primary and secondary manufacturers of PFAS-containing materials and certain service sectors as indicated by industry, national and global inventories, and research. However, this list is not exhaustive or representative of all current uses, applications, recovery and recycling practices, or treatment technologies that could affect the volume and characteristics of the resulting waste streams. EPA recognizes the need for continued research to better characterize the multi-media PFAS-containing materials targeted for destruction or disposal, as discussed in Section 4.a.

2.a.i Solid-phase wastes

Primary manufacturing and secondary industrial use of PFAS can generate solid waste streams with PFAS-containing materials (OECD, 2011, 2015). For example, some PFAS synthesis processes can produce tars and polymers consisting of high-molecular weight byproducts that are either fully or partially fluorinated. These byproducts can be recycled back into the process or treated as waste (3M Company, 2000a, 2000b). Solid wastes such as fly ash (e.g., some thermal treatment) or spent GAC (e.g., drinking water treatment) can also be produced from PFAS incineration and other treatment processes.

Other important solid-phase materials include sludges and biosolids (see Section 2.c) that result from stabilizing or treating process waters and wastewaters, either on site or at a municipal wastewater treatment plant (WWTP)[11] that receives influent from industrial sources (Venkatesan and Halden, 2013). In addition to solids produced via treatment, spent water treatment media (such as activated carbon and ion exchange resins) are part of this waste stream (see Section 2.e). Other direct industrial sources of solid wastes containing PFAS include intentional residuals, such as cuttings and fibers from textile manufacturing (see Section 2.d), and materials unintentionally produced outside of product specification. The concentrations and composition of PFAS in solid wastes generated from primary and secondary industrial sources vary by facility and depend on factors such as facility- or industry-specific production processes and the types and quantities of PFAS produced or used (ITRC, 2020).

The characteristics of these solid-phase, PFAS-containing wastes vary significantly, depending on several factors. As discussed in Section 3.b, the type of PFAS (e.g., polymeric, soluble, or volatile PFAS) as well as the type of waste with which the PFAS is comingled (e.g., biodegradable or non-biodegradable) dictates the potential and pathways for environmental release. The type of environmental release will, in turn, inform the most appropriate disposal option(s) for each type of PFAS-containing solid waste.

2.a.ii Liquid-phase wastes

Primary manufacturers and secondary industrial users of PFAS can generate liquid-phase wastes in the form of: (1) liquid byproducts of PFAS synthesis to be recycled or disposed of (e.g., to a landfill) following stabilization, solidification, or another management method; (2) wastewater resulting from activities using PFAS as a processing aid (e.g., surfactant, emulsifier, mist suppressant, sizing agent) and production of finished products containing PFAS; (3) spills or unintentional releases of liquid wastes and products containing PFAS; and (4) AFFF/water/foam mixtures from the use of fire-extinguishing agents (see Section 2.b) for emergency response activities and emergency response training activities at industrial facilities. Table 2-1 provides examples of liquid wastes containing PFAS generated by industrial sources and their uses. This is not an all-inclusive list of industries nor waste streams.

Another liquid-phase waste stream is wastewater effluent discharged directly from a primary manufacturer or secondary industrial PFAS user. Effluent from wastewater treatment facilities that receive wastewater from industrial PFAS sources may also contain PFAS. According to several studies, conventional wastewater treatment technologies are generally ineffective at destroying or controlling PFAS (Schultz et al., 2006) and may result in higher measurable PFAAs (e.g., PFOA, perfluorooctane sulfonate [PFOS], and their homologues) when precursor compounds (e.g., fluorotelomers) are degraded during the treatment process (Buck et al., 2011; Dauchy et al., 2017a; Schultz et al., 2006;

[11] Regulations at 40 CFR part 122.2 and part 403.3 identify these “municipal wastewater treatment plants" as treatment works treating domestic sewage (TWTDS) or publicly owned treatment works (POTW), dependent on their ownership.

Sinclair and Kannan, 2006). Less often, primary industrial PFAS manufacturers have opted to transport liquid wastes off site for incineration (North Carolina Department of Environmental Quality, 2017).

2.a.iii Gas-phase wastes

Studies suggest that PFAS in air emissions from manufacturing facilities are a source of both localized (i.e., within a short radius of the facility) and long-distance (i.e., global) transport of PFAS within the environment (Davis et al., 2007; Dreyer et al., 2009). Non-volatile forms of PFAS, such as the anionic PFAAs (e.g., PFOA, PFOS, their homologues), are associated with airborne particulates when emitted as aerosols from stack emissions at primary manufacturing facilities (Barton et al., 2006; Dreyer et al., 2015). Gas phase emissions of volatile and semivolatile PFAS, and the subsequent transformation of precursor compounds into persistent PFAAs, are a potential mechanism for the atmospheric transport of PFAS. For example, volatile fluorotelomer alcohols (FTOHs) and perfluoroalkyl sulfonamides can transform into perfluoroalkyl carboxylic acids (e.g., PFOA and homologues) and perfluoroalkyl sulfonates (e.g., PFOS and homologues) which can be deposited at significant distances from their origin, and may result in soil and groundwater contamination (Dreyer et al., 2009; Ellis et al., 2004; Martin et al., 2006; Schenker et al., 2008).

Table 2-1. Examples of PFAS Waste Streams by Industry Type.
This is not an all-inclusive list of industries or waste streams

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Primary chemical manufacturing	PFAS synthesis, feedstocks for primary products, feedstocks for secondary users, processing aids (fluoropolymers).	Process byproducts (tars), sludges/residuals, off-spec materials[b], treatment residuals (GAC/anion exchange resins), spill residues (replacement and legacy), *particulate emissions.*	Degraded/stabilized process wastes, wastewater effluent, *stack emissions condensate.*	Stack emissions, fugitive volatiles.	3M Company (1999, 2000b)
Secondary Manufacturing (Industry Users of PFAS-Containing Materials)[c]					
Adhesives manufacturing	Component of solvent- and water-based adhesives, rubber to allow bonding to steel, and urea-formaldehyde adhesive resins for wood particleboard bonding.	*Used filter media and filter residues, residues of cured adhesives, empty containers, used shop rags (from cleaning), contaminated soil (from spill cleanup residues).*	*Residues of liquid adhesives, off-spec products[b], contaminated wastewater (from spill cleanup residues).* *For cleaning: equipment startup, cleaning, and flushing wastes; spent cleaning solvents; and contaminated wastewater.*	Stack emissions, fugitive volatiles.	ASC (n.d.), RadTech International North America (2010)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Cleaning product manufacturing	Component of household cleaners; car wash products; automobile waxes; wiper fluid; strongly acidic or basic cleaners for concrete, masonry, airplanes. Used for removal of adhesives, dry cleaning of textiles or metal surfaces, machine parts cleaning after nickel plating, and removal of calcium sulfate from reverse osmosis membranes.		*Off-spec products[b], liquid residues from empty containers, and spills.*	Stack emissions, fugitive volatiles.	3M Company (1999)
Computers/ electronics manufacturing	Component of sealant for electric circuits, zinc battery electrolyte, wetting agents in solders, polar solvents used before welding. Used for removal of cured epoxy resins from integrated circuit modules, treatment of insulated wire, alkaline manganese battery MnO_2 cathode treatment, production of polymer electrolyte membrane for fuel cells, cleaning of electronic components, and coating of the surface of magnetic recording devices.	*Collected airborne particulates for cleaning/surface preparation.*	*Spent acid solution for cleaning/surface preparation, liquid residues from empty containers, and spills.*	Stack emissions, fugitive volatiles.	U.S. EPA (1990)
Film/ lithography manufacturing	Used in coatings for surface tension, static discharge, and adhesion control for films, papers, and printing plates, and as a surfactant in mixtures used to process imaging films.	Rags and wipes discarded by applicator; solids coated with PFAS from processing, sampling, quality assurance; off-spec products.[b]	Solvent waste, liquid residues from empty containers, spills, and unused application mix.	Coating application exhaust	3M Company (1999), Bowden et al. (2002)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Metal plating/ fabrication	Used as a surfactant, wetting agent, and mist suppressing agent; as a wetting agent fume suppressant for chromium plating and chromium anodizing; as a dispersion product used to coat metals; as a blocking agent for aluminum foil; in plating baths; and to treat metal surfaces.	*Off-spec products.*[b]	Spent plating or etching baths, rinse water effluent, liquid residues from empty containers, and spills.	Stack emissions, fugitive volatiles.	3M Company (1999), U.S. EPA (2009b)
Oil and gas drilling/ extraction/ refinery/ support	Component of chemical barrier used for containing oil spills. Used as a surfactant for recovery in oil/gas recovery wells, a jet fuel/hydrocarbon solvent, and in hydraulic oils. Used as a gasoline/petroleum product evaporation inhibitor in storage tanks in the following forms: a floating layer of cereal grains treated with PFAS, an aqueous layer containing PFAS.		Applied product[d] (oil spills, oil and gas recovery wells), *liquid residues from empty containers, and spills.*		UNEP (2011), Kissa (2001)
Paint/coating manufacturing	Component of coatings, paints, varnishes, dyes, ink jet printer inks, and ski waxes.	*Pigment dust*	*Unused paint products, off-spec products*[b]*, liquid residues from empty containers, and spills.*	*Fugitive volatiles, atomized paint.*	Waste Management and Research Center (1992)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Paper products/ packaging manufacturing	Waterproofing and grease proofing for products including food contact paper (e.g., plates, popcorn bags, pizza box liners, food containers, wraps), non-food contact applications (e.g., folding cartons, carbonless forms, masking papers).	Dusts; *solids coated with PFAS from processing, sampling, quality assurance; off-spec products.*[b]	Spillage, cleanup, and releases during opening, rinsing, and cleaning of PFAS totes.	Fugitive volatiles	U.S. EPA (2009a)
Pesticide/ fertilizer/ other agriculture chemical manufacturing	Pesticide and herbicide ingredients and packaging.	*Particulate emissions*	*Liquid residues from empty containers, spills, off-spec products*[b]*, cleaning of equipment, and process wastewaters.*	*Fugitive volatiles*	U.S. EPA (2023)
Plastic materials/ resins/ rubber product manufacturing	Used to make membranes used in fuel cells; chlor-alkali cells; water, caustic soda, and caustic potash electrolyzers; silicone rubber sealants; composite resins; polytetrafluoroethylene (PTFE, or Teflon); and polyvinylidene fluoride or polyvinylidene difluoride (PVDF). Processing aid for PVDF manufacture, mold-release agent in foam molding, and antiblocking agent for rubbers.	Dusts, spillage (micropowders and resins), cuttings, scrap, debris, and off-spec products[b]; particulate emissions.	*Liquid residues from empty containers, spills, and unused application mix.*	Fumes from PTFE heating (volatile)	Ebnesajjad (2015)
Textiles/ apparel/ leather/ carpets/ fiber manufacturing	Dispersion products that coat fabrics: jackets, shoes, umbrellas, carpets, upholstery, leather, tents, sails.	Solids coated with PFAS from cutting, shearing, packaging, laboratory and color sampling, quality assurance; flakes or dust containing PFAS; *off-spec products.*[b]	Spills, wastewater effluent from product adhering to inside of drum, and unused application mix.	Releases of vapors and aerosols during application of surface treatment and mechanical finishing.	U.S. EPA (2009a)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Aerospace component manufacturing	Mechanical components such as tubing, hoses, and seals; brake and hydraulic fluid additive; wire and cable insulation; used in coating and paint.		*Wastewater effluent*		FluoroCouncil (2019)
Automotive component manufacturing	Mechanical components such as tubing, hoses, and seals; brake and hydraulic fluid additive; anti-mist film on windshields; used in coating/paint; used in coatings or surface treatments of textiles and upholstery.		*Wastewater effluent*		FluoroCouncil (2019), ITRC (2020)
Semiconductor manufacturing	Etching solutions for photolithography, glass etching, plastics etching, fused silica, aluminum; liquid etchant in photo mask rendering.		Spent plating or etching baths, PFOA residues from photoresist developers associated with semiconductor liquid waste streams, liquid residues from empty containers, and spills. Photoresists and antireflective coatings stripped off from semiconductor devices before shipment are present in waste solvent streams.	Photoresists and antireflective coatings stripped off from semiconductor devices before shipment are present in waste gas streams.	Bowden et al. (2002), Tremblay (2015)
Building and construction materials manufacturing	Component of cement and primers used to coat cement mortar; used in wire and cable insulation and coatings for wood particleboards.	*Cuttings and debris, off-spec materials.*[b]	*Wastewater effluent*		Buck et al. (2012), FluoroCouncil (2019), U.S. EPA (2009a)

Industry Type	Uses	Examples of Waste Streams[a]			Source
		Solid	Liquid	Gas	
Mining industry	Surfactant for recovery of metals from ores; used in ore flotation to separate metal salts from soil, electrowinning of metals, and nitrogen flotation to recover uranium.	Contaminated rock from applied product.[d]	Applied product[d]		ITRC (2020)
Medical uses	Video endoscopes; catheters; saline solutions for in vitro diagnostics; treatment/coatings for textiles such as hospital gowns, curtains, drapes; dialysis machines.	*Laboratory/medical solid wastes (e.g., tubing, filters, films).*			FluoroCouncil (2019), Posner (2012)
Cosmetics and personal care product manufacturing	Used in cosmetics, hair conditioning formulations, hair creams, and toothpaste.	*Off-spec materials*[b]	*Wastewater effluent*		Danish EPA (2018), FluoroCouncil (2019), Schultes et al. (2018)
Fire suppression systems[e]	AFFF and certain dry fire-extinguishing agents.	Contaminated soil and debris from applied product.[d]	Applied product[d]		See Section 2.b for more information. Gaines (2023)

[a] The italicized waste streams may contain PFAS, given the wastes the relevant industry sectors are known to generate and given applications of PFAS. The presence and concentration of PFAS have not been quantified.

[b] "Off-spec materials" or "off-spec products" are materials or products that do not meet specified standards or requirements and are discarded rather than sold or used.

[c] Some industries listed under "Secondary Manufacturing" may also include primary manufacturing of PFAS. The waste streams resulting from manufacture of PFAS in these industry sectors are addressed in the first row, "Primary chemical manufacturing."

[d] "Applied product" refers to the intentional application of a PFAS-containing product to the environment.

[e] Fire suppression systems, which include AFFF, are commonly found in manufacturing, storage, extraction and refining, and national defense facilities, as well as airports, fire departments, and other federal facilities (e.g., facilities operated by the National Aeronautics and Space Administration [NASA] and the U.S. Department of Energy [DOE]). Although this is an industrial use, not an industrial sector, the prevalence of AFFF in the above primary and secondary PFAS manufacturing industries warrants highlighting these waste streams.

2.b Aqueous film-forming foam

AFFFs are a group of PFAS-containing fire extinguishing agents for low-flashpoint hydrocarbon fuel fires (Tuve et al., 1964) and are intended for use where a significant flammable liquid fire hazard exists (FFFC, 2016).

AFFFs are based on synthetic fluorosurfactants that provide unique low surface tension and positive spreading coefficient characteristics. When mixed with water and applied, AFFFs form an aqueous film and a foam solution to coat the liquid fuel, seal fuel vapor, and reduce oxygen availability which extinguishes the fire and prevents burnback (FFFC, 2016; SERDP, 2020; Sheinson et al., 2002).

Until application, AFFF is managed as a concentrated product containing less than 2 percent PFAS fluorosurfactants, by weight, for a typical 3 percent AFFF concentrate (ITRC, 2020). AFFF is stored in either fixed, structural dispensing systems, such as those in hangars and aboard vessels, or in mobile, vehicle-based systems (i.e., aircraft rescue firefighting [ARFF] vehicles) (Field et al., 2017). Reserve AFFF concentrate inventory may be stored in hangars or warehouses. The amount of AFFF concentrate in the finished foam varies by manufacturer and application circumstances, but is usually between 1 and 6 percent, meaning the fluorosurfactants are diluted to less than a fraction of a percent (FFFC, 2016; ITRC, 2020).

A 2004 inventory estimated that there were 4.6 million gallons of legacy PFOS-containing AFFF in the United States (Darwin, 2011). AFFF inventory depletion is determined by frequency of use for firefighting, training, or testing; transfers between locations; and other factors. However, AFFF's characteristically long shelf life means there should be little disposal due to expiration (FFFC, 2016), increasing the possibility that legacy PFOS-containing AFFF concentrate remains in service or reserve inventories. Fluorotelomer-based AFFF surfactant products became available in the 1970s (Prevedouros, 2006). In 2017, the U.S. Department of War (DoW) edited its military specification for AFFF to include no more than 800 parts per billion (ppb) of PFOA and PFOS in the concentrate, the limit set by the DoW *Quality Systems Manual 5.1*[12]. However, this specification does not mention any other PFAS standards.

In the United States, AFFF and associated systems are or have been in service at federal facilities, civil airports, and oil refineries. Civilian fire departments also use or have used AFFF. The federal government is working to identify areas of current and former federal properties where PFOS- or PFOA-containing AFFFs have been used (Darwin, 2011; DoD, 2020). Through March 31, 2025, DoW has determined that 723 active military installations, base realignment and closure (BRAC) locations, National Guard facilities, and formerly used defense site (FUDS) properties require an assessment of PFAS use or potential release. DoW is performing preliminary assessments/site inspections (PA/SIs) at these installations, which is the first phase of the cleanup process and may take two to three years to complete. As of March 31, 2025, DoW has completed the PA/SI phase at 703 installations. The Department has determined that no further action is required at 117 of these installations, while 586 installations are proceeding to the next step in the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) process (DoW, 2025).

The FY 2020 NDAA prohibits AFFF use at any military installation, effective October 1, 2024, or up to two years later if the Secretary of War deems a waiver necessary. DoW issued a policy in January 2016 to discontinue land-based AFFF training and testing activities, unless the AFFF could be captured and properly disposed. Since then, DoW has managed any mission-critical AFFF use in response to an emergency event as a spill response to mitigate impacts to the environment (DoD, 2020; DoW, 2019). DoW, among other entities, is also investing in research and development for fluorine-free AFFF alternatives (SERDP, 2020). In 2023, DoW issued a new military specification for fluorine-free foam (MIL-

[12] Available at: *https://www.denix.osd.mil/edqw/denix-files/sites/43/2017/04/FINAL-QSM-5.1-SIGNED-010517-1.pdf*.

PRF-32725) (DoD, 2023). On *August 11, 2025*[13], DoW extended its deadline to end the use of AFFF until October 1, 2026, to provide more time to successfully transition to PFAS-free alternatives.

Examples of AFFF users and locations in the United States are listed in Table 2-2. Note that the list of sources in the table is non-exhaustive.

Table 2-2. Examples of AFFF Users and Locations in the United States

AFFF User	Locations	Comments
DoW	• Hundreds of military installations (active and former) with AFFF use. • In-service systems installed at an estimated 1,350 locations in aircraft hangars and on an estimated 3,000 ARFF vehicles.	• In 2016, DoW discontinued AFFF use for military installation training and testing unless the AFFF could be captured and properly disposed and is investing in fluorine-free alternatives. • The FY 2020 NDAA, asa modified by the FY 2026 NDAA, requires DoW to end use of AFFF at military installations by October 1, 2026 (with extensions possible until 2028). • Sources: DoD (2017, 2020); DoW (2019); CBO (2019); SERDP (2020)
NASA	• Multiple properties with AFFF apparatus. • Five properties with fixed systems.	• In late 2018, NASA issued order to cease training with AFFF. • Source: SERDP (2020)
DOE	• Lawrence Berkeley National Laboratory. • Brookhaven National Laboratory. • Los Alamos National Laboratory. • Strategic Petroleum Reserve facilities (Gulf of America).	• Sources: DOE (2021 *DOE Initial Assessment of PFAS at DOE Sites*[14]); Darwin (2011)
Airports and supporting facilities	• 523 Federal Aviation Administration (FAA)-certified civilian airports in 2018. • Since 2006, an annual average of nearly 600 certified airports. • Supporting facilities include firefighting training sites, such as the FAA Technical Center's Fire Training Area.	• Starting in 1972, FAA regulations allowed for the use of AFFF among a number of different extinguishing agents at civilian airports; since 2006, FAA guidance (FAA, 2006) provides that AFFF must conform to the applicable military specification (AC 150/5210-6 and MIL-F-23485F) at most civilian airports.[a] • 80 percent of respondents to a 2017 survey of U.S. and Canadian airports reported training-related discharge directly to the ground; two-thirds reported testing-related discharge directly to the ground. • FAA has taken steps to reduce AFFF discharges during testing since 2019. • Sources: DOT (2019); FAA (2006, 2019); Thalheimer et al. (2017); U.S. EPA (2020c)

AFFF User	Locations	Comments
Fire departments	• At civilian fire departments throughout the United States.	• AFFF may be present at fire departments. • Some states have begun inventorying and reporting having AFFF (e.g., Michigan, New Hampshire). • Some states (e.g., Vermont) have take-back programs to help local fire departments identify AFFF in inventory and assist with removal and disposal. • Sources: Michigan PFAS Action Response Team (n.d.); New Hampshire Department of Environmental Services (2020); Vermont Agency of Natural Resources (n.d.)
Ships and other vessels	• Ships and other marine vessels, including the United States Coast Guard.	• Little information is available about AFFF quantities on ships. • There has been a shift toward non-fluorinated AFFF for some uses including testing and training, though the Coast Guard has indicated that certain uses (e.g., required inspections) must continue to use fluorinated AFFF. • Source: U.S. EPA (2020e)

[a] An exception exists for airports with low departure traffic and serving aircraft less than 90 feet in length. See 14 CFR 139.317 for more information (FAA, 2006).

Fate and transport of PFAS in AFFF after use depends on the release circumstances and chemical-specific properties. Though sometimes classified as incidental releases (Thalheimer et al., 2017), equipment failure, accidental releases, or operator error can result in substantial leaks (Anderson et al., 2016; Resolution Consultants, 2016; Leidos, 2016).

Engineering controls (such as dikes, barriers, or basins) may be installed at facilities with significant flammable liquid hazards to contain foam solution and runoff for later disposal (FFFC, 2016). Where such hazards do not significantly exist, or installed engineering controls are otherwise not practicable, firefighting personnel may block sewer drains or deploy portable dikes as containment measures (FFFC, 2016). Runoff can then be pumped out, and the affected environmental media can be removed for disposal (ITRC, 2020). C&D debris originating from facilities where AFFF was historically released may also be a source of PFAS in landfills and groundwater (Solo-Gabriele et al., 2020).

Though subject to site-specific characteristics and conditions, studies demonstrate AFFF use at airports is a source of PFAS in soil and groundwater (Ahrens et al., 2015; Dauchy et al., 2017b; Høisaeter et al., 2019). Further, PFAA precursors from original AFFF concentrate products may transform in the environment to more mobile products over time (Houtz et al., 2013), expanding plumes long after AFFF use is discontinued.

2.c Soils and biosolids

As required by Clean Water Act (CWA) Section 405(d), EPA established requirements for the final use or disposal of sewage sludge when it is: (1) applied to land as a fertilizer or soil amendment, (2) placed in a surface disposal site (e.g., sewage sludge-only landfill), or (3) incinerated. The regulation at 40 CFR part 503 defines sewage sludge as "solid, semi-solid, or liquid residue generated during the treatment of domestic sewage in a treatment works." Sewage sludge includes scum or solids removed in primary, secondary, or advanced wastewater treatment processes and any material derived from sewage sludge (e.g., a blended sewage sludge/fertilizer product) but does not include grit and screenings or ash generated by the incineration of sewage. Sewage sludge treated for land application is commonly referred to as "biosolids." Part 503 considers domestic septage as sewage sludge and sets separate requirements for domestic septage applied to agricultural land, forests, or reclamation sites.

Influent that contains PFAS entering wastewater treatment facilities may result in the presence of certain PFAS in biosolids (Thompson et al., 2023; Helmer et al., 2022; Venkatesan and Halden, 2013). When biosolids are applied to land, there is the potential for leaching or runoff (Schaefer et al., 2022; Navarro et al., 2016; Lindstrom et al., 2011; Sepulvado et al., 2011; Washington et al., 2010). If landfilled instead, there are potential concerns with PFAS releases via landfill leachate and gaseous emissions, especially for highly organic material (Section 3.b). Alternatively, if incinerated, there is the potential for PFAS to be emitted as PICs (Section 3.a). Research needs and resources on possible emerging PFAS destruction technologies for biosolids (e.g., pyrolysis/gasification coupled with a thermal oxidizer and supercritical water oxidation) are discussed in Sections 4 and 5. Across disposal and destruction technologies, there are capacity concerns, and more research is needed on potential PICs/PIDs.

Total nationwide biosolids generation and management statistics in 2024 (reported to the EPA as of September 25, 2025) and data considerations are presented in Table 2-3. EPA does not have data on the volume or percentage of biosolids that contain PFAS. Additionally, EPA released the Draft Sewage Sludge Risk Assessment for PFOA and PFOS in January 2025 for public comment (U.S. EPA, 2025a).

Table 2-3. Biosolids Generation and Management in 2024

NPDES permits issued to POTW[a]	**16,109**
Biosolids NPDES permits[b]	9,834
Biosolids annual reporters (2024)[c]	2,350
Sewage Sludge generated in 2024 (dry metric tons)[d]	**4,008,886**
Land application of biosolids (dry metric tons)	2,386,861
Land disposal (also called surface disposal) (dry metric tons)	102,456
Incineration (dry metric tons)	558,360
Landfilling (dry metric tons)	879,721
Other management (dry metric tons)	81,488

[a] An NPDES permit is typically a license for a facility to discharge a specified amount of a pollutant into a receiving water under certain conditions. A POTW is a treatment works treating domestic sewage (TWTDS) that is owned, and usually operated, by a local or regional government agency (U.S. EPA, 2020b).

[b] Biosolids permits apply to any person or treatment works that prepares sewage sludge, applies sewage sludge to the land, or fires sewage sludge in a sewage sludge incinerator and to the owners/operators of surface disposal sites, as well as the exit gas from sewage sludge incinerator stacks (U.S. EPA, 2019).

[c] Annual reports are required for POTWs that have a design flow rate equal to or more than one million gallons per day, that can serve populations of 10,000 or more, that are Class I Sludge Management Facilities (POTWs required to have approved pretreatment programs or facilities classified as such by the EPA or state), or that are otherwise required to report (U.S. EPA, 2025b).

[d] The total amount of biosolids generated is reported by each treatment works treating domestic sewage (TWTDS) and may not equal the sum of component amounts reported for each management method. Biosolids totals do not represent PFAS presence in biosolids.

Release of PFAS into soils can occur through use of PFAS-containing products such as AFFF, and the discharge or application of treated industrial or municipal wastewater containing PFAS. Unintentional contact, such as spills or leaks during the production, handling, transport, or use of PFAS-containing materials can also be the source of PFAS in soils (see Table 2-4 for examples of industrial sources of PFAS in soils). Remediation wastes such as soils excavated during the cleanup of sites or during decommissioning of facilities where PFAS was manufactured, used, or applied may contain diverse mixtures of PFAS in elevated concentrations.

2.d Textiles, other than consumer goods, treated with PFAS

Because PFAS can repel oil, water, and stains, the textile industry uses these chemicals in a broad range of textile products other than consumer goods (apparel or household textiles). For example:

- PFAS can be used to treat outdoor equipment such as tents and sails (UNEP, 2011).
- Technical or occupational textiles, such as protective clothing for firefighters, can be treated with PFAS or woven from fluoropolymers (OECD, 2013).
- Medical garments can be treated with fluorinated polymers (OECD, 2013).
- Fluoropolymers can be spun into fibers and used to make sailcloth and fabric for fire suppression needs (Tokarsky and Uy, 2003).
- Textiles made from fiberglass coated or saturated with PFAS are used for high-temperature or corrosive industrial environments. Kevlar and perfluoroplastic composite textiles are used for similar industrial environments (Robco, 2020).

Examples of typical PFAS-containing waste streams generated from textiles include discarded industrial or commercial textiles such as apparel, carpets, or personal protective equipment; solids coated with PFAS from cuttings and shearing; and fugitive volatiles from spray applications of textile surface treatments. The destruction and disposal technologies used for these waste streams include landfill disposal and thermal treatment. For examples of industrial waste streams from the textiles/apparel manufacturing industry, see Table 2-4.

2.e Spent water treatment materials

On April 10, 2024, EPA announced the final National Primary Drinking Water Regulations (NPDWR) for six PFAS. On May 14, 2025, EPA announced that the Agency will keep the NPDWR for PFOA and PFOS. EPA also announced its intent to extend the PFOA and PFOS Maximum Contaminant Level compliance deadlines. Additionally, EPA announced its intent to rescind the regulations and reconsider the regulatory determinations for PFHxS, PFNA, HFPO-DA (commonly known as GenX), and the Hazard Index mixture of these three PFAS plus PFBS to ensure the determinations and any resulting drinking water

regulation follow the Safe Drinking Water Act process. Additionally, as of March 2023, 9 states have established separate state level MCLs limiting PFAS in drinking water

EPA has identified "best available technologies" for treating drinking water for PFAS to comply with the NPDWR, and these technologies will produce residuals. The 2026 Interim Guidance details options available to manage these residuals while minimizing environmental exposures and releases to the extent feasible. EPA notes that there are multiple approaches for water systems to manage PFAS residuals that are generated when PFAS is removed from drinking water. As of January 2026, there are no specific federal regulatory requirements for PFAS disposal, and the presence of PFAS in treatment residuals does not impose any additional federal requirements.

Conventional drinking water treatment methods such as coagulation, flocculation, sedimentation, disinfection, and filtration do not remove PFAS found in source water. Therefore, residues from these processes such as grit, spent membranes, or filter elements are unlikely to contain significant PFAS.

Although novel technologies for removing PFAS from drinking water sources and groundwater are being developed, current processes known to be effective are activated carbon, anion exchange resins, and high-pressure membranes (reverse osmosis [RO] and nanofiltration [NF]) (U.S. EPA, 2022a, 2022b). This section discusses the residual streams of these three processes (see Section 3 for discussions on treatment and disposal considerations, Appendix D for costs and considerations, and Section 4 for discussions of research needs for more novel treatments) and regulatory considerations for drinking water treatment utilities.

Table 2-4 shows the primary residual streams by water treatment process, with options for reactivation, destruction, and disposal of these residuals.

Table 2-4. Destruction and Disposal Options for Drinking Water Treatment Residuals Containing PFAS

Treatment Process	Residuals Generated	Destruction/ Disposal Option(s)	Section Reference
Granular Activated Carbon (GAC)	Spent GAC	Reactivation	3.a.i.2
		Incineration	3.a
		Landfill	3.b
Powdered Activated Carbon (PAC)	Spent PAC	Incineration	3.a
		Landfill	3.b
Ion Exchange	Single use and regenerative ion exchange: spent resins	Incineration	3.a
		Landfill	3.b
	Regeneration brine	Interim Storage	1.c.
		Underground Injection	3.c.ii.1
RO/NF	Brine	Permitted discharge, direct or indirect	Not described in this guidance. Refer to permit.

The practices discussed in Table 2-4, which may help reduce and/or control unintentional PFAS releases to the environment, are not presented in hierarchical order and should be chosen based on site-specific conditions.

2.e.i Activated carbon

Activated carbon (discussed more extensively in Section 3.a.i) is manufactured from carbon-rich sources such as coal or wood and is used to treat water or air by filtering contaminants (U.S. EPA, 2012). Activated carbon can be used in either PAC or GAC form. In PAC treatments, carbon is powdered and added to the water to be treated, and chemicals in the water stick to the powdered carbon as the water passes through and typically carries the PAC along. In GAC treatments, chemicals in water adsorb to small pieces of carbon in a bed as the water passes through.

PAC application will remove some PFAS from water, though the amount of PFAS removed depends on many factors. For PAC treatment, the residual stream is the sedimentation sludge or the filter backwash solids that contain the PFAS-laden PAC along with the coagulant, coagulant aids (if used), natural particulates, and enmeshed organic carbon (Dudley et al., 2015). Given the many conditions that affect treatment, the weight percent of PFAS in a PAC residual stream varies by many orders of magnitude but will be in the same range as GAC treatment, as discussed below.

For GAC, the range of PFAS concentrations on spent media can be estimated in several ways (Crone et al., 2019; U.S. EPA, 2020d). A conservatively high loading of PFAS onto GAC (using a GAC with a high-capacity potential, a strongly adsorbing PFAS, few competitive contaminants, low organic levels, and a high concentration in the feed water treated) is on the order of 2 percent by weight (e.g., 0.02 grams PFOS per gram of GAC). For more common treatment scenarios, or for PFAS that are adsorbed more weakly (i.e., the shorter-chain PFAS), the weight percent of PFAS will be orders of magnitude lower—about $1x10^{-5}$ grams PFAS per gram of GAC.

GAC can be reactivated and reused (see Section 3.a.i.2 for a discussion on GAC reactivation). If the GAC is landfilled, PFAS can desorb off the carbon into the landfill leachate if the GAC contacts a water stream that contains low PFAS, or more strongly adsorbing constituents that can displace the PFAS. Desorption will occur due to the disequilibrium between the liquid and solid phases and will accelerate at higher temperatures where adsorption becomes less favorable for exothermically-adsorbed contaminants. Therefore, the resulting PFAS concentrations in the landfill leachate impacted by spent GAC will vary greatly depending on conditions.

Typically, deep-bed GAC does not require backwashing because the particulates in the water are removed ahead of the GAC system, but there may be instances where particulates deposit onto the GAC, creating a headloss that will require backwashing. If so, the backwash water may contain a PFAS foam that may need to be managed.

2.e.ii Ion exchange resins

Like GAC, ion exchange resins are utilized in fixed-bed adsorbers. Similarly, the residual stream from this treatment is the spent media; however, ion exchange resins cannot be thermally reactivated like GAC. Due to several factors, the market is moving toward single-use media for anion exchange resin treatment with incineration as the final disposal point for the spent resin.

Final PFAS loadings onto resins vary widely. A conservatively high estimate of loading (calculated using a PFAS-selective resin, few competitive constituents, and a PFAS known to adsorb well) is expected to be in the order of 10 percent by weight for the strongly adsorbing PFAS (e.g., 0.1 grams of PFOS per gram of resin). The higher percent weight than GAC is due to the high capacities of PFAS-selective resins. Like

GAC, more typical scenarios for PFAS that are adsorbed more weakly (i.e., shorter-chain PFAS) will yield much lower average weight percent of PFAS.

Assuming single-use resin is employed, landfilling may be less expensive than incineration. If the resin is landfilled, PFAS can desorb off the resin if the resin contacts a water stream whose counter ions can displace the PFAS. The resulting leachate concentrations will vary tremendously depending on conditions. In rare cases, it may be appropriate to regenerate the ion exchange resins with a brine; however, the latest science has shown that an alcohol solvent is needed along with the inorganic exchange ion. This is difficult to do at full scale, especially for drinking water facilities. If done in this manner, the resulting regenerate brine will have high concentrations of PFAS and will need to be disposed of appropriately. In rare cases, there may not be a ready disposal option for this regenerate brine and interim storage may be appropriate. Before selecting interim storage, it is important to consider that the volume of waste which is generated routinely can accumulate up over time, and the additional waste may become more difficult to store than originally envisioned. Otherwise, regenerate brine may be handled like other high-strength liquid PFAS wastes.

Typically, resin beds do not require backwashing because the particulates in the water are removed ahead of the resin system, but there may be instances where particulates deposit onto the resin, creating a headloss that will require backwashing. If so, the backwash water may contain a PFAS foam that may need to be managed.

2.e.iii High-pressure membranes (reverse osmosis and nanofiltration)

High-pressure membranes are extremely effective for removing many PFAS from water to a high degree (Crone et al., 2019; U.S. EPA, 2020d). As high-pressure membranes are based on a rejection phenomenon, water treatment using these systems creates a waste stream with potentially high concentrations of PFAS as well as treated water with a lower pH. These waste streams also have high concentrations of salts, other contaminants, and dissolved organic matter.

Treatment of the concentrated residual stream can be challenging, and the cost will likely be high, similar to those for landfill leachates, ion exchange spent regenerates, and waters from highly contaminated sites. Many variables could affect the cost of treating these waste streams. At this time, there is no obvious treatment technology choice, especially given that the concentrated retentate stream is typically 20 percent of flow (Baruth, 2005). This represents a sizeable amount, especially for large membrane treatment systems, such as those used by large municipalities (e.g., treating 20 million gallons per day [4 million gallons per day concentrate flow]). This large-volume flow would prevent the use of batch treatment processes, which have higher efficiencies because they can process the water multiple times before discharge.

When the membranes lose their integrity or foul to the point of needed replacement, they must be disposed. It is not anticipated that the materials of construction are high in PFAS unless they are specifically made of PFAS materials (e.g., Nafion™). Also, the mass of PFAS remaining on the membrane surfaces should be minimal except in extreme cases.

2.f Landfill leachate containing PFAS

Landfill leachate (discussed in more detail in Section 3.b.iii.5) is the liquid formed by rainwater percolating through waste in landfills. Leachate generation may continue even after a landfill's closure

period, due to liquids inherent in the waste or if the cap system fails. There are different types of solid waste landfills characterized by the types of wastes managed, which also dictate the environmental controls employed. Hazardous waste landfills and most MSW landfills are required to collect the liquid leachate captured within the landfill liner and subsequently manage or treat the leachate. While PFAS concentrations in different landfill leachates have been documented (see Table 3-3 in Section 3), there are no monitoring or reporting requirements at the federal level for PFAS in landfill waste or leachate. Thus, existing treatment methods are being used to process leachate irrespective of PFAS concentrations.

Landfill leachate can be treated on site or off site. The most prevalent off-site management approach is to export leachate to a POTW or TWTDS, where it is mixed with wastewater and treated. However, as noted in Section 2.a.ii, conventional wastewater treatment technologies are generally unable to treat or control PFAS (see Table 3-4). Other off-site treatment methods include incineration and underground injection (see Sections 3.a and 3.c, respectively). The on-site leachate treatment technologies employed at landfills are explored in Table 3-2 in Section 3.b.i. Additional research is needed to determine the efficacy of landfill leachate treatments for PFAS (see Section 4).

2.g Summary

PFAS are synthetic chemicals used in a diverse array of industrial and commercial applications. Industrial waste streams containing PFAS stem from two main sources: (1) primary manufacturing facilities of PFAS chemistry, and (2) secondary industries that use PFAS-containing products and/or manufacture finished products containing PFAS. Ultimately, PFAS can end up in solid, liquid, or gas waste streams from industrial facilities that manufacture or use PFAS and PFAS-containing products. Other common PFAS-containing waste streams include AFFF, biosolids, textiles, spent water treatment materials, and landfill leachate. Any of these waste streams can contribute to PFAS entering environmental media, including soil and groundwater. The potential destruction, disposal, and treatment technologies for processing these streams are discussed in Section 3.

3. Technologies for the Destruction and Disposal of PFAS and PFAS-Containing Materials

EPA has identified three existing and potentially available destruction and disposal technologies that may be effective for managing PFAS and PFAS-containing materials. These technologies are thermal treatment (Section 3.a), landfilling (Section 3.b), and underground injection (Section 3.c). Each subsection describes various considerations for these technological solutions, including types of treatment, potential for releasing PFAS into the environment, and uncertainties. References appear at the end of each subsection. See Section 5 for a discussion of emerging technologies that show potential to destroy PFAS. See Appendix A for EPA guidance on conducting PFAS emissions field testing at commercial thermal destruction sources. See Appendix D for a summary of costs and considerations.

What's New in Section 3 of the 2026 Guidance Document?

- Section 3.a:
  - Added 2024 test reports on PFAS destruction at two incinerators (Clean Harbors and Veolia) and a recent study on treatment of HFPO-DA.
  - Discussed recent studies using sewage sludge incinerators (SSIs) and thermal oxidizers with carbon adsorbers for PFAS treatment.
- Section 3.b:
  - Discussed recent studies on using sewage sludge incinerators for PFAS treatment.
  - Added PFAS concentration data for MSW and ash landfill leachate, MSW LFG condensate, and LFG from RCRA Subtitle D landfills.
  - Added data on landfill liner permeability and gas collection systems and the implications for PFAS transport and transformation.
  - Updated the section regarding on- and off-site PFAS treatment technologies for landfill leachate.
  - Added new information on non-targeted analysis, uncertainties, and unknowns.
- Section 3.c:
  - Updated Class I well inventory using 2023 data.

3.a Thermal treatment

As the industrial and commercial use of fluorinated organic compounds has grown over the past 70 years, so has their presence and concentration in materials that need to be destroyed or disposed. Organic fluorine-containing materials including flame suppressants, refrigerants, long- and short-chain PFAS, fluoropolymers, and their precursor chemicals have been treated using a variety of thermal treatment technologies. These range from permitted HWCs and industrial furnaces to MWCs, SSIs, and thermal oxidizers designed to treat materials and process gas emissions. Compared to landfills and underground injection, thermal treatment offers the potential advantage of mineralizing PFAS and preventing further release into the environment.

Thermal treatment units generally use high-temperature combustion and incineration to destroy organic materials and control organic pollutants. Incineration is an effective and permitted method for destroying certain halogenated organic chemicals including chlorinated solvents, polychlorinated

biphenyls (PCBs), dioxin-laden wastes, brominated flame retardants, refrigerants, and ozone-depleting substances.

Combustion is described by complex sets of physical processes and elementary reactions involving many intermediate and free radical species. Even combustion of a simple fuel, such as methane, involves several hundred elementary reactions. For more complex fuels or systems that include additional elements, such as fluorine, elementary reactions can number in the thousands or more. These elementary reactions describe pathways or mechanisms whereby large molecules, such as PFAS, decompose and transform during combustion. Generally, breaking carbon-fluorine (C-F) bonds require more energy and higher temperatures than needed to break C-C, C-Cl, and C-H in analogous molecules. Due to their thermal stabilities, short-chain perfluoroalkanes such as hexafluoroethane (C_2F_6) may be good indicators of broader PFAS decomposition (Guzman et al., 2025; Shields et al., 2025a; Troxler et al., 2025; Ram et al., 2025). In addition, these short-chain perfluoroalkanes may be relatively easy to monitor by FTIR (Weber et al., 2025) and are targets measured in whole gas samples by OTM-50 making them candidates for broad PFAS thermal decomposition. The exceptional stability of CF_4 requires much higher temperatures (above 1,400°C) to destroy compared to other fluorinated organics. Thus, while unrepresentative of broader PFAS destruction, CF_4 may be a useful species during PFAS thermal destructibility trials to confirm recovery of gases by FTIR or OTM-50.

Thermal treatment of halogenated organic compounds yields the corresponding halogen acid when utilizing sufficiently high temperatures, residence times, and mixing to promote mineralization. In the case of fluorinated organics, mineralization yields hydrogen fluoride (HF), carbon dioxide (CO_2), and water. If any of these parameters are insufficient, this treatment may lead to the formation of fluorinated PICs. Some of the PICs produced in the decomposition process may have higher thermal and chemical stabilities than the parent PFAS.

Introducing PFAS directly into a hydrocarbon-based flame can assist in their adequate destruction and mineralization. The flame may provide reactive free radicals which facilitate the initial decomposition of PFAS. Hydrogen containing radicals (e.g., H and OH) and water vapor facilitate the breakdown of remaining species resulting in HF formation (Weber et al., 2025). Fluorocarbon radicals generated from incomplete thermal treatment of PFAS contribute to fluorinated PICs due to their thermal stability and propensity to undergo radical-radical recombination (Krug et al., 2022; Xu et al., 2025; Guzman et al., 2025). Thus, it is important for hydrogen to be in stoichiometric excess relative to fluorine to minimize the formation of fluorinated PICs.

Many PFAS are composed of highly stable fluorinated carbon chains and relatively weakly-bonded, non-fluorinated functional groups. Often, the functional group is easily removed, allowing the fluorinated chain to decompose or react with other radicals and create a variety of intermediates and products. For example, Shields et al. (2023) observed temperature-dependent production of 1H-perfluoroalkanes and other volatile fluorinated PICs during pilot-scale incineration of an AFFF containing PFOS and PFHxS. Additionally, Rocchio et al. (2025) and Weber et al. (2025) recently demonstrated that inadequate thermal treatment of PFOA or HFPO-DA, respectively, may lead to regeneration of shorter perfluorocarboxylic acids as PICs.

Certain thermal technologies can potentially achieve the operating conditions (e.g., temperature, residence time, turbulence) needed to adequately destroy and mineralize fluorinated organic compounds, but not every unit typically operates at these conditions. Recent data shows promise for two facilities, but data are lacking about the effectiveness of the operating conditions in different

thermal destruction technologies and facilities. Further methods development to evaluate more classes of potential PICs and testing at individual facilities are needed to help determine the overall effectiveness of thermal treatment. As a result, EPA does not have specified conditions for the adequate destruction of PFAS, but promising results inform the recommendation for comprehensive testing following procedures in Appendix A at any thermal treatment facility planning to treat PFAS-containing waste.

Hazardous waste combustion technologies (e.g., commercial incinerators, cement kilns, and LWAKs) can potentially achieve temperatures and residence times sufficient to break apart the PFAS contained in the waste stream being thermally treated, but not every unit currently operates at those conditions and those that do may not operate at those conditions at all times. To assess the capability of HWCs to destroy the materials fed into them and ensure that harmful emissions into the environment are minimized, it is standard practice to evaluate the DRE of one or several principal organic hazardous constituents (POHCs) during a trial burn. POHCs are selected to be at least as difficult to destroy as the feed material, based on an incinerability index scale (i.e., the relative level of difficulty for destroying a particular compound); however, the existing index does not include PFAS compounds. Permitted hazardous waste facilities have stringent regulatory controls on temperatures and other important operating parameters and require greater than 99.99-percent DRE for each selected POHC. Some HWC are also permitted under TSCA to incinerate PCBs and have a further requirement to demonstrate a DRE of 99.9999 percent for PCBs as well as even more stringent operating requirements with respect to residence time and temperature (40 CFR 761.70(a)(1)) when incinerating PCBs.

For HWCs, DRE is calculated based on the amount of a specific chemical (e.g., POHC) entering a thermal treatment device compared to the amount of that chemical present at the exit. While the compound selected for DRE determination in an HWC is chosen based on the difficulty of destroying it, DRE does not account for chemical transformations into different organic compounds (i.e., PICs). Thus, DRE is not an accurate indicator, by itself, of complete PFAS mineralization. Shields et al. (2023) demonstrated that PIC formation can occur even when high DRE is measured at temperatures below 1,000°C. Therefore, it is not accurate to state that a high DRE of the parent molecule by itself indicates complete destruction of all PFAS. It is difficult to ascertain the complete destruction of the added PFAS, and subsequent PICs produced due to measurement limitations. Instead, the term “adequate destruction” is used in this guidance to represent appropriate PFAS and PIC attenuation, given the gaps in accuracy of current measurement methodologies. To fully evaluate whether adequate destruction is occurring, EPA and other investigators need to sample and analyze a range of chemicals present at the outlet of a thermal treatment device, including the specific PFAS in the feed material, other PFAS beyond those in the feed (i.e., potential PICs), and other fluorinated compounds. EPA is developing test methods for measuring most PFAS before and after the incineration process, and new methods are being advanced that will provide more information in the coming years. Currently, OTM-45 is available for a targeted list of polar semivolatile PFAS and OTM-50 for volatile fluorinated compounds (VFCs). Test methods are in development for semivolatile nonpolar PFAS as surrogates for the class of PFAS compounds and fluorinated compounds (see Section 3.a.iv).

For this version of the interim guidance, PFAS destruction is defined as the severing of all carbon–fluorine bonds in a PFAS molecule and the mineralization of carbon and fluorine to HF, CO_2, and water. HF and some of the other products of combustion can be effectively removed in pollution control devices designed for acid gas removal, although more research regarding the efficacy of these technologies for controlling PFAS PICs is warranted (see Section 4).

EPA currently has limited data characterizing emissions from HWCs that burn PFAS (Focus Environmental, 2021, 2022) (see Appendix B), a comprehensive test including an evaluation of PICs at Clean Harbors in Aragonite, Utah (Troxler, et al. 2025), a comprehensive test including an evaluation of PICs at Veolia in Port Arthur, Texas (Veolia North America, 2025), and data from a pilot-scale study at an EPA research facility (Shields et al., 2023, 2025a; Weber et al., 2025). These recent tests at Clean Harbors in Aragonite, Utah (Troxler et al., 2025) and Veolia in Port Arthur, Texas (Veolia North America, 2025), which include determination of PICs, are promising and indicate that some HWCs can operate under conditions where high mineralization of PFAs and minimal formation of PIC are possible. As each HWC is optimized for the type of waste it treats, additional testing is necessary to determine if and what site-specific conditions are necessary to achieve high DRE with a corresponding minimization of PIC formation. Additional studies are necessary to more fully measure and evaluate the ability to approach complete mineralization and eliminate potential formation of PICs. EPA is working to advance new measurement methodologies (see Section 3.a.iv.1) and gather additional information to conclude whether potential PICs are adequately controlled (see 6.cAppendix A).

This section focuses on considerations associated with thermal treatment of PFAS and PFAS-containing materials and discusses:

- The types of thermal treatment units that manage PFAS-containing materials and their ability to effectively destroy PFAS.
- The potential for environmental releases during these thermal treatment operations.
- PFAS monitoring methods relevant to these thermal treatment operations.
- Uncertainties and unknowns associated with thermally treating PFAS-containing materials, including the ability to effectively measure and monitor thermal treatment performance.

3.a.i Types of thermal treatment

The following subsections describe the types of thermal treatment devices that may have directly or indirectly received and treated the PFAS-containing materials identified in Section 2.a. These subsections focus on design and operation parameters that are important for destroying PFAS. Treatment devices described here include HWCs, non-hazardous waste combustors, carbon regeneration and reactivation units, and thermal oxidizers. Waste incinerators are typically classified by the type of waste they combust. Suggested resources for locating such facilities are included in Section 1.c.ii.

3.a.i.1 Hazardous waste combustors

HWCs include hazardous waste incinerators (HWIs), cement kilns, LWAKs, boilers, and hydrochloric acid production furnaces that burn hazardous waste. Two types of HWCs that have treated PFAS waste in the United States are commercial[15] incinerators and LWAKs. Currently, no LWAKs fire hazardous waste.

[15] Commercial thermal treatment units primarily treat waste received from other facilities.

All HWCs are subject to RCRA and Clean Air Act (CAA) permitting requirements[16,17] that provide additional regulatory oversight and include operating requirements and emission limitations to safely and effectively treat regulated hazardous contaminants which may not be required for non-permitted facilities. These types of HWCs are subject to CAA Title V permitting requirements, and to maximum achievable control technology standards pursuant to Section 112 of the CAA (40 CFR part 63, subpart EEE). These standards include emission limitations for metals, dioxins/furans, particulate matter, hydrogen chloride (HCl) and chlorine gas, and carbon monoxide or hydrocarbons, as well as limits on minimum organic DRE, but do not include emission limitations for PFAS. Also, under the authority of RCRA's "omnibus" clause (Section 3005(c)(3); see 40 CFR 270.32(b)(2)), RCRA permit writers may impose additional terms and conditions on a site-specific basis as may be necessary to protect human health and the environment. Due to these additional safeguards, permitted HWCs may operate under conditions more conducive to destroying PFAS and controlling related PICs relative to thermal treatment units that do not have both RCRA and CAA permits. Further, incinerators permitted to fire liquid PCBs are required to meet even more stringent operating requirements with respect to time and temperature (40 CFR 761.70(a)(1)) when incinerating PCBs, and these operating conditions may be even more conducive to destroying PFAS and controlling PIC formation. The following sections generally describe the design and operational parameters of commercial HWIs, LWAKs, and cement kilns, focusing on parameters that are important for destroying PFAS. Design and operation information summarized for HWCs is generally based on background support documents for previous rulemakings (U.S. EPA, 2005b). Information on the numbers of HWC facilities is based on a 2019 national hazardous waste capacity assessment report (U.S. EPA, 2019) which also provides a list of these facilities. In addition to the commercial HWCs, many chemical facilities operate captive hazardous waste boilers and incinerators that only burn waste generated by that particular site or other sites owned by that parent company. These captive units may operate at temperatures lower than that of typical commercial units because of their narrow waste profile. Data gathered from commercial incinerators may not be indicative of potential control of a particular captive unit due to site-specific design and operating conditions.

3.a.i.1.1 Commercial hazardous waste incinerators

Currently, there are 10 commercial HWI facilities operating in the United States. HWIs are designed to optimize temperatures, residence times, turbulence, and other parameters to ensure compliance with organic DRE requirements.[18] Three of these facilities are also permitted for incineration of PCBs. Most commercial HWIs use rotary kilns as primary combustion chambers to facilitate the thermal treatment of containerized wastes (e.g., in drums) and solid wastes such as contaminated soils. Aqueous wastes that have low heating values may also be pumped into the rotary kiln.

The kiln maintains a continuous standing flame fueled by wastes with high heating values and auxiliary fuels that maintain high temperatures. Typically, solids retention time in the kiln is 0.5 to 1.5 hours,

[16] Hazardous waste is regulated pursuant to RCRA authority. See 42 U.S.C. 6903. The regulatory definition is found in 40 CFR 261.3. PFAS is currently not a listed or characteristic hazardous waste, but a PFAS-containing waste may meet the regulatory definition of hazardous waste if PFAS is mixed with a listed hazardous waste or if a PFAS-containing mixture exhibits a hazardous characteristic (e.g., corrosivity or another characteristic stemming from the material that is mixed with PFAS). Waste managers must comply with RCRA hazardous waste requirement for the specific regulated hazardous waste, including storage limits, land disposal restrictions, and utilizing disposal and destruction facilities that are permitted to receive hazardous wastes.

[17] Hazardous-waste-burning cement kilns and LWAKs are a small subset of the total cement kiln and LWAK universe—i.e., most kilns do not burn hazardous waste.

[18] DRE = $[1 - (W_{out} / W_{in})] \times 100\%$, where: W_{in} = mass feed rate of an organic compound into the combustion device and W_{out} = mass emission rate of the same organic compound in exhaust emissions. HWCs are required to achieve at least 99.99% DRE.

while gas residence time through the kiln is usually around two seconds. Kiln flame/solids temperatures range from 650°C to 1,650°C (1,200°F to 3,000°F) (U.S. EPA, 2005b).

After combustion in the rotary kiln, wastes may be moved to an afterburner or secondary chamber. If an afterburner is used, additional gaseous and liquid wastes with high heating values and auxiliary fuels may be added. The afterburner/secondary chamber is typically operated at about 1,100°C to 1,370°C (2,000°F to 2,500°F) with a gas residence time from one to three seconds to maximize organic destruction and minimize the formation of PICs (U.S. EPA, 2005b). Depending on the fuels used and waste streams introduced, combustion products might include CO_2, water, nitric oxide, a variety of acid gases (sulfur dioxide, hydrochloric acid, HF, etc.), organic PICs, fly ash, and bottom ash constituents. Bottom ash is removed at the end of the kiln and from the bottom of the afterburner/secondary chamber and is typically disposed of in hazardous waste landfills (see Section 3.b). Fly ash entrained in the gas is removed downstream by fabric filters (FFs) or electrostatic precipitators (ESPs), and acid gases are removed by gas scrubbers. Some HWIs use activated carbon injection systems to control mercury, dioxin/furan, and other emissions, and some also use TMT-15 (1,3,5-triazine-2,4,6(1H,3H,5H)-trithione, trisodium salt) injection for additional control of mercury and metal emissions.

EPA currently has limited data characterizing emissions from HWI that burn PFAS:

- Multi-year tests of a specially designed thermal oxidizer at a Chemours production facility (Focus Environmental, 2021, 2022, 2023, 2024), see Appendix C.
- A comprehensive test including an evaluation of PICs at Clean Harbors in Aragonite, Utah (Troxler et al., 2025).
- A pilot-scale study at an EPA research facility (Shields et al., 2023, 2025a; Weber et al., 2025).
- A comprehensive test including an evaluation of PICs at Veolia in Port Arthur, Texas (Veolia North America, 2025).

The Clean Harbors, EPA pilot-scale, and Veolia studies summarized below, and the Chemours production facility data summarized in Appendix C, provide some insight on the potential efficacy of thermal treatment in an HWI. To date, the commercial facility studies have focused on the removal of easily transformed PFAS target compounds, which is a significant limitation.

Clean Harbors Environmental Services. Two testing campaigns (2021 and 2022) were conducted at Clean Harbors Environmental Services' hazardous waste incinerator located in Aragonite, Utah (EA Engineering, Science, and Technology, Inc., PBC., 2021, 2022). These tests are summarized in detail in Appendix B. The incinerator is permitted under both the RCRA and TSCA programs. Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented PFAS Feed (Condition 2, where known amounts of four or five target PFAS were fed to the incinerator), and Post-spiking Normal Operations (Condition 3, where AFFF was included in the incinerator feed). OTM-45 (Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources) was used for stack gas sampling and analysis. The 49 targeted PFAS analytes were measured using liquid chromatography/tandem mass spectrometry (LC/MS/MS) with isotope dilution. Utilizing the available analytical methods at the time, the Clean Harbors study demonstrated a DRE for the legacy PFAS in the 99.9999-percent range at temperatures around 1,100°C. Of the 49 compounds detected by OTM-45, 34 were non-detectable in the stack gas and only 15 were detectable at extremely low concentrations. The tests appear to demonstrate that the facility's primary objective was met: "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed

during normal process operating conditions." Although a high DRE was achieved (greater than 99.999 percent) for the five selected PFAS compounds that were subjects of these studies, these tests did not collect data to fully support demonstration of adequate destruction as the production of PICs were not evaluated due to methodology limitations.

A third test campaign (conducted by EPA, Clean Harbors, and SERDP in 2024 at Clean Harbors in Aragonite, Utah) performed the comprehensive testing outlined in Appendix A (Troxler et al., 2025). During the test, PFAS-containing AFFF and nine additional PFAS were added to the incinerator along with the typical hazardous waste feeds. The gaseous, liquid, and solid end products were sampled and analyzed for the presence of PFAS and other fluorinated compounds. The kiln exit temperature during testing was greater than 1,097°C (2,006°F) and the secondary combustion chamber was operated at greater than 1,120°C (2,048°F). Results showed that the measures of the incinerator's DRE ranged from 99.95 to 99.9999 percent for the added PFAS tested under these conditions. Additionally, the analyses of the gas phase emissions showed low to non-detectable levels of VFCs that could be considered destruction of PFAS PICs using OTM-50 and SW-846 Method 0010/8270. Finally, test runs were performed with the quantitative addition of C_2F_6 with the waste streams to investigate its potential use as a surrogate compound. The resulting DRE for C_2F_6 ranged from 99.999 to 99.9999 percent and were similar to those of the other spiked compounds. These results suggest correlation between high C_2F_6 DRE and the absence of PICs. While this result is promising, more field data is required to establish C_2F_6 as an appropriate surrogate compound. There were uncertainties and limitations to the data that should be considered when evaluating the overall effectiveness of thermal treatment for PFAS.

EPA PFAS thermal destruction research. EPA completed an initial study examining the relationship between destruction efficiency (DE) and PICs (Shields et al., 2023). This study used a pilot-scale research furnace and atomized a PFOS-dominant AFFF at various furnace locations and combustion environments. These included atomization through the flame with the natural gas auxiliary fuel and at various post-flame locations so that the AFFF would experience decreasing peak temperature exposures ranging from approximately 1,200°C to 800°C (2,192°F to 1,472°F). Stack measurements included OTM-45 and OTM-50. Instead of DREs, this study calculated DEs because samples were collected before any pollution control (i.e., removal equipment), including fabric filter and alkaline wet scrubber. Analysis of the AFFF and OTM-45 samples was used to calculate DEs for 10 PFAS quantified in the AFFF. OTM-50 was used to quantify concentrations of 30 PFAS PICs. Results indicate that several idealized operating conditions with peak temperatures above 1,090°C (1,976°F) resulted in high DEs (greater than 99.99 percent) and low PIC emissions that were near or below the detection limits. However, several conditions below 1,000°C (1,832°F) yielded substantial concentrations (milligrams per cubic meter [mg/m^3]) of volatile fluorinated PICs, despite achieving over 99.99-percent DE for PFAS quantified in the AFFF. The study concluded that DE alone may not be the best indication of PFAS destruction. Additionally, EPA recently assessed thermal treatment of atomized aqueous solutions of HFPO-DA (Weber et al., 2025). Here, HFPO-DA was destroyed efficiently (DE above 99.99 percent) at peak furnace temperatures at or above 750°C, but yielded fluorinated PICs whose concentrations decreased with increasing peak temperatures.

Veolia Environment SA. Veolia conducted two test campaigns at their HWI located in Deer Park, Texas in Summer and Fall 2024 (Veolia North America, 2025). The two campaigns consisted of multiple test conditions, firing of AFFF, AFFF-contaminated soil, AFFF with lime injection (1 test run), spent activated carbon, and an assessment of CF_4 as a potential POHC (1 run). Prior to each test campaign feed variation, a baseline test run was conducted while no PFAS were fed to the combustor. In addition to

stack samples analyzed by OTM-45 and OTM-50, liquid and solid residues (scrubber blowdown, ash, slag, and filter cake) were sampled and analyzed. The kiln exit temperature during testing was greater than 816°C (1,500°F) and the secondary combustion chamber was operated at temperatures greater than 1,093°C (2,000°F). During the baseline tests, even without detectable PFAS in the waste feeds, small amounts of some PFAS were detected at the stack. Some of these were detected in the process water used in the quench, the scrubbers, and the wet ESP (WESP) indicating the possibility of the process water being a contributing source to emissions. DRE was determined for all potential PFAS, but with decreasing input, DRE determinations become less reliable indicators, as the potential noise and detection limits become dominating factors in the calculations. DRE was assessed for every target PFAS according to OTM-45. In many cases, these evaluations were not indicative of performance due to the low feed rate and detection limits at the stack. The DRE results of 20 PFAS with the highest feed rates ranged from 99.807 to 99.9999 percent. For all PFAS introduced at a feed rate greater than 0.02 lb/hr, the DRE exceeded 99.99 percent. Results of the OTM-50 sampling for volatile, nonpolar PFAs showed detectable emissions of CF_4 in only 3 of 15 sample runs (including the DRE test run where CF_4 was spiked) and a single test run where heptafluoropropyl 1,2,2,2-tetrafluoroethyl ether was detected near the method detection limit (MDL). The single spiked run of CF_4 seems to indicate that it is not appropriate as a POHC with a DRE of 43 percent for CF_4 under identical conditions to those tests showing high DRE of select PFAS and minimal PIC formation (as demonstrated by the results of the OTM-50 analysis).

These recent tests at Clean Harbors in Aragonite, Utah (Troxler et al., 2025) and Veolia in Port Arthur, Texas (Veolia Environment SA, 2025) including determination of PICs are promising, indicating that some HWCs are capable of operating under conditions where high mineralization of PFAS and minimal formation of PIC are possible. As each HWI is optimized for the type of waste it treats, additional site-specific testing is necessary to determine if, and what site-specific conditions are necessary to achieve high DRE with a corresponding minimization of PIC formation. Additional studies are necessary to more fully measure and evaluate the ability to approach complete mineralization and eliminate potential formation of PICs. EPA is working to advance new measurement methodologies (see Section 3.a.iv.1) and gather additional information to conclude whether potential PICs are adequately controlled (see Appendix A).

3.a.i.1.2 Hazardous-waste-burning cement kilns

Currently, there are 11 hazardous-waste-burning cement kiln facilities in the United States. A cement kiln is a long, cylindrical, slightly inclined rotating furnace designed to calcine a blend of raw materials such as limestone, shale, clay, or sand to produce a key ingredient of Portland cement. These cement kilns burn hazardous-waste-derived fuels to replace some of the fossil fuels needed for combustion. Most kilns burn liquid waste, although some may also burn solids and small containers containing viscous or solid hazardous waste fuels.

Extreme combustion conditions such as temperatures above 1,650°C (3,000°F), turbulent mixing, and extended gas-phase residence time (e.g., from four to as high as 16 seconds in long kilns) may effectively treat hazardous waste. Cement kilns use either ESPs or baghouses to collect particulate and metal emissions, referred to as cement kiln dust (CKD). Portions of the CKD can be fed back into the kiln as a raw material feed or used in other industries as neutralizers or additives, but usually the excess CKD is land-disposed. Add-on acid gas APCDs, such as wet or dry scrubbers, are typically not used. The high alkaline content of the raw material feeds already prevents or minimizes the formation and release of acid gases by providing for in situ absorption of chlorine and other halogens and sulfur.

Several laboratory studies have examined the potential benefit of treating PFAS wastes in cement kilns where the calcium in the raw limestone can react with fluorine to form calcium fluoride (CaF_2). These studies indicate that calcium species react readily with PFAS at relatively low temperatures (400 to 800°C) to promote mineralization of PFAS waste (Wang et al., 2011, 2013, 2015; Riedel et al., 2021). However, the currently available laboratory-scale data are insufficient to determine with confidence the effectiveness of treating PFAS waste in commercial cement kiln operations.

A cement kiln in Australia has received an operating permit from the government of Queensland to burn PFAS wastes. The permit requires annual monitoring for 21 PFAS (Department of Environment and Heritage Protection, 2018). Test results from 2017 indicate that a DRE greater than 99.99 percent is possible for specific PFAS compounds at the conditions of the test (Cement Australia, 2017), but the results do not present data on overall PFAS destruction or potential formation of PICs.

3.a.i.1.3 Hazardous-waste-burning lightweight aggregate kilns

The one LWAK facility in the United States that burned hazardous waste ceased operation in early 2024. LWAKs thermally process raw material (clay, shale, and slate) in slightly inclined, rotating furnaces to produce a coarse aggregate used in lightweight concrete products. In hazardous-waste-burning LWAKs, liquid wastes are either blended directly with conventional fuels burned in the hot end of the kiln or pumped separately into the hot end flame. High combustion gas flame temperatures (above 1,650°C [3,000°F]) and high kiln gas residence times (over two seconds) are used to destroy hazardous organics. Kiln exhaust gases leave the cold upper end of the kiln at a temperature from 205°C to 540°C (400°F to 1,000°F). LWAKs use FFs to control dust contained in the exhaust gas. The collected dust can be recycled back into the kiln (at the hot or cold end) or mixed into the lightweight aggregate product. Some LWAKs also use wet or dry scrubbing for acid gas emissions control. For example, the currently permitted hazardous-waste-burning LWAK has dry scrubbing for acid gas control. There are insufficient data to determine the effectiveness of commercial LWAK facilities in treating PFAS waste.

3.a.i.2 Carbon regeneration and reactivation units

Carbon reactivation units or "furnaces" use high temperatures to thermally desorb contaminants from GAC, which allows for the carbon to be used again. Over a dozen large-scale companies and utilities in the United States reactivate sizeable quantities of GAC. In all, these entities operate about 17 commercial furnaces (Roskill Information Services Ltd., 2017). Four of these commercial furnaces operate under RCRA permits and applicable air permits. RCRA permits provide additional regulatory oversight and include operating requirements and emission limitations to promote safe and effective treatment of the hazardous contaminants; non-RCRA-permitted carbon reactivation furnaces may not be subject to such requirements. Due to these additional safeguards, RCRA-permitted furnaces may operate under conditions more conducive to destroying PFAS and controlling related PICs, relative to furnaces without RCRA permits. This discussion focuses on RCRA-permitted furnaces because EPA has more design and operational information on these devices because of the RCRA permitting process. Reactivation[19] of spent carbon is generally carried out in multiple-hearth ("multi-hearth") or rotary kiln furnaces, although fluidized bed and infrared furnaces are also options. While the furnace designs vary,

[19] "Reactivation" refers to a regeneration process that requires high temperatures. Regeneration also includes low-temperature processes, such as those using brines, solvents, oxidants, biological treatment, etc. These processes may not be as effective as reactivation for GAC (AWWA, 2018); therefore, they are not considered for this discussion.

they all use high temperatures and residence times designed to eliminate the adsorbed contaminants and return the carbon to its original state for reuse.

During reactivation, spent GAC is typically exposed to drying, desorption, pyrolysis, and oxidation as it moves through the furnace. The drying stage eliminates moisture via evaporation and occurs when hot combustion gases at temperatures ranging from 100°C to 110°C (212°F to 230°F) contact the carbon. During the desorption stage, hydrocarbons, hydrogen, and water vapor escape the pores of the granular carbon at temperatures of 315°C to 400°C (600°F to 750°F). The pyrolysis stage eliminates any volatile compounds adsorbed within the carbon porosity, including residual moisture, and thermally decomposes other less-volatile compounds. Pyrolysis occurs when the carbon is exposed to temperatures up to 800°C (1,472°F) under inert conditions (i.e., low oxygen). A residue of carbonized char is formed from the adsorbed compounds during pyrolysis, which occupies some of the carbon porosity and must be removed in the next stage. The oxidative stage involves the controlled gasification of the pyrolyzed carbon at temperatures of around 800°C (1,472°F) in the presence of a mildly oxidizing atmosphere, usually steam or CO_2 or a mixture of both. This results in the elimination of most of the charred residue and exposes the original carbon-pore structure (Miguel et al., 2001).

The residence times required for carbon reactivation vary by unit design and the contaminant loads and concentrations. For example, two facilities using multi-hearth furnaces have residence times of at least 38 minutes at one facility and between 90 and 120 minutes at the second facility (Kentucky Energy and Environment Cabinet, 2019; U.S. EPA, 2018).[20]

To ensure adequate destruction and removal of any remaining contaminants, reactivation furnaces are typically equipped with afterburners/thermal oxidizers. To meet regulatory requirements, afterburners are designed to achieve 99.99-percent DRE via thermal oxidation. DRE for a reactivation/regeneration furnace is evaluated on a "total hydrocarbon" basis rather than for a specific most-difficult-to-destroy component, as is done for HWCs. This adds additional uncertainty to the question of whether a thermal treatment unit can effectively destroy PFAS. The temperature required to achieve 99.99-percent DRE depends on residence time as well as on the concentration of contaminants, but minimum temperatures are around 885°C (1,625°F) and maximum temperatures are as high as 1,316°C (2,400°F), with a minimum residence above one second (U.S. EPA, 2018).

Depending on the process or waste streams treated, a reactivation furnace can be equipped with add-on air pollution control equipment to ensure environmental standards are met. Equipment can include venturi scrubbers for particulate matter control, packed-bed scrubbers for acid gas and particulate matter control, and WESPs or baghouses for additional particulate matter control. As discussed in Section 3.a.ii, carbon reactivation systems can degrade PFAS even at the lower temperatures (150°C to 700°C, or 302°F to 1,292°F)

A study on a full-scale carbon reactivation furnace (DiStefano, 2022) consisting of OTM-45 and EPA Method 26A measurements of HF conducted before and after the thermal oxidizer showed DRE greater than 99.99 percent for select PFAS, with most of the destruction occurring prior to the thermal oxidizer. However, these test data do not demonstrate adequate destruction of PFAS due to the lack of data concerning PIC formation. Another recent study on a full-scale carbon reactivation furnace

[20] These two references are RCRA permits for Evoqua Water Technologies LLC and Calgon Carbon Corporation (two companies that accept spent activated carbon from off-site sources). They each hold RCRA permits, which allow them to treat spent carbon that meets the definition of hazardous waste.

(Mayerberger et al., 2025) utilized OTM-45 to calculate DREs of GAC-bound PFAS. Temperatures and operating conditions tested at this study yielded DREs greater than 99.99 percent for most detected PFAS (excluding GenX), with the majority of PFAS destruction occurring within the reactivation furnace, (i.e., prior to thermal oxidizer and other pollution control devices). The authors reported high levels of GenX in the OTM-45 test blanks, possibly due to contamination or method interference, complicating a reliable GenX DRE calculation. Additionally, OTM-50 and EPA Method 0010/8720 were employed to characterize fluorinated PICs/PIDs, resulting in no detectable PICs/PIDs at the kiln outlet and stack (e.g., pre- and post-pollution control device) locations. These results serve as a successful (albeit limited) example of adequate PFAS destruction within a GAC reactivation furnace, though subsequent demonstrations of destruction and removal of GAC-bound PFAS and secondary PICs/PIDs at similar facilities are warranted.

3.a.i.3 Non-hazardous-waste combustion sources

Non-hazardous-waste incineration units in the United States includes SSIs at wastewater treatment facilities and MWCs. Under Section 129 of the CAA, these units are regulated for emissions of particulate matter, carbon monoxide, dioxins/furans, sulfur dioxide, nitrogen oxides, HCl, lead, mercury, and cadmium. Because of these requirements, the APCDs employed by these units are intended to control these nine pollutants primarily. The following sections generally describe these incinerator types and their design and operational parameters that may influence the treatment of PFAS-containing waste (U.S. EPA, 1995).

3.a.i.3.1 Sewage sludge incinerators

An SSI is a combustion device used to combust dewatered sewage sludge. As of a 2016 EPA inventory, there are 170 SSI units operating at 86 facilities in the United States (U.S. EPA, 2016). The main types of SSIs are multi-hearth furnaces (MHFs) and fluidized bed combustors (FBCs).

The basic MHF is a vertical cylinder divided into zones. The sludge is dried at temperatures from 425°C to 760°C (800°F to 1,400°F) (U.S. EPA, 1995). Sludge combustion occurs as the temperature is increased to about 925°C (1,700°F) in successive zones. The gas residence times are typically four or five seconds. Emission controls on multiple hearths can include wet scrubbers, WESPs, afterburners, and regenerative thermal oxidizers.

An FBC consists of a vertically oriented outer steel shell with nozzles designed to deliver fluidizing air at the base of the furnace within a refractory-lined grid. Air is injected into the furnace to fluidize the sludge and the sand. The combustion of the sludge occurs at temperatures from 750°C to 925°C (1,400°F to 1,700°F). The gas residence times are typically two to five seconds. Emission controls on FBCs can include venturi scrubbers, multicyclones, FFs, activated carbon injection, and carbon bed absorbers.

There is substantial variation in the design and operation of SSIs, and it has not been shown that standard operating conditions are effective for the treatment of PFAS. A study of a laboratory-scale continuous bubbling FBC operating at 1,562°F (850°C) examined DRE for 5 PFAS. While the DRE of individual PFAS was not assessed, the total PFAS DRE (with respect to the 5 compounds) was greater than 99.9 percent. However, these test data do not demonstrate adequate destruction of PFAS due to the lack of data concerning PIC formation (Urciuolo et al., 2025). A second study of PFAS emissions from two full-scale SSIs yielded unusable OTM-45 results due to issues with the analysis of samples, and the DRE estimates provided (95 percent) are overstated due to the analytical issues. This study also showed measurable PFAS in the process water supplied to the wet scrubber, and those same PFAS in the stack

samples, but could not determine if the emissions were a result of stripping in the scrubber. Emissions of short-chain volatile PFAS (CF_4, C_2F_6, and C_3F_8) were detected using EPA Method 320, suggesting incomplete mineralization of PFAS was occurring (Winchell et al., 2024). The data currently available are insufficient to determine the effectiveness of SSIs in treating PFAS.

3.a.i.3.2 Municipal waste combustors

There are 193 MWC units operating at 75 facilities in the United States (Michaels and Krishnan, 2018). Three main classes of technologies are used to combust MSW: mass burn, refuse-derived fuel (RDF), and modular combustors. Mass burn and RDF combustors are the predominant designs. Emission controls on MWCs can include spray dryer or dry sorbent injection, ESPs, FFs, selective or non-selective catalytic reduction, and activated carbon injection.

With mass burn units, the MSW is combusted without any preprocessing other than removal of items too large to go through the feed system or hazardous materials, such as pressurized containers. In a typical mass burn combustor, refuse is placed on a grate that moves the waste through the combustor. The grate typically has three sections. On the initial grate section, referred to as the drying grate, the moisture content of the waste is reduced before ignition. Evaporated moisture is combined with the moisture from combustion and treated with the resulting combustion gases. The second grate section, referred to as the burning grate, is where most of the active burning takes place. The third grate section, referred to as the burnout or finishing grate, is where remaining combustibles in the waste are burned. Typical combustion temperatures for mass burn units can range from 800°C to 1,100°C (1,500°F to 2,012°F) (Reddy, 2016).

RDF combustors burn waste that has been processed to varying degrees to raise its heating value and provide a more uniform fuel. Most boilers designed to burn RDF use spreader stokers and typically operate at around 680°C (1,250°F). RDF-fired FBCs typically operate at bed temperatures of around 815°C (1,500°F) (Reddy, 2016).

Residence times of gases within MSW combustors vary from unit to unit, depending on design and operational factors such as furnace volume, excess combustion air percentage, use of flue gas recirculation, and combustor operating load parameters (Scavuzzo, 1990; Themelis and Reshadi, 2009). Overall combustion air residence times have been calculated in the 7- to 10-second range for a small sampling of MWC design loads (Themelis and Reshadi, 2009). At temperatures above 980°C (1,800°F), the approximate residence time is about two seconds for full combustor loads (Scavuzzo, 1990).

Research and testing of PFAS destruction performance within MWCs is extremely limited, primarily comprising laboratory- and pilot-scale studies (Aleksandrov et al., 2019; Taylor et al., 2014). For example, to assess whether PTFE is destroyed or reformed as PFAS, the Aleksandrov et al. (2019) study uses a pilot-scale rotary MWC with afterburner chamber combusting PTFE granules added to wood pellets (also firing natural gas). This study looked at a half-load scenario of 870°C (1,600°F) with a four-second residence time and a full-load scenario of 1,020°C (1,870°F) with a 2.7-second residence time. The study analyzed the flue gas samples collected for 31 PFAS compounds, which were assumed to represent a broad range of PFAS. While the laboratory- and pilot-scale studies conclude that MSW incineration of PTFE is not a significant source of PFAS, the laboratory thermal reactor and the pilot incinerator used in these studies may not be representative of the design of MWC units currently operating in the United States. These studies determined emissions, but did not assess the destruction efficiency of the laboratory thermal reactor and the pilot incinerator. For example, the pilot-scale unit in the Aleksandrov et al. (2019) study is a rotary combustion chamber followed by an upflow afterburner.

No MWC units operating in the United States have a similar configuration. In addition, while these studies conducted analysis for several PFAS species, it is important to note that there are far more PIC species possible, and no studies have thoroughly evaluated the types and quantities of PICs.

There is substantial variation in the design and operation of MSW combustors. The data currently available are insufficient to determine the effectiveness of MSW combustors to treat PFAS.

3.a.i.4 Thermal oxidizers

Thermal oxidizers are used to treat process gases and destroy volatile organic compounds (VOCs) and organic hazardous air pollutants (HAPs) at a manufacturing or production facility. Some types of thermal oxidizers are also able to accept liquid feed streams. Each thermal oxidizer is designed to optimize temperatures, residence times, and turbulence to address the composition of the particular feed stream at that unit and to meet the requirements of a regulation or permit. Depending on the type of thermal oxidizer (direct-fired, regenerative, recuperative, or flameless), the operating temperature ranges from 760°C to 1,200°C (1,400°F to 2,190°F). The residence time of thermal oxidizers ranges from 0.5 to two seconds, depending on site-specific criteria. Catalytic thermal oxidizers operate at lower temperatures than other types of thermal oxidizers—typically at about 400°C (750°F) with similar residence times to non-catalytic thermal oxidizers—while achieving the same efficiency in destruction of VOCs.

Emission controls for thermal oxidizers vary widely depending on the facility and the composition of the feed streams. Existing thermal oxidizers may have no additional pollution controls or may use prefiltration (to prevent fouling of the oxidizer) and/or wet or dry scrubbers or FFs. Thermal oxidizers have historically not been designed with destruction of PFAS as the primary focus, so most currently installed thermal and catalytic oxidizers may not be optimized for PFAS destruction. However, some thermal oxidizers are being used for halogenated wastes, including PFAS precursors. The operating conditions for some thermal oxidizers have the potential to effectively treat PFAS, but the data currently available are insufficient to determine effectiveness.

Annual testing campaigns (2020 and through 2025 tests reports are available and summarized in Appendix C) were conducted on a thermal oxidizer installed to control PFAS emissions at a Chemours chemical and plastics manufacturing plant located in Fayetteville, North Carolina. The objective of the tests was to ensure the thermal oxidizer and 4-stage scrubber system achieve a 99.99-percent emission reduction for hexafluoropropylene oxide dimer acid (HFPO-DA) and other PFAS. The test reports demonstrate a PFAS destruction efficiency above 99.99 percent for the specific compounds that were tested, although there was no discussion of possible PICs in the reports. The thermal oxidizer at the Chemours facility appropriately destroys the five PFAS compounds of interest that have been identified at the facility.

The thermal oxidizer at Chemours' Fayetteville works was sampled using OTM-50 for nonpolar VFCs that may be potential PICs. The published results and compliance data show that tetrafluoromethane was the only volatile fluorinated compound measured in the thermal oxidizer emissions (Shields et al., 2025b). The high concentrations of fluorinated compounds in the influent create high concentrations of fluorine radicals that can bond to trifluoromethyl radicals to form tetrafluoromethane that is too stable to be destroyed. From the percent-level PFAS and fluorochemical fed into the thermal oxidizer, only 2 to 4 parts per million by volume (ppmv) of tetrafluoromethane were measured. However, removal processes for more polar PICs or destruction of potential compounds not studied but potentially found in the facility waste streams are still unclear.

A test was performed in November 2021 on the regenerative thermal oxidizer at the Saint-Gobain Performance Plastics Merrimack, New Hampshire facility (Barr Engineering, 2022). This test included evaluations of OTM-45 at the inlet and the outlet of the thermal oxidizer and showed a DRE of 92 percent for PFOA and 75 percent for PFOS. However, these test data do not demonstrate adequate destruction of PFAS due to the lack of data concerning PIC formation. Further data are needed to assess the variety of configurations and operating conditions associated with thermal oxidizers, as exemplified by the broad range of DRE determinations and the lack of data on PIC formation.

3.a.ii Limitations and considerations in thermal treatments

Incinerator designs vary, resulting in differing operational and waste feed approaches (see Section 3.a.i). HWIs typically operate at very high average temperatures and employ auxiliary, primary, and secondary flames. The primary focus of hazardous-waste-burning cement kilns and LWAK is the production of cement or lightweight aggregate and not the destruction of waste, so product considerations may limit the usage of these types of units for destruction of PFAS-containing materials. MWCs typically operate at lower temperatures and often do not employ auxiliary primary or secondary flames. SSIs vary in design, often operating as dryers with very low temperatures. Even within the same incinerator, wastes can be introduced at different locations and can experience different residence time, temperature, and mixing histories. PFAS introduced into the main burner of a hazardous waste rotary kiln incinerator, along with auxiliary fuel, may experience very different conditions than the same waste introduced to the kiln as contained charges with solid wastes. These factors are expected to affect PFAS destruction and PIC formation. Limited studies have investigated the influence of various factors on PFAS destruction and PIC formation (see Section 3.a).

Carbon reactivation systems can degrade PFAS even at the lower temperatures (150°C to 700°C, or 302°F to 1,292°F) seen in bench-scale research studies (Watanabe et al., 2018). Experimental data suggest that thermal destruction of PFAS occurs in two stages: first during reactivation of the GAC, and then when the off-gas is introduced into a high-temperature zone with temperatures reaching 1,000°C (Forrester, 2018; Watanabe et al., 2016, 2018; Xiao et al., 2020). DiStefano et al., (2022) showed greater than 99.99 percent destruction of PFAS at a full-scale commercial reactivation facility with a large percentage of the PFAS destruction occurring in the furnace. The fluoride mass balance was reported to be 61.4 percent. Although this low percentage could be due to a number of factors, it may be due to the formation of PICs that were not quantitated in the analytical method. While carbon reactivation systems, with the concomitant use of off-gas incineration (i.e., afterburners) and gas scrubbing units, have the potential to remove and destroy PFAS from the activated carbon, there is insufficient data to make a determination on its effectiveness. However, as discussed elsewhere in this interim guidance, more work is needed for confirmation, particularly with regard to full-scale reactor conditions, differing carbons, and PICs.

Thermal oxidizers have historically not been designed with destruction of PFAS as the primary focus, so most currently installed thermal and catalytic oxidizers may not be optimized for PFAS destruction. However, some thermal oxidizers are being used for halogenated wastes, including PFAS precursors. Thermal oxidizers are being employed to destroy PFAS-containing and gaseous streams, but the data are insufficient to allow conclusions on the overall efficiency of thermal oxidizers, in general, for PFAS destruction. For example, annual testing at Chemours Company's Fayetteville Works (Focus Environmental, Inc., 2020, 2021, 2022, 2023, and 2024) focused on five specific PFAS of interest found in waste gas streams at the facility. While the tests seem to prove a DRE of 99.999 percent for the five PFAS compounds, they do not present data on overall PFAS destruction and the potential formation of

PICs was investigated with OTM-50 only one time (Shields et al., 2025b). The results are promising but more studies would be beneficial (see Appendix B and Appendix C for summaries of the Clean Harbors and Chemours test data, respectively). EPA is currently unaware of any catalytic oxidizers being used specifically for the destruction of PFAS, particularly considering their site-specific design and optimization. Though data on the efficacy of thermal and catalytic oxidizers in destroying PFAS is currently limited, a properly optimized thermal oxidizer can readily achieve a DRE of 99.99 percent for VOCs.

In addition to incinerators and thermal oxidizers, cement kilns are also used for the destruction of hazardous wastes. Cement kilns operate at very high temperatures (exceeding 1,800°C [3,270°F]), exhibit very large gas and solid residence times, and have the added advantage of providing a caustic environment for halogen reaction and acid neutralization. A cement kiln in Australia has received an operating permit from the government of Queensland to burn PFAS wastes. The permit requires annual monitoring for 21 PFAS (Department of Environment and Heritage Protection, 2018). Test results from 2017 indicate that a DRE greater than 99.99 percent is possible for specific PFAS compounds at the conditions of the test (Cement Australia, 2017), but the results do not present data on overall PFAS destruction or potential formation of PICs.

Processes involving calcium and alumina may have benefits and may require lower energies to destroy PFAS. Recent research (Wang et al., 2011, 2013, 2015) has investigated PFAS interactions with calcium oxide (CaO) and calcium hydroxide ($Ca(OH)_2$) at moderate temperatures (200°C to 900°C, or 390°F to 1,650°F) and found that these calcium species exhibit a pseudo-catalytic effect promoting PFAS destruction and fluorine capture at relatively low temperatures. Similar studies by the electronics industry indicate that alumina catalysts can effectively convert residual CF_4 and related species (generated by plasma arc techniques for etching purposes) to CO_2 and HF at comparable temperatures.

It is not well understood how effective high-temperature combustion is at completely destroying PFAS or whether the process can form fluorinated or mixed halogenated organic byproducts. Few experiments have been conducted under oxidative and temperature conditions representative of different field-scale incineration devices used for PFAS destruction. Limited studies on the thermal destructibility of fluorotelomer-based polymers found no detectable levels of PFOA after two seconds of residence time at 1,000°C (1,830°F) (Yamada et al., 2005; Taylor et al., 2014). Recent field studies examining the performance of a specially designed thermal oxidizer in destroying PFAS in process gases at a Chemours production facility near Fayetteville, North Carolina, indicated greater than 99.999 percent destruction of five PFAS (Focus Environmental, Inc., 2020, 2021, 2022, 2023, and 2024). Similarly, the 2021 and 2022 Clean Harbors studies appear to show that the facility was able to achieve its primary objective: “demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions.” A high DRE was achieved (greater than 99.999 percent) for the five selected PFAS compounds that were subjects of these studies (EA Engineering, Science, and Technology, Inc., PBC., 2021, 2022). However, these test data did not include characterization of potential PICs due to previous methodology limitations. More recent testing at Veolia Port Arthur (Veolia North America, 2025) and Clean Harbors (Troxler et al., 2025) included an examination of volatile PIC formation using OTM-50 and have promising results, indicating both high DRE of specific PFAS as well as minimal volatile PIC formation.

The Chemours annual tests and Clean Harbors 2021 and 2022 test results indicate the PFAS compounds measured were changed by the treatment, but the tests did not investigate PIC formation to show

adequate destruction of the original PFAS. As discussed previously, emission studies, particularly for potential PICs, are largely incomplete due to lack of validated sampling and measurement methods for the potentially large number of fluorinated and mixed halogenated organic compounds that might be formed. EPA continues to seek information on PFAS that may be present in APCD media (e.g., scrubber water, particulate matter control device media) and the presumed effectiveness of these air emission controls. The Veolia Port Arthur (Veolia North America, 2025), and 2025 Clean Harbors test (Troxler et al., 2025) both examined residuals from the control devices as well as the process water. These tests suggest that contaminated process water is a potential source of remission of PFAS into the environment. See Section 4 for more information about ongoing research and research needs.

Incineration may be a viable PFAS destruction technology if done under certain conditions. The preliminary research on thermal treatment of PFAS suggests that the minimum conditions for PFAS destruction include well mixed environments with temperatures greater than 1,100°C and optimized combustion stoichiometry (Shields et al., 2023). Full sale testing at Veolia, with the kiln operating at greater than 816°C and the secondary combustion chamber operating at greater than 1,093°C, provide results with high DRE and minimal PIC formation (Veolia North America, 2025). The Clean Harbors 2025 testing at Aragonite, Utah (Troxler et al., 2025), with the kiln operating at greater than 1,097°C and the secondary combustion chamber operating at greater than 1,120°C, also showed high DRE with minimal PIC formation. These conditions may adequately destroy PFAS and minimize PICs. However, evaluations have only been done on liquid-fired materials. No comparative studies that include PIC measurements on solids or containerized wastes have been performed. Liquids should preferably have direct flame contact or at least well mixed exposure to temperatures sufficient for adequate destruction of PFAS.

EPA encourages additional tests be performed to demonstrate the ability of thermal treatment technologies to mineralize PFAS. EPA encourages testing to demonstrate destruction of parent compounds (OTM-45) and volatile PICs (OTM-50) based on suggested procedures in Appendix A) to show efficient thermal destruction of atmospherically transformative PICs of health and environmental concern.

3.a.ii.1 Other thermal treatment byproducts of concern

Thermal treatment systems including HWIs, MWCs, and SSIs are configured such that gas-phase effluent from the combustion chambers passes through a series of pollution control devices to remove acid gases, particulate matter, and sometimes mercury and other specific HAPs. The behavior of PFAS and PFAS-related PICs in these unit operations is largely unknown (see Section 4 for more information about research on this topic and others). Additionally, these control devices produce secondary waste streams in the form of fly ash and scrubber blowdown solutions, and PFAS and PFAS-related PICs may be present in these solid and liquid effluents depending on their vapor pressure and solubility.

Thermal oxidation processes used for treating PFAS-containing waste, such as incineration, generate HF as the most stable product from combustion of fluorocarbon compounds. HF is a CAA-listed HAP and is highly corrosive, which creates significant operation and maintenance issues by damaging thermal system materials such as furnace refractory and metal ductwork. Both wet scrubbing and semi-dry scrubbing processes have been applied to control HF emissions from thermal treatment sources.

A thermal treatment system with a potential for HF emissions typically uses a wet scrubber integrated with the oxidizer to control HF emissions. In a typical system, hot flue gas exiting the thermal treatment is cooled rapidly in a quenching unit, and HF (which has high water solubility) is removed by the

quenching water. The cooled flue gas then flows up through a multistep wet scrubbing tower for further HF removal. Flue gas is scrubbed by a sodium hydroxide solution to neutralize the residual HF as the final scrubbing step. After exiting the tower, flue gas is emitted through a stack. All effluents, including those from the quenching unit and scrubber tower, are mixed with a $Ca(OH)_2$ solution in a reactor where calcium is combined with fluorine and precipitation of water-insoluble CaF_2 occurs. After dewatering, dry CaF_2 is sent to a landfill for disposal (see Section 3.b) or used to produce fluorine gas for new PFAS production, and wastewater is discharged from the plant after it is treated by activated carbon to remove trace fluorinated contaminants. Rapid cooling of hot flue gas is known to be effective in reducing catalytic reformation of chlorinated PICs such as dioxins during cooling of incineration flue gas.

A thermal treatment system equipped with a quenching unit to treat PFAS-containing wastes may also limit catalytic reformation of fluorinated PICs, if they are formed in the oxidation/combustion chamber. Those PICs may be subsequently transferred into the liquid phase in the wet scrubber and then be partitioned between solid CaF_2 and water in the precipitator (most of the PICs retained in water are then removed by activated carbon adsorption). EPA is not aware of peer-reviewed studies that measure levels of fluorinated contaminants remaining in both the treated scrubber water stream and the dry CaF_2 stream. Such measurements could be useful for evaluating the potential environmental impacts of byproducts and residuals generated from thermal oxidation of PFAS-containing wastes.

Spray dryer absorber (SDA) technology has been applied to control emissions of halogen acids (including HCl and HF) from both MWCs and HWIs. This semi-dry scrubbing process is designed to inject an alkaline slurry, typically lime, to control acid and fly ash. Water in the fine slurry droplets is vaporized by heat carried by the flue gas, and the lime carried in the droplets neutralizes the halogen acids simultaneously in this two-phase reaction process. The cooled flue gas carries the dried acid neutralization product downstream to a particle collection device, typically an FF. PAC may also be injected into flue gas upstream of the FF to control emissions of mercury and chlorinated dioxins/furans from both MWCs and HWIs. Fly ash, dried acid neutralization product, and PAC are captured by the FF. The SDA/FF with PAC injection flue gas cleaning train produces no scrubber water. The addition of lime (a calcium compound) into the flue gas is known to be effective for forming CaF_2 through hydro-defluorination of PFOS at a moderate temperature of about 350°C (660°F) (Wang et al., 2015), which suggests that the SDA may provide a potential co-benefit of controlling fluorinated PICs. The injection of PAC upstream of the FF may create another potential co-benefit for capturing fluorinated PICs. Studies evaluating PFAS mitigation via SDA/FF with PAC injection (e.g., see research activities in Section 4) will help develop data on this potentially viable technology option.

3.a.iii Potential for releases for thermal treatment technologies

Thermal treatment devices that may be used to treat PFAS-containing waste (see Section 3.a.i for descriptions of these devices) are located in both rural and more densely populated areas throughout the United States. Two possible sources of PFAS emissions from thermal treatment are stack emissions and the management of scrubber water and bottom ash/fly ash. As previously discussed, emissions from thermal treatment activities may contain PFAS if adequate combustion conditions are not achieved or if adequate acid gas scrubbers or other pollution control devices are not used. EPA is aware of a limited number of peer-reviewed studies that have investigated the extent to which emitted PFAS are transported and deposited to surrounding areas (see Section 2.a.iii). EPA plans to conduct research in this area to better characterize the extent to which PFAS deposition may occur near thermal treatment devices (see Section 4 for more information about these types of research activities).

Volatile PFAS releases from thermal treatment equipment (e.g., fugitive emissions) and waste storage activities are another potential source of PFAS releases, if they are not adequately controlled.[21] There is also the potential for releases from management of thermal treatment process residuals, such as APCD media, incinerator bottom ash, and liquids from acid gas scrubbers. For example, incinerator bottom ash disposed of in a landfill would be a possible source of release if the ash contained PFAS and the landfill lacked adequate controls (see Section 3.b for more information on landfill types and controls). HWIs, however, typically dispose of incinerator bottom ash in hazardous waste landfills, minimizing the potential for the release of PFAS to the environment.

3.a.iv Testing and monitoring

Validated measurement methods are limited and under development for reliably identifying and quantifying whether PFAS are released into the air from stationary sources. The limited scope of standardized methods to measure PFAS emissions and the limited availability of data using these methods to evaluate PFAS destruction at a variety of treatment devices introduce uncertainty in the understanding of the efficacy of thermal treatment approaches for destroying PFAS.

Ongoing method development by EPA has a broad focus that will address PFAS in various waste streams, stack and fugitive emissions, and ambient air (see Section 4 and Appendix A). Method development also includes identification of PFAS that are potential PICs, not targeted in established water methods such as Methods 533 and 537.1. Due to the number and complexity of PFAS that have already been identified, surrogates are also being investigated to determine if measurement of a single compound or a small group of compounds is adequate to characterize the completeness of thermal treatment for both targeted PFAS and potential PICs.

3.a.iv.1 Semivolatile PFAS sampling and analysis

Initial development of methods to measure PFAS in ambient air or emissions sources has focused on compounds whose physical state is liquid or solid at room temperature. Methods for measuring gas concentrations have included the target compounds commonly found in water methods. The basis for measuring PFAS compounds in ambient air or from emissions sources involves evaluating and then modifying existing sampling and analysis methods for semivolatile organic compounds.

Filtered particulate, solid sorbent, and aqueous impinger media sampling procedures have been used to collect and recover a wider range of PFAS and associated byproducts in ambient air and source emissions (Barber et al., 2007; Martin et al., 2002). However, these sampling methods have some limits, including poor retention or chemical conversion of the PFAS during sampling and poor recovery during sample preparation prior to chemical analysis (Arp and Goss, 2008).

Ambient sampling for semivolatile PFAS roughly follows either the high-volume air sampling protocol described in EPA compendium Method TO-13a (U.S. EPA, 1999) or the National Atmospheric Deposition Program (NADP) approaches for wet and dry deposition sampling (NADP, 2020). High-volume air samples collect both water-soluble PFAS acids and salts and water-insoluble telomer alcohols. NADP

[21] For example, CAA and RCRA regulations applicable to HWCs require controls to prevent/minimize combustion system leaks (e.g., due to positive pressure events in the combustion chamber), as well as controls to minimize releases from equipment and tanks that store or manage hazardous waste. See 40 CFR 63.1206(c)(5) and 264.1050–1090.

sampling has focused on condensable and particulate-bound PFAS captured in polypropylene buckets to evaluate deposition due to rain.

Current sampling of stationary source air emissions for semivolatile PFAS targets is based on EPA SW-846 Method 0010. Analysis of samples for a list of PFAS compounds is based on EPA Method 533, modified to include collection of both targeted and non-targeted PFAS in a single sampling system. Sampling includes heated or stack temperature probe extraction of emission gases followed by collection on filters, XAD sorbent media, and aqueous impingers. EPA released OTM-45 (Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources) in January 2021 and revised the method in January 2025 (U.S. EPA, 2025a). Experience indicates that OTM-45 is an effective and sensitive approach to measure a list of PFAS included in the method.

These field sampling procedures collect samples that are subsequently transported to a laboratory for extraction and analysis. Analysis procedures include those based on established water methods for targeted compounds and/or non-targeted analysis (NTA) for unknown PFAS. NTA is a research tool that can be used on OTM-45 and OTM-50 samples to investigate semivolatile polar and volatile nonpolar PFAS recovered by these methods. High-resolution mass spectrometry can be used for both targeted analysis and NTA. Qualitative identification of PFAS by NTA reveals PICs/degradants formed during the thermal treatment of PFAS-contaminated media (Aleksandrov et al., 2019; McCord and Strynar, 2019; Newton et al., 2020). NTA currently relies on mass spectrometry, which generates qualitative information about the molecular formula of unknown PFAS, is an important component in characterizing thermal treatment emissions because it provides an approach for identifying unknown PFAS or PICs.

3.a.iv.2 Gaseous volatile PFAS sampling and analysis

Volatile PFAS targets and thermal treatment byproducts from ducted emissions or in ambient air have been sampled using a variety of whole gas sample collection approaches, such as Tedlar® bags and passivated canisters, as well as sorbent traps and cryogenic solvents. EPA and private sector investigators have sampled with specialized commercial sorbent traps and Tedlar® bags in laboratory-scale thermal destruction and ambient volatile PFAS measurement of targeted and non-targeted PFAS (Wang et al., 2013, 2015; Yamada et al., 2005). Issues such as sample reactivity, breakthrough volumes, and quantitative transfer to the analysis instrument complicate these approaches. Direct instrumental methods for measuring volatile PFAS (such as FTIR) can suffer from lack of sensitivity compared with extractive methods that allow concentration prior to analysis.

EPA released OTM-50 (Sampling and Analysis of Volatile Fluorinated Compounds from Stationary Sources Using Passivated Stainless-Steel Canisters) in January 2025 (U.S. EPA, 2025b; Wallace et al., 2025) which enables analysis of non-polar VFCs and PFAS. OTM-50 utilizes silanized steel canisters to measure targeted VFCs and PICs emitted from thermal treatment facilities, as well as industrially-produced compounds (such as FC-116, HFC-23, HFC-125, E1, and E2) and potential PIDs (such as CF_4 through octadecafluorooctane). EPA is also developing the ability to characterize a more diverse set of possible PFAS PICs and measure VFCs at trace concentrations. The ability to measure trace concentrations will allow investigators to introduce a known concentration of a hard-to-destroy fluorocarbon and evaluate the behavior of this compound when exposed to specific thermal environments which is EPA's preferred approach to characterize a more diverse set of possible PFAS PICs. Though insufficient by itself, this approach is consistent with the EPA approach for determining the DRE of fluorinated greenhouse gas abatement equipment in electronics manufacturing (U.S. EPA, 2010).

NTA has also been performed on the same samples. These tools and OTM-45 are examples of monitoring methods that could be considered as additions to a potential PFAS waste management system or permit (e.g., RCRA).

EPA continues to evaluate FTIR as a suitable real-time measurement technique for volatile, non-polar fluorinated compounds (e.g., CHF_3, C_2HF_5, C_3F_8). Measurement of CF_4 and C_2F_6 by FTIR in stationary source emissions has been successfully demonstrated at pilot- (Krug et al., 2022) and commercial-scale (Troxler et al., 2025) operations. Additionally, the aluminum industry has used FTIR for several decades to monitor CF_4 and C_2F_6 formation (World Aluminium 2020). Favorable results have been noted between non-polar fluorinated PICs where both FTIR and OTM-50 were used (Weber et al., 2025; Troxler et al., 2025).

EPA has also recently investigated online chemical ionization mass spectrometry (CIMS) for measuring gas-phase PFAS compounds (Riedel et al., 2019). This technique was applied toward real-time monitoring of short-chain perfluorocarboxylic acids and other fluorinated PICs produced during pilot-scale experiments incinerating AFFFs (Mattila et al., 2024), and single-component aqueous solutions of PFOA (Rocchio et al., 2025) and HFPO-DA (Weber et al., 2025). A recent EPA-led study also used online CIMS to investigate CaO assisted thermal treatment of fluorotelomer alcohols (FTOHs) (Riedel et al., 2021). This technique performed comparably to thermal desorption-gas chromatography/mass spectrometry (TD-GC/MS) for monitoring temperature-dependent FTOH removal efficiencies. Additionally, this technique may be sufficiently sensitive for PFAS fugitive emissions and fenceline monitoring, though further research is needed to determine its efficacy for these applications.

The quantitative measurement of total organic fluorine (TOF) is also being evaluated to represent all, or most, of the PFAS class of compounds. This approach represents a simpler and more comprehensive measurement alternative to target list approaches that focus on a limited number of PFAS (Forster et al., 2023; Idjaton et al., 2024). Several potential techniques warrant consideration and additional evaluation, including (but not limited to) combustion–ion chromatography (CIC), particle-induced gamma emission spectrometry (PIGE) (Smith, et al., 2024), and X-ray photo-electron spectroscopy (XPS). For air and thermal treatment emissions, TOF must measure highly volatile as well as semivolatile PFAS. TOF analysis is an ongoing research area and data users must recognize the benefits of receiving general screening data for a wide array of potentially present PFAS, while also recognizing the limitations and uncertainties inherent in not knowing which PFAS or class of PFAS is present in the sample, including uncertainties associated with potential health risk. Non-targeted methods like extractable organofluorine/absorbable organofluorine (EOF/AOF) have higher quantitation limits (e.g., in the ppb range), which may be insufficient for capturing low PFAS concentrations in the environment. High-resolution mass spectrometry (HRMS) is crucial for identifying PFAS byproducts and degradation pathways, offering structural insight at low concentrations that EOF/AOF assays lack (Smith, et al., 2024). In addition, to minimize the risk of PFAS false positives, techniques within a validated method or methods must be developed that demonstrate effective separation and removal of inorganic fluorine from organic fluorine (Koch et al., 2020). TOF is not specific to PFAS, and any fluorine-containing compounds (e.g., pesticides, pharmaceuticals) that are retained during extraction would be included in the organic fluorine measurement.

HF measurement is included in stationary source measurements to evaluate emissions and control efficiency of HF as a HAP at emission outlets. Multiple studies of PFAS thermal decomposition and HF monitoring have demonstrated that EPA compliance methods for HF measurement are adequate to

meet this need. However, HF is difficult to transport through treatment and control equipment and is therefore not a candidate for using a mass balance approach to evaluate PFAS destruction efficiency. GC-HRMS is essential for analyzing volatile organofluorine compounds in gaseous emissions due to the difficulty of direct quantification without reference standards. Consideration should be given to closing the fluorine mass balance by combining non-targeted methods like EOF and total oxidizable precursor (TOP) analyses with targeted studies (Smith et al., 2024).

3.a.v Uncertainties/unknowns

EPA is planning to collect additional information and conduct additional research to better understand PFAS destruction and evaluate emission control efficiency (see Section 4). EPA is also working to develop a standardized validated methodology for measuring PFAS gaseous emissions (see Section 3.a.iv); however, EPA lacks detailed information on the amounts and concentrations of PFAS-containing materials that are generated and managed in thermal treatment devices.

Development of sampling and analytical methodologies must continue (see Section 4 research activities) so that emissions and other media from thermal treatment devices burning PFAS-containing materials can be adequately characterized.

Uncertainties such as the overestimation of destruction and disposal capabilities, or a failure to account for potential PIC production and subsequent transformation back to PFAS of concern, could have consequences for all nearby communities.

To reduce uncertainties and provide more detailed recommendations, further data on the ability of thermal treatment units to mineralize PFAS-containing materials is necessary (see Appendix A and Section 4.a). Performance testing of all types of combustors is lacking. EPA recommends that full-scale thermal destruction facilities conduct performance testing prior to accepting and processing PFAS materials. Objectives of the testing should include:

- Demonstrating destruction of parent compounds and potential production of semivolatile and volatile PICs (using OTM-45 and OTM-50) to show efficient thermal destruction.
- Characterizing PFAS being fed, including the feed rate, whether it is a concentrated or diluted stream, and how the PFAS are fed (e.g., containerized or direct feed).
- Demonstrating utilization of key combustion parameters (temperature, residence time, other conditions that impact mineralization) and including relevant data in the report.
- Characterizing release of PFAS and PICs through the system by sampling at multiple points in the process (e.g., before and after a scrubber) and sampling all relevant effluent streams (e.g., scrubber blowdown and fly ash). Documenting and reporting operating parameters for all relevant control devices to EPA and relevant state, territorial, or Tribal authorities.

Further details on suggested parameters and procedures are provided in Table 4-1 and Appendix A.

3.a.vi Treatment commercial availability

Section 3.a.i describes the commercial availability of thermal treatment devices. The United States has about 22 commercial HWC facilities[22] in operation, including over a dozen large-scale, commercial

[22] This includes commercial incinerators, cement kilns, and LWAKs that are permitted to burn hazardous waste.

carbon reactivation companies with approximately 17 furnaces, 193 MSW incineration units at 75 facilities (as of 2018), and 170 SSIs at 86 facilities (as of 2016).

3.a.vii Summary

PFAS-containing waste can potentially be treated in several types of thermal treatment devices, including HWCs, MWCs, SSIs, and activated carbon reactivation furnaces, but further research is needed to gain a better understanding of what may be possible in practice. These treatment devices operate differently and handle different types of PFAS-containing media with varying concentrations. Even within the same category of thermal treatment device, designs and operating conditions may vary across sources ways that could affect PFAS treatment efficiency. As a general approach, EPA encourages decision-makers to prioritize the use of destruction and disposal technologies that have a lower potential for PFAS release to the environment, over destruction and disposal technology options with a greater potential for environmental release of PFAS given similar costs or other considerations. EPA acknowledges that each destruction and disposal technology has limitations. However, managing PFAS to minimize environmental releases during destruction and disposal activities supports protection of human health and the environment.

There are limited characterizations of potential PFAS emissions from thermal treatment devices that burn PFAS-containing media, with a few tests at HWIs and a single test at a thermal oxidizer with a more complete emissions characterization, but EPA is not aware of any full emission characterizations that have been conducted at HWCs, MWCs, SSIs, or activated carbon reactivation furnaces or any studies to evaluate the formation of PICs resulting from inefficiency to convert PFAS into CO_2 and HF. EPA is also not aware of any studies that have been conducted on the extent to which PFAS contaminants partition to APCD residuals or bottom ash, which may also be a concern. This is likely (in part) because PFAS emission measurement methods and other analytical methodologies (e.g., for fly ash, other waste streams) are limited and continue to be developed. Data, however, from pilot-scale experiments conducted by EPA researchers suggest that temperatures above approximately 1,100°C (2,012°F) may result in high destruction efficiencies and few detectable fluorinated PICs.

Given the unique characteristics of fluorine combustion chemistry (particularly the strength of the carbon–fluorine bond), adequate thermal destruction of PFAS requires high temperatures and long residence times and likely benefits from direct flame contact. Hazardous waste combustion technologies (commercial incinerators, cement kilns, and LWAKs) can potentially achieve temperatures (~1,100°C [2,012°F]) and residence times sufficient to break all C-F bonds in the PFAS contained in the waste stream being thermally treated. Permitted hazardous waste facilities have stringent regulatory controls on temperatures and other important operating parameters to achieve a 99.99-percent and greater destruction efficiency for other (non-PFAS) organic chemicals. These facilities also have APCDs to prevent certain gaseous and particulate pollutants from entering the atmosphere. However, information on the efficacy of PFAS destruction in these facilities is currently limited and EPA has limited data characterizing PIC emissions from these sources when they burn PFAS. EPA is working to develop measurement methodologies as well as to gather information to conclude whether PICs are adequately controlled. EPA recognizes that PICs are inevitable (even for nonfluorinated compounds); however, based on the unique characteristics of fluorine combustion chemistry, EPA believes it is important to determine whether thermal treatment devices and their associated post-combustion control devices are adequately controlling PICs, especially fluorinated PICs. Given all these factors, there is a current need to continue research activities investigating incineration of PFAS. After sufficient research has been

completed to address the related knowledge and data gaps, EPA can make a more informed recommendation on disposal of PFAS compounds and PFAS-containing substances using incineration.

Similar conclusions can be drawn for activated carbon reactivation furnaces as for HWCs. Experimental data suggest that thermal destruction of PFAS will occur in two stages: first during reactivation of the GAC, and then when the off-gas is introduced into a zone with temperatures as high as 1,000°C (1,832°F). As referenced in Section 3.a.i, an activated carbon reactivation furnace can be equipped with an afterburner to treat off-gases at high temperatures to achieve 99.99 percent DRE of VOC. In addition, scrubbers can be installed to remove acid gases. This is a promising treatment method, but more information is needed, including confirmation that PICs are controlled based on actual operations, establishment of standard operating conditions for activated carbon reactivation furnaces of various designs to ensure optimal destruction of PFAS, and an understanding of how thermal treatment influences the physical and chemical properties of GAC (in ways that can affect GAC's adsorption behavior and sorption capacity for PFAS).

Research and testing of PFAS destruction performance within MWCs is extremely limited, primarily comprising laboratory- and pilot-scale studies (Aleksandrov et al., 2019; Taylor et al., 2014). While the laboratory- and pilot-scale studies conclude that MSW incineration of PTFE is not a significant source of PFAS, the laboratory thermal reactor and the pilot incinerator used in these studies may not be representative of the design of MWC units currently operating in the United States. In addition, while these studies analyzed several PFAS species, it is important to note that there are far more PIC species possible, and no studies have thoroughly evaluated the types and quantities of PICs.

As noted earlier in this section, Wang et al. (2013) investigated PFAS interactions with CaO and $Ca(OH)_2$ at moderate temperatures (200°C to 900°C, or 390°F to 1,650°F), both with and without sewage sludge. These experiments were conducted in a laboratory (i.e., combustion in a crucible within a muffle furnace) and found that these calcium species exhibit a pseudo-catalytic effect promoting PFAS destruction and fluorine capture at relatively low temperatures. The study did not investigate the evolution of PICs during the thermal treatment process. While this study shows promising results for the use of catalysts to achieve PFAS destruction and fluorine capture at low temperatures, along with the potential for full-scale application (since lime is occasionally added to sewage sludge to control odor at SSIs), it is important to note that, as with the MWC studies described above, there are caveats for applying these results to the real-world design and operation of SSIs.

More research is needed to address these issues and develop reliable measurement techniques. Section 4 summarizes EPA's continuing PFAS research, as well as a general proposal to collaborate with stakeholders to address these uncertainties promptly. See Appendix D for a summary of costs and considerations.

3.b Landfills

RCRA regulations define a landfill as "an area of land or an excavation in which wastes are placed for permanent disposal, and that is not a land application unit, surface impoundment, injection well, or waste pile" (40 CFR 257.2). The goal of solid waste landfills is to contain waste and thereby restrict the release of pathogens and contaminants within the landfill from entering the environment. Landfills are commonly classified by the types of waste they accept and/or by their ownership status.

Landfills control waste and corresponding pollutants through containment. Because of their many and varied uses, PFAS enter landfills as part of the general MSW stream, in industrial waste, or in other PFAS-containing wastes, with a range of concentrations. The two major categories of landfills under RCRA are Subtitle C hazardous waste landfills and Subtitle D non-hazardous waste landfills. Subtitle D landfills include MSW landfills, ash monofils, C&D debris landfills, and industrial landfills. These landfills are required to have different types of control technologies depending on the types of wastes they are designed to contain (see Table 3-2) and, therefore, they can vary in their effectiveness to control releases of PFAS. In addition, there is a subclass of small landfills in the United States that are exempt from RCRA requirements 40 CFR 258.1(f).

The PFAS loading into different types of landfills will also vary markedly depending on the sources and types of wastes they receive. MSW landfills, for example, can include a diverse array of wastes with highly variable PFAS concentrations (e.g., household waste, biosolids, remediation wastes). In contrast, concentrations in wastes from industries that use PFAS directly in their operations (e.g., leather tannery, chrome plating, textile industry waste) can be considerably and consistently higher (USCPSC and RTI International, 2023; Gilchrist, 2022).

The behavior of PFAS in landfills is a complex and multifaceted process that involves various abiotic and biotic transformation and partitioning pathways. While the exact mechanisms and rates of transformation are not fully understood, both aerobic and anaerobic conditions in landfills have been demonstrated to facilitate conversion of PFAS precursors into more persistent, terminal PFAS species. The behavior of these terminal PFAS can differ markedly from precursors. While some information is available, EPA continues to collaborate with industry and the academic community to conduct research to address information and data gaps (see Section 4), including efforts to better understand the effects of PFAS on liner integrity, gaseous emissions from landfills, the effectiveness of leachate treatment for PFAS removal, and the levels and types of PFAS in landfill leachate.

As described in more detail in Section 3.b.i, while generalizations can be made for the properties of classes of PFAS (e.g., perfluoroalkyl acids, fluorotelomer carboxylic acids [FTCAs]), each class encompasses a wide range of physical-chemical properties based on the molecular structure of the individual PFAS, such as chain length. For example, while many perfluoroalkyl acids have high aqueous solubility, the degree of solubility decreases markedly at higher chain lengths. FTCAs are likewise regarded as soluble, but have also been measured in LFG and LFG condensate. Work is still ongoing to better understand the constraints of and conditions that promote transformation and partitioning.

While landfills are designed to serve as long-term containment sites, it is unclear how effective they are at containment of water-soluble or volatile PFAS for an extended duration. PFAS will not break down under the environmental conditions found inside a landfill; consequently, PFAS will persist in landfills for the life of the compounds. Therefore, since landfills are a containment rather than destruction method, landfills will emit volatile and soluble PFAS as long as LFG and leachate generation continue.

Section 3.b focuses on the viability of landfilling as a means of controlling releases of PFAS from contaminated wastes, including consideration of:

- The types of PFAS in wastes and how they behave within a landfill.
- The types of landfills that receive PFAS-containing waste.
- The types of environmental control technologies used for landfills and their ability to effectively contain or remove PFAS.
- The potential for environmental releases of PFAS associated with landfilling.
- Recommendations for deciding what type of landfill is most appropriate for PFAS-containing waste.
- Methods to monitor PFAS at landfills and corresponding waste streams.
- Uncertainties and unknowns associated with landfilling PFAS-containing waste.

3.b.i Types of PFAS and Potential for Release from Landfills

As described in Section 1 ,the term PFAS refers to very large group of synthetic chemicals that due to their strong carbon-fluorine bonds, can be very persistent in the environment. EPA's ***CompTox Chemicals Dashboard*** [23] maintains a master list of more than 12,000 chemicals that are potential PFAS, including 10,200 chemicals containing a specific defined structure and an additional 1,300 without explicit structures (polymers and other chemical substances of unknown or variable composition). It is not known how many of these compounds are in production or have already come to be disposed of in landfills. NTA techniques have identified as many as 651 different PFAS compounds in landfill leachate from China (Liu et al., 2022a). This number may increase as the ability to detect and measure PFAS further evolves. When disposed of in a landfill, different types of PFAS compounds may behave differently from one another and may require different considerations for the types of landfills that are suitable for disposal and the types of emissions controls that are necessary to contain the PFAS over time.

Descriptions of the different types of PFAS provided below are specific to the landfills section and are intended to provide context regarding PFAS release from landfills (e.g., in landfill leachate or in LFG).

PFAS Polymers. Stable PFAS polymers (e.g., PTFE or Teflon™) are generally inert, insoluble, and non-volatile and are unlikely to be released via landfill leachate or LFG. Stable polymers are less likely to migrate within a landfill by partitioning to the gas or liquid (i.e., leachate) phases. However, soluble and volatile PFAS have been identified in fluoropolymers as synthesis byproducts or incomplete reactants. Although stable polymers are highly resistant to chemical and thermal degradation, they can still be broken down by weathering and physical strain, increasing their dispersion and bioavailability (Lohmann et al., 2020). For example, studies have shown that physical abrasion of the polymers can create fluorinated microplastics that are then suspended in landfill leachate (He et al., 2019). However, because exposure to ultraviolet radiation and physical disturbance of the waste are expected to be relatively low after final placement in landfills, the bulk of stable polymers would be expected to be retained for a long duration. Side-chain fluorinated polymers (SFPs), which can be fluorotelomer- or perfluoroalkyl sulfonyl fluoride-based, are distinct from stable PFAS polymers in that they include fluorocarbon groups attached to a non-fluorinated backbone. The fluorinated side chains on SFPs can

[23] Available at: *https://comptox.epa.gov/dashboard/*.

cleave to form volatile or soluble PFAS. As such, EPA recommends using similar controls as are recommended for soluble PFAS. Information about the fate and transport of SFPs is limited.

Soluble PFAS. For the purposes of this section, soluble PFAS are those that would be found in landfill leachate. PFAS monomers, including perfluoroalkyl acids (e.g., PFAAs, PFOA, PFOS, PFHxS, PFBA, HFPO-DA) and precursors that can ultimately degrade to these acids, more readily and rapidly partition into landfill leachate than other types of PFAS due in part to ready dissociation of these compounds into anions over the range of pH values typically encountered within landfills. Landfills without an appropriate liner and leachate collection system (see Section 3.b.iii) may allow leachate containing these soluble PFAS to flow into the subsurface and enter groundwater. Note that longer-chain PFAS are less soluble (Lyu et al., 2022) and have higher affinity for solids. Therefore, C_9 (perfluorononanoic acid) and greater chain length perfluoroalkyl acids are less likely to stay in the aqueous phase (Kurwadkar et al., 2022).

Volatile PFAS. For the purposes of this section, volatile PFAS are those that would be found in LFG. Alcohols (e.g., FTOHs and FASEs) and precursors that degrade to volatile PFAS can partition into the gas phase and be emitted from landfills in LFG due to the shorter chain length and non-ionic structure associated with higher vapor pressures. The rate of volatilization may be influenced by site conditions, such as landfill temperature, and co-occurrence of other LFG. Landfills without appropriate LFG collection and control systems in place and operating (see Section 3.b.iii.6) may result in fugitive emission to surrounding ambient air.

For example, FTCAs are soluble intermediate transformation products of volatile precursors such as FTOHs (Wang et al., 2025). Accumulation of FTCAs has been documented under biologically active, anaerobic landfill conditions, and their presence in groundwater is considered an indicator of landfill leachate contamination. For this reason, volatile PFAS-containing wastes should be managed in landfill environments which are also appropriate for soluble PFAS disposal.

The environmental and health risks associated with different methods for PFAS destruction remain the subject of emerging research. In the interim, while alternate management methods are developed, EPA recommends that the focus of land disposal strategies be on minimizing releases from landfills. This includes low-permeability liner and gas collection systems installed prior to disposal of biodegradable PFAS-containing waste. Given these different potential pathways for release, Table 3-1 summarizes the recommended engineering controls at landfills accepting PFAS waste based on both the type of PFAS and the biodegradability of any comingled waste. Also note that soluble PFAS that are comingled with biodegradable waste should have both liquid and gaseous emissions controls (i.e., leachate collection and gas control).

Table 3-1. Recommendations for Disposal of PFAS-Containing Waste by Type of PFAS, Waste Biodegradability, and Type of Landfill Controls to Reduce Risks of Environmental Release

Type of PFAS	Degradability of Comingled Waste	Landfills with Liner and Leachate Collection	Landfills with Gas Collection and Control
PFAS Polymers (e.g., PTFE)	Biodegradable		✓
Soluble PFAS (e.g., PFAAs)	Biodegradable	✓	✓
	Non-biodegradable	✓	
Volatile PFAS (e.g., FTOHs)	Biodegradable	✓	✓

Type of PFAS	Degradability of Comingled Waste	Landfills with Liner and Leachate Collection	Landfills with Gas Collection and Control
	Non-biodegradable	✓	✓

3.b.ii Types of landfills

Landfills are typically classified by ownership status and by the type of solid waste they are permitted to receive, which determines the types of environmental controls they must employ. Depending on the type of waste disposed, a landfill could be subject to regulation and permitting under RCRA, the CAA, and/or TSCA. RCRA regulates two types of landfills: Subtitle C facilities receive hazardous waste, while Subtitle D landfills are primarily intended for the management of non-hazardous waste and can include MSW landfills, industrial waste landfills, C&D waste landfills, and ash landfills. The CAA regulates air emissions from MSW landfills and TSCA regulates landfills that contain PCBs. The CWA (40 CFR Part 503) regulates management practices for the disposal of treated sewage sludge (i.e., biosolids) in monofills. The requirements under RCRA, CAA, TSCA, and CWA determine how the landfill must be constructed, operated, controlled, maintained, monitored, and closed when it reaches its final capacity.

Table 3-2 identifies the environmental controls required by RCRA and CAA for the landfill types defined in RCRA Subtitles C and D. RCRA regulations focus on the containment of solid waste and leachate, while CAA regulations focus on collection of LFG and control (i.e., destruction) of targeted pollutants. The landfill types differ in how they are constructed, operated, controlled, monitored, and closed. Subtitle C landfills and Subtitle D MSW landfills are subject to specific federal design standards, resulting in greater consistency in construction across the country. Controls at other Subtitle D landfills can vary more widely from state to state, and even from unit to unit. Requirements for bottom liners, leachate collection, and final cover requirements at industrial and C&D landfills may range from unspecified to comparable to federal standards.

Table 3-2. Required Environmental Controls by Landfill Type

Landfill Type	Federally Regulated Under	Bottom Liner and Leachate Collection System	Gas Collection and Control System	Final Cover
Hazardous waste	RCRA Subtitle C	Yes (double liner or better)	No	Flexible membrane liner (FML) cap
MSW	RCRA Subtitle D 40 CFR part 258 CAA 40 CFR parts 60 and 63	Yes (composite liner or better)	Yes (when regulatory size and emission thresholds are triggered)	FML cap
Ash monofills	RCRA Subtitle D 40 CFR part 258	Yes (composite liner or better)	No	FML cap
Industrial	RCRA Subtitle D 40 CFR part 257	Varies by state, from no liner requirement to composite liner	No	Varies by state, from no requirements to FML cap
C&D debris	RCRA Subtitle D 40 CFR part 257	Varies by state, from no liner requirement to composite liner	No	Varies by state, from no requirements to FML cap

PFAS concentrations have been detected in landfill leachates from various types of landfills, as shown in Table 3-3. Variation between studies for similar landfill types can be partly attributed to differences in the number and types of PFAS measured. Further, PFAS concentration data reported for landfills outside of the United States may be grossly different as the amounts and compositions of PFAS-containing materials disposed of, as well as weather, and landfill operations and controls may not be comparable and thus are provided for outside reference.

Table 3-3. Range of PFAS Concentrations in Different Types of Landfill Leachate Reported in Published Studies. Adapted from Tolaymat et al., 2023.

Matrix	Number of PFAS Detected (Number of PFAS in Method)	∑PFAS Range (ng/L)	Country	Reference
MSW Leachate	26 (26)	~2,000 – ~20,000	USA	Chen et al. (2024)
	44 (92)	36,000 – 74,000	USA	Smallwood et al. (2023)
	36 (91)	8,000 – 39,900	USA	Cerlanek et al. (2024)

BDL = below detection limit; ng/L = nanograms per liter.

The following subsections describe the types of landfills that are expected to contain PFAS or PFAS-containing materials, with a focus on design and operation aspects that EPA considers important from a PFAS-treatment perspective.

3.b.ii.1 Hazardous waste landfills

Subtitle C hazardous waste landfills are permitted to receive waste that is defined as "hazardous" under RCRA. Hazardous wastes include certain listed manufacturing or industrial process wastes or discarded commercial chemical products and wastes that exhibit one or more hazardous characteristics (i.e., toxicity, corrosivity, reactivity, or ignitability) as defined by RCRA (40 CFR Part 261 Subparts C and D). Hazardous wastes are generally required to be treated with specific technologies to reduce or eliminate the hazards their disposal would otherwise present, and many types of treated hazardous wastes are also required to meet numeric standards for underlying hazardous constituents prior to land disposal (40 CFR part 268). Federal RCRA regulations do not identify any PFAS-containing wastes as hazardous, but most states are authorized to implement RCRA Subtitle C regulations, and their regulations may be more stringent.

Subtitle C hazardous waste landfills are required to have control technologies (e.g., a double liner with a leachate collection/treatment system and leak detection) and practices (e.g., comprehensive record keeping of waste inputs) to minimize the risk of groundwater contamination. Additionally, when closed, these types of landfills must have a final cover consisting of an FML covered by soil. Hazardous waste landfills are generally not required to have gas collection and control systems because they are not intended to accept biodegradable wastes (e.g., biosolids, food scraps). As such, they are generally not biologically active and do not evolve large amounts of gases that could entrain volatile PFAS and lead to high levels of air emissions. However, LFG collection systems could be installed in a Subtitle C landfill to minimize risks related to gas release or gas emissions.

Although few states have proposed regulating PFAS-containing wastes as hazardous wastes, some states have recommended the use of specific treatment technologies for certain PFAS-containing wastes. For instance, some states such as Washington, encourage solidification/stabilization (S/S) of waste AFFF in a neutral material such as concrete prior to landfilling (Washington State Department of Ecology, 2024). A study by the United States Department of Transportation found that the addition of powered activated carbon to S/S pozzalonic binders significantly reduced PFAS leachate concentrations from PFAS-contaminated soil from a historic aviation fire training facility (Mishewitz and Ruehl, 2022).

Hazardous and non-hazardous solid wastes can contain PFAS, and hazardous waste landfills have been used for disposal of non-hazardous wastes containing PFAS. Therefore, it is likely that PFAS-containing wastes will continue to consume a fraction of hazardous waste landfill capacity. Although waste containing PFAS is currently not defined as hazardous waste under RCRA (unless the particular wastes are hazardous for some other reason), some waste generators, perhaps to be cautious, have been sending PFAS-containing wastes to hazardous waste facilities. To ensure hazardous waste landfill capacity is available in the future, EPA reviews and analyzes the *Biennial Hazardous Waste Report*[24] and other data to develop and then publish an assessment of national capacity for hazardous waste management.[25] The last such capacity assessment indicated that existing nationwide capacity remains adequate through 2044, and a new assessment is currently underway to incorporate new information and extend the time horizon. EPA will continue to work with states to monitor hazardous waste treatment and disposal capacity and report on the status.

3.b.ii.2 Municipal solid waste landfills

EPA estimates that in 2018, 50 percent of the MSW generated was landfilled (U.S. EPA, 2024). Wang et al. (2025) identified PFAS in common consumer products that ultimately are disposed in MSW landfills, and this type of landfill may routinely receive lower-concentration PFAS waste such as biosolids, phytoremediation biomass, and contaminated soils.

An MSW landfill typically has at least a bottom liner and an extensive gas collection and control system (GCCS) to collect the LFG generated when the biodegradable waste, such as food scraps and office paper, degrades over time. Also, under RCRA, MSW landfills that received waste after 1993 must install a composite liner that meets design criteria (40 CFR 258.40). However, MSW landfills that receive less than 20 tons of waste per day are exempt from installing a liner and monitoring groundwater under RCRA (40 CFR 258.1(f)(1)). MSW landfills that exceed specified thresholds for size (based on design capacity) and emissions of non-methane organic compounds (NMOCs) are required to install gas collection systems under current CAA regulations. LFG must be collected and managed according to the requirements of the CAA standards of performance (40 CFR part 60 subparts Cc, Cf, WWW, and XXX). Therefore, a subset of MSW landfills do not have gas collection and could release fugitive PFAS associated with LFG emissions. Similarly, unlined MSW landfills are ineffective at managing the release of mobile PFAS to groundwater (see Section 3.b.iii.1). The fate of PFAS in LFG managed through on-site GCCS including on-site flares, engines, boilers, and turbines is the topic of ongoing investigation.

Most modern Subtitle D MSW landfills, when constructed and operated with appropriate environmental controls (e.g., a flexible membrane liner system and leachate and LFG collection and management

[24] Available at: *https://www.epa.gov/hwpermitting/assessment-national-capacity-hazardous-waste-management*.

[25] Background information and links to related documents are available at *https://www.epa.gov/hwpermitting/assessment-national-capacity-hazardous-waste-management*.

systems), can help to contain PFAS. However, research indicates that up to 5 percent of the PFAS may be released in the LFG and 11 percent may be released in the leachate annually (Tolaymat et al., 2023). Some MSW landfills have accepted PFAS manufacturing wastes, and as a result, PFAS concentrations in leachate are higher than the typical range expected in MSW landfill leachate (NWRA, 2020). Landfill leachate may be sent to wastewater treatment plants (WWTPs) that are incapable of treating or destroying PFAS. Thus, the PFAS in landfill leachate, unless pretreated before entering the WWTP, may be discharged in WWTP effluent or may end up in biosolids that are subsequently land-applied, incinerated, or returned to a landfill for disposal. There is a need for additional research regarding the effectiveness of emerging PFAS separation and destruction treatment technologies on a landfill leachate matrix. There also is a need for additional research on the physical and chemical properties, fate and transport, and transformation processes for PFAS precursors and intermediate and terminal degradation products.

3.b.ii.3 Ash monofills

Ash monofills are a subtype of Subtitle D landfills that mainly receive ash from MSW combustors, but could also receive smaller volumes of ash from other combusted waste streams, such as biosolids from POTWs. Ash monofills typically have a bottom liner and final cover requirements similar to other MSW landfills. However, they usually do not require LFG collection and control systems due to the use of combustion to remove biodegradable waste. Solo-Gabriele et al. (2020) found that ash monofills have lower PFAS concentrations than other landfill types, as shown in Table 3-3. While some landfilled wastes, such as MSW combustion ash, may have low PFAS concentrations, the inclusion of higher-concentration PFAS waste types in MSW combustion feed streams may increase MSW combustion ash PFAS content and potential for PFAS release. The PFAS in MSW combustion ash are remnants of incomplete combustion, since these facilities are generally designed to recover heat and generate electricity and not (currently) PFAS contaminant destruction.

New comparative studies show that the total detected PFAS concentration in MSW leachate samples ($\sum_{26}$PFAS mean: 9,641 ng/L) was higher than in MSW incinerator ash leachate samples ($\sum_{26}$PFAS mean: 2,621 ng/L) (Zhang et al., 2024). The variability of total detected PFAS concentrations in leachate was also higher for the MSW landfill (coefficient of variation, CV = 43 percent) compared to the MSW incinerator ash landfill (CV = 16 percent) (Zhang et al., 2024).

Studies have also examined PFAS concentrations in leachate at landfills where ash was co-disposed with other types of waste. A comprehensive study of co-disposal of MSW combustion ash (30 percent) with MSW (70 percent) and at a separate landfill with sewage sludge (4 percent) and ash (96 percent) found that PFAS concentrations were closer to those found in MSW landfill leachate or sludge leachate regardless of the amount of co-disposed ash ($\sum_{26}$PFAS). This phenomenon was hypothesized to occur due to preferential flow of leachate through the wastes instead of the ash which had lower hydraulic conductivity (Liu et al., 2022b).

With limited data on the breadth and concentrations of PFAS in ash monofill leachate, more research is needed to determine the PFAS and precursor content of ash from different combustion technologies and air pollution control systems.

3.b.ii.4 Industrial landfills

Industrial landfills receive non-hazardous solid waste from industrial operations (i.e., non-municipal) and are often designed to manage specific waste streams (e.g., furnace slag, pulp and paper mill sludges,

plastics) and the designs of industrial landfills vary widely based on the characteristics of the waste they receive. Requirements for environmental controls at these landfills also vary from state to state. Depending on the waste types and size of the landfill, some states do not require a liner; however, if a liner is required, a membrane cap can also be required.

Landfills that have historically received PFAS manufacturing wastes have been associated with high concentrations of PFAS in the leachate and environmental impacts (MPART, 2020). Some waste types received at industrial landfills, including plastics and materials with polishes or coatings, contain PFAS (OECD, 2013). Specifically, industrial processes such as leather tanning, chrome plating, and textile manufacture contribute to PFAS in the industrial solid waste stream (ITRC, 2022). Due to the variability in control technologies, industrial landfills may not be effective at containing PFAS and so are generally not believed to be an appropriate disposal option for PFAS-containing wastes.

3.b.ii.5 Construction and demolition landfills

C&D landfills receive waste from construction, renovation, and demolition projects, as well as other inert materials that are generated in high volumes, comparable to MSW waste generation (U.S. EPA, 2020b). GCCSs are not federally required in C&D landfills, due to the low levels of biodegradable waste received compared to MSW landfills, and there are also no federal regulations for C&D landfills to be equipped with a liner. States create their own requirements for environmental controls at these landfills, so requirements vary widely from state to state, ranging from no liner to a required composite liner. However, if a liner is required, a membrane cap may also be required.

C&D landfills are known to receive PFAS-containing wastes (e.g., building materials and carpeting with PFAS treatments) (OECD, 2013; Solo-Gabriele et al., 2020; Bečanová et al., 2016; Liu et al., 2024), and PFAS have been measured in the leachate from C&D landfills equipped with a leachate collection system (Chen et al., 2023). Thelusmond et al. (2025) estimated that C&D landfills in North Carolina generated more than double the PFAS mass flow (5.1 kg/year) from leachate production than MSW landfills (2.3 kg/year).

Due to the variability in state requirements for GCCSs, PFAS-containing wastes that also include a biodegradable component should not be disposed of at C&D landfills and C&D landfills that lack composite liners, leachate management systems, and GCCSs are unlikely to prevent release of soluble or volatile PFAS. Because stable PFAS polymers (e.g., PTFE found in some electrical insulation and membrane materials) are not expected to undergo chemical transformation in a C&D landfill, these types of PFAS compounds are likely to be contained in the C&D waste mass for a long period. However, C&D landfills may not be suitable for more mobile PFAS, such as non-polymer PFAS and SFPs, because these types of PFAS compounds are expected to release soluble PFAS and are a concern for C&D landfills.

3.b.iii Ability of engineered landfill components to contain PFAS

PFAS are emitted from landfills via LFG and landfill leachate, which is any liquid that has contacted solid waste and is typically derived from the breakdown of waste itself or infiltration of rainwater into the waste. As such, controls to manage contaminants in landfills focus primarily on these two releases.

LFG results from the natural decomposition of organic material in landfill wastes under anaerobic conditions. Traditionally, LFG is composed of roughly 50 percent methane, 50 percent CO_2, and a small amount of NMOCs. Leachate can contain a combination of soluble, suspended, and miscible materials

extracted from the waste. As shown in Figure 3-1, landfills constructed with environmental controls (e.g., bottom liner, leachate collection system, gas collection system, final cover system) manage the release of contaminants into the environment. This figure is designed to be inclusive of all controls commonly encountered at landfills. However, it should be noted that the actual configuration of a particular landfill can vary widely by site due to differences in types of waste accepted, operating practices, site conditions, and state regulations.

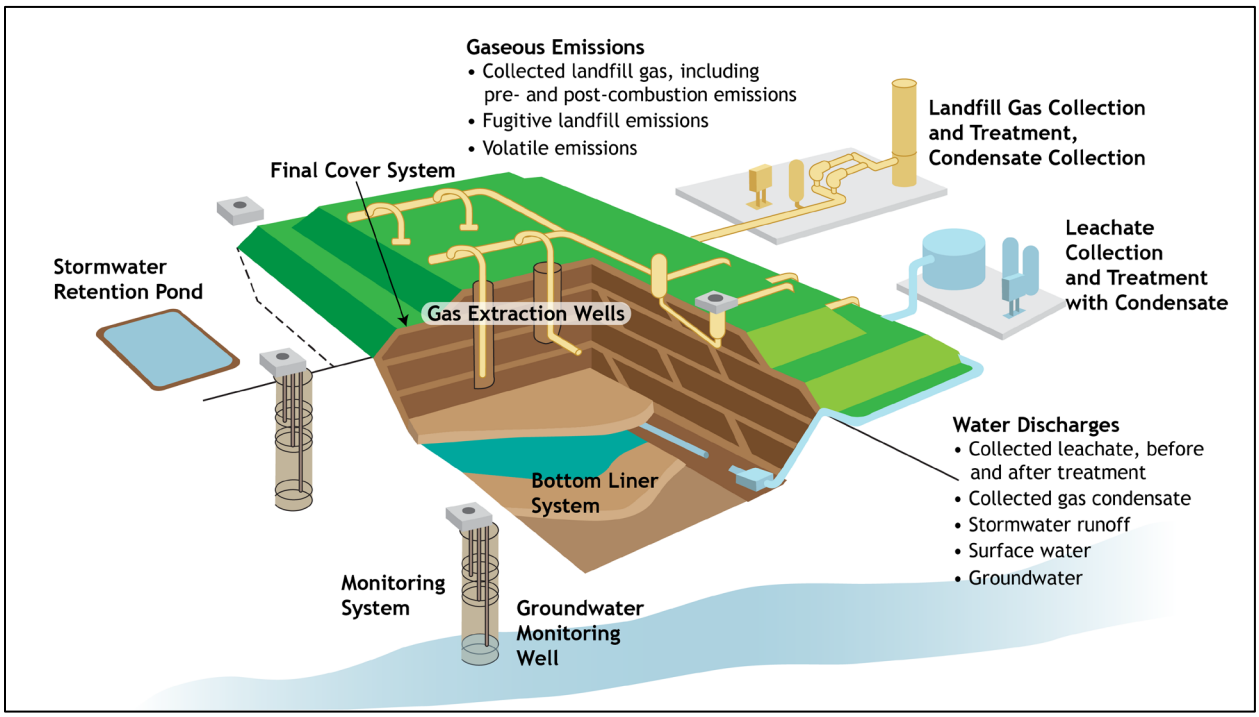

Figure 3-1. Engineered landfill components and potential PFAS release pathways.

3.b.iii.1 Bottom liner and leachate collection system

Under RCRA (Subtitle C), any new landfill, replacement of an existing landfill, or lateral expansion of an existing landfill that received hazardous waste must have a double liner and leachate collection system to limit leachate through the bottom of the landfill. A liner is built of layers of clay and/or polymers (i.e., FMLs) designed to withstand the weight of waste and soil. Leachate generated inside the landfill will collect on top of the liner, so its design includes a leachate collection system contoured to collect leachate through a network of pipes leading to a low point called a sump. The collected leachate is pumped from the landfill and managed as liquid waste (see Section 2.f and Section 3.b.iii.5).

Most landfills regulated under RCRA (Subtitle D) to receive non-hazardous waste are subject to design criteria that require either a composite liner and leachate collection system or a state-approved design that satisfies performance standards to ensure that regulated chemicals do not migrate beyond a specified distance from the landfill.

Uncontrolled leachate could result in the release of PFAS into the environment. Because state requirements for landfill liners vary and some landfills are not required to have liners because of waste type or quantities received, the variation of landfill requirements among states poses a challenge for the

long-term containment of existing PFAS in landfills. Additionally, RCRA-exempt sites may not require any liner system (40 CFR 258.1). Because PFAS are not a RCRA-regulated hazardous waste, existing unlined landfills could receive PFAS-containing wastes that are readily released into the underlying groundwater.

PFAS interactions with landfill liner materials have been the subject of limited studies. The most common types of FML are made with polyethylene geomembranes. PFAS diffusion through linear low-density polyethylene is reported below detection diffusion rates (Di Battista et al., 2020), and diffusion through high-density polyethylene (HDPE) may be even slower due to differences in material structure. PFAS likely pass through clay liners, which are required to have low hydraulic conductivity on the order of 10^{-6} centimeters per second, at the same rate as leachate and other constituents such as chloride (Li et al., 2015).

The most significant pathway for leachate (and PFAS) transmission through geomembrane or composite liners is via imperfections (e.g., flaws or tears) (Di Battista et al., 2020). A review of landfill liner performance reported median leakage rates of 44 and 33 liters per hectare per day for geomembrane and composite liners, respectively, and overall liner collection efficiency of 98 percent (Jain et al., 2023). Even if liners successfully prevent leachate from reaching groundwater, very few data exist on whether concentrated PFAS waste interacts with the different types of geotextiles used for landfill liners, thus affecting the performance of the liner. While the performance of clay liners may not be affected drastically, there is currently no research on the long-term stability of FML in the presence of PFAS.

New research on double HDPE geomembrane liner systems indicates that PFAS were detected in all primary and secondary leachate samples, at concentrations not significantly different from one another, suggesting their transport to secondary leachate collection systems (Robey et al., 2025). HDPE liner permeation experiments with PFAS (specifically PFAAs) indicate migration via permeation an unlikely possibility, given the quickest breakthrough times for 60-millimeter HDPE liners were estimated at approximately 1,500 years (Ahmad et al., 2024). Based on comparing chloride concentrations, PFAS concentrations in secondary leachate were often higher than expected if having been leaked from the primary liner, with PFAAs more likely to exceed expected levels (Robey et al., 2025). These disproportionately higher concentrations suggest that conditions within the secondary leachate collection system itself may be contributing to increased PFAS transformation, and/or that PFAS may be derived from another source, such as LFG (Robey et al., 2025). Wang et al. (2025) and Zhang et al. (2013) showed that FTOHs, the predominant PFAS found in LFG (Titaley et al., 2023), can biodegrade to FTCAs and eventually to PFCAs, both of which were found to be in higher proportions within the secondary leachate (Robey et al., 2025). Further, groundwater PFAS concentrations were found to represent a very small fraction (on average, 0.3 percent) of the total PFAS in secondary leachate, suggesting that the PFAS in the secondary leachate are mainly derived from within the landfill itself (Robey et al., 2025). Thus, PFAS migration through landfill liners and potential groundwater impacts remains a concern, highlighting the need for diligent leachate management and landfill liner quality control (Robey et al., 2025). The study underscores the importance of continued research into PFAS migration mechanisms and the potential environmental impacts of unidentified precursor PFAS in landfills (Robey et al., 2025).

3.b.iii.2 Landfill gas collection system

Landfills use GCCSs to manage gas generated from decomposing organic waste; however, not all landfills are required to collect LFG (see Table 3-2). A GCCS consists of a network of perforated pipes sunken into the waste mass. These “gas wells” are connected to a central blower that pulls gas from the wells. Despite the presence of a GCCS, gas can still migrate both through the surface of the landfill and

underground through the bottom of the landfill. The gas produced by MSW landfills contains about 50 percent methane that is usually collected and burned at the site via flares or for energy recovery.

As noted in Section 3.b.iii.6.1, research has found that soluble PFAS with relatively high vapor pressures can be emitted into the atmosphere via the gas generated at landfills (Ahrens et al., 2011; Hamid et al., 2018; Wang et al., 2020; Weinberg et al., 2011). Direct sampling methodologies are currently under development, and published concentrations of PFAS measured in situ are limited (Titaley et al., 2023; Lin et al., 2024). Many LFG destruction systems (e.g., flares, engines, boilers) generally operate lower than the 1,100°C necessary to achieve the mineralization of PFAS. Nonetheless, LFG collection and management systems (e.g., flares) must be present at MSW landfill sites that accept PFAS waste, especially biodegradable PFAS waste such as biosolids (Tansel et al., 2024) and some paper-based food packaging (Ye et al., 2024). The use of GAC prior to the flaring of LFG can be effective in removing contaminants of concern from LFG (Smallwood et al., 2024). Data on the fate of PFAS in LFG that is managed through on-site GCCS, including flares, are still limited. See Section 4 for potential research needs.

LFG is identified as a significant pathway for the release of volatile PFAS, as noted in studies by Lin et al. (2024) and Titaley et al. (2023). Research has detected various PFAS in landfill leachate, including perfluoroalkyl acids (PFAA), FTCAs, perfluoroalkyl acid precursors, and fluorotelomer alcohols (FTOHs), according to Lang et al. (2017), Robey et al. 2024 and 2025, Zhang et al. (2024), and Smallwood et al. (2023). Among these, volatile FTOHs are predominant in gas-phase PFAS within LFG, with concentrations ranging from 0.46 micrograms per cubic meter (µg/m³) to 14.0 µg/m³, as reported by Titaley et al. (2023) and Lin et al. (2024). These concentration levels are approximately two orders of magnitude greater than FTOH levels reported in ambient air collected near landfills. FTOHs are the most common neutral PFAS, constituting 87 to 97 percent of the total neutral PFAS concentration, as noted by Lin et al. (2024). Specifically, the 8:2 FTOH accounts for 50 to 79 percent of the total neutral PFAS in LFG (Lin et al., 2024).

The observed concentrations of neutral PFAS in LFG range from 22,000 to 33,000 ng/m³, with extrapolated total concentrations (i.e., beyond their calibration range) reaching between 210,000 and 940,000 ng/m³, which is significantly higher than previously reported levels, as highlighted by Lin et al. (2024). Even with conservative estimates, the mass of fluorine released in LFG (32 to 76 percent) is comparable to or exceeds the mass released in landfill leachate (24 to 68 percent), as stated by Lin et al. (2024).

PFAS are typically released early in the decomposition cycle of packaging materials, within about 10 days for high-fluorine materials, indicating that some PFAS may be released before LFG collection systems are installed, as Ye et al. (2024) suggest.

3.b.iii.3 Final cover system

After a regulated landfill has reached its designed and permitted capacity, it must be capped with a cover system. This system typically consists of some combination of soil and membrane materials and is primarily intended to reduce infiltration of rainwater into the landfill to minimize further leachate generation. The cover system also helps increase the efficiency of the GCCS and reduce uncontrolled gas emissions by acting as a barrier. Synthetic membranes and caps are more effective at controlling release of PFAS than earthen covers because of the lower overall hydraulic conductivity. Earthen covers are also more subject to wet/dry and freeze/thaw cycles and cracking that disrupt the compaction of the soil and

can result in greater LFG emissions (Ahrens et al., 2011; Tian et al., 2018; Wang et al., 2020; Weinberg et al., 2011).

3.b.iii.4 Other environmental controls and monitoring systems

In addition to the major design infrastructure discussed above, solid waste landfills implement other practices and systems to protect human health and the environment. In active landfill cells, soil or other inert material covers are applied daily to exposed solid waste. Daily cover reduces leachate generation, gas emissions, and direct exposure to humans and wildlife. Access control for a landfill site, such as a fence, is typically also required to reduce direct human and ecological exposure to waste. Extensive monitoring networks are generally required by states to measure the landfill's impact on groundwater. RCRA Subtitle C requires all hazardous waste landfills to install groundwater monitoring wells. See Section 3.b.iii.5 for leachate discharge controls.

3.b.iii.5 Leachate discharge controls

3.b.iii.5.1 Leachate characteristics

Leachate is the liquid effluent from landfills primarily generated through the percolation or infiltration of rainwater through waste. Leachate often contains high concentrations of biodegradable and non-biodegradable organic matter, dissolved and suspended solids, heavy metals, ammonia, and sulfur compounds (Mukherjee et al., 2015; Renou et al., 2008). PFAS concentrations in leachate are correlated with several physicochemical parameters, including leachate-specific conductivity, alkalinity, total organic carbon (TOC), ammonia, and chemical oxygen demand (COD) (Zhang et al., 2023). However, correlation between leachate PFAS and these parameters does not necessarily indicate causation (Zhang et al., 2023).

The waste type, age, climate at the landfill site, and methods of landfill operation all influence the characteristics of leachate. Some studies found that fresh leachate (from raw waste in transportation vehicles without any processing) initially had no measurable PFAS, but aged leachate showed higher PFAS concentrations, implying that non-target PFAS precursors may transform to measurable intermediate and terminal PFAS degradation products during the aging process (Busch et al., 2010; Eggen et al., 2010; Zhang et al., 2023). Liu et al. (2021) found significantly greater PFAS concentrations in landfill leachate than in leachate from waste transportation vehicles which also could have resulted from transformation processes (Liu et al., 2021). Moreover, landfills in wet, warm climates are most likely to have higher PFAS concentrations in the leachate, as heavy rainfall facilitates the leaching process (Lang et al., 2017; Tolaymat et al., 2024; Wei et al., 2019). Higher PFAS concentrations have also been measured in leachate from an elevated temperature MSW landfill (up to or exceeding 100°C) as compared to concentration in another cell from the same landfill at a lower temperature (less than 60°C), implying temperature-dependent increase in PFAS release and/or precursor transformation rates (Collins et al., 2024).

Leachate from older accumulated wastes (more than 10 years old) contained lower levels of PFAA precursors due to progressive biotransformation over time (Lang et al., 2017; El-Barkaoui et al., 2025). Similarly, waste subjected to prolonged anaerobic degradation exhibited higher PFAS concentrations and higher concentrations of terminal PFAAs relative to measurable PFAS precursors (Liu et al., 2021b; Tolaymat et al., 2023; El-Barkaoui et al., 2025). During the methanogenic phase, organic matter degradation can elevate pH, consequently deprotonating waste surfaces (e.g., organic matter), thereby

reducing their sorption capacity for PFAS and eventually increasing PFAS concentrations in the leachate (Allred et al., 2014; El-Barkaoui et al., 2025).

These factors result in highly variable leachate characteristics across landfill types and on a site-by-site basis. Subtitle C hazardous waste landfills are required to use a leachate collection system during their active and post-closure care periods to mitigate adverse impact to human health and the environment. Since the use of leachate collection systems at Subtitle D landfills varies by landfill type and state requirements, the efficacy of leachate management and PFAS emissions depends on the controls implemented. Because of the persistence of PFAS, the potential remains for leaching of PFAS during the post-closure care period and far beyond. Ideally, leachate collected at the bottom of the landfill is removed and managed to minimize impacts to human health and the environment. See Section 2 for a more detailed discussion on the types of leachates and associated PFAS.

3.b.iii.5.2 Off- and on-site management of leachate

The most common method for non-hazardous waste leachate disposal is off-site treatment at municipal WWTPs, where leachate is mixed with wastewater and treated. The dynamic nature of leachate characteristics, the presence of non-biodegradable compounds and ammonia, and the presence of emerging contaminants (such as PFAS) in the leachate may make it difficult for WWTPs to effectively treat the influent water. In some cases, a landfill with elevated PFAS in its leachate may burden the ability of a WWTP to treat, or remove, these compounds before discharge to the environment (Masoner et al., 2020). Thelusmond et al. (2025) calculated that, generally, leachate is a small contributor to PFAS mass loading of WWTPs; however, for small WWTPs (approximately 3,800 m^3/day), a large landfill receiving more than 51 centimeters (cm) of annual rainfall may contribute comparable PFAS mass loadings as those received from the domestic wastewater.

As mentioned in Section 2.a.ii, wastewater treatment technologies used at most municipal WWTPs are generally ineffective at destroying or controlling PFAS (Schultz et al., 2006). As a result, PFAS is more likely to accumulate in biosolids or be discharged to surface water in plant effluent, which can lead to uncontrolled release of PFAS into the environment. To date, no federal requirements exist for landfill leachate to be monitored or treated for PFAS prior to WWTP consideration for acceptance. However, WWTPs may need to establish additional monitoring and controls to ensure compliance with state-issued permits. For example, local limits developed at the municipal level in accordance with 40 CFR 403.5(c) to prevent the pass through of PFAS through the WWTP or prevent the inhibition of WWTP processes may require contributing sources (e.g., landfills) to install treatment, meet numeric discharge quality levels, or follow best management practices to reduce PFAS prior to introducing the leachate to the WWTP. The selected controls may be tailored to site specific end uses of the WWTP biosolids or effluent. For these reasons, some WWTPs have requested that landfill operators pretreat leachate on site, while others are implementing surcharges based on the leachate quality. Underground injection is another form of off-site leachate management in the United States (see Section 3.c).

Table 3-4 presents leachate management or treatment methods for the on-site management of leachate. Multiple technologies in the table are marked for further research—technologies for which, at the time of publishing, are under development (Sabba et al., 2025). “Secondary treatment required” refers to the remaining concentrated or captured PFAS, which must be disposed of after treatment. “Potential secondary release” refers to the potential for PFAS release or breakthrough during the treatment process. Leachate characteristics are site-specific; therefore, the effectiveness of leachate

technology should be evaluated on a site-by-site basis. (Table 3-3 lists average PFAS concentrations observed in different types of landfill leachate.)

Landfill operators should identify management or treatment methods that: (1) are suitable for the leachate at their specific sites, and (2) meet the leachate discharge standards for chemicals and characteristics of leachate that are regulated. For example, leachate from a hazardous waste landfill is regulated as a listed hazardous waste (F039) and must be managed appropriately, but that does not necessarily mean that treatment technologies are adequate to control the release of PFAS into the environment. The geography of the landfill site and cost-effectiveness of the methods play a crucial role in the identification of viable approaches to leachate management or treatment. The use and effectiveness of leachate management strategies in removing or destroying PFAS during treatment varies (and, as noted in Section 3.b.vi, methods to quantify effectiveness are still under development). Leachate treatment technologies can be largely categorized into physiochemical processes, physical processes, biological processes, natural processes, and other management methods, as grouped in Table 3-4. Considering that leachate contains a variety of chemicals, a combination of physiochemical treatment processes can be used to narrowly target specific parameters for pre-treatment, or as part of a multi-step treatment strategy.

Recirculation of leachate within a landfill—a management strategy unique to MSW landfills—keeps the leachate within the landfill. Although recirculation can filter heavy metals and improve leachate quality, it is primarily used as a management option that may also help accelerate biodegradable waste decomposition. The recirculation of leachate in the landfill would return any PFAS to containment within the landfill. Although recirculation tends to increase PFAS content and may result in larger fugitive emissions due to faster waste degradation, it can also decrease long-chain PFAS concentrations. This process potentially transforms landfills into 'PFAS sinks' rather than 'PFAS sources,' thereby minimizing the environmental footprint of these substances (Saha et al., 2024). Strategic placement of PFAS-containing waste in the upper landfill layers, where degradation can be controlled once the final cover is in place, can further reduce PFAS leaching (Saha et al., 2024). This method limits the likelihood of precipitation reaching the waste, thereby minimizing PFAS migration into the leachate (Saha et al.,2024).

Table 3-4. Existing Landfill Leachate Treatment Technologies for PFAS Removal or Destruction

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Physiochemical Processes				
GAC	Adsorption	• Familiar technology • Effective for long-chain PFAS	• Secondary treatment required • Short-chain PFAS breakthrough • Potential secondary release • Cost	• McCleaf et al. (2017), Pan et al. (2016), Ross et al. (2018)
PAC with coagulation	Adsorption	• Effective for long-chain PFAS	• Secondary treatment required • Costly for high-volume leachate • Potential secondary release	• Bao (2014), Pan et al. (2016)
Polymeric adsorption	Adsorption	• Tailored for specific compounds	• Secondary treatment required • Potential secondary release	• Liu (2017)
Ion exchange resin	Ion exchange adsorption	• Specified for certain compounds • More effective than GAC for long-chain compounds	• Secondary treatment required • Less effective for short-chain PFAS • Potential secondary release	Dickenson and Higgins (2016), McCleaf et al. (2017), Ross et al. (2018)
Zeolite	Ion exchange adsorption	• Inexpensive	• Secondary treatment required • Low surface area compared to GAC • Unknown reaction with short-chain PFAS	Chiang et al. (2017), Ochoa-Herrera and Sierra-Alvarez (2008)
Ozonation/ ozofractionation	Oxidation	• Potentially effective multi-contaminant removal	• Potential side-product formation • Secondary treatment required	Franke et al. (2019), Lin et al. (2012), Rahman et al. (2014), Ross et al. (2018)
Fenton oxidation	Oxidation	Limited data available	Limited data available	None identified

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Photocatalytic advance oxidation process	Oxidation	• Permanent degradation	• Potential side-product formation • Cost	Lockwood (2018), Ross et al. (2018)
Coagulation-flocculation	Precipitation	Limited data available	Limited data available	Bao (2014), Dickenson and Higgins (2016), ITRC (2018), Rahman et al. (2014)
Chemical precipitation	Precipitation	Limited data available	Limited data available	None identified
Air stripping	Volatilization	More research needed	• Potential secondary emissions	None identified
Foam fractionation	Separation	More research needed	• High PFAS emissions to the air	Smith et al. (2022 and 2023)
Physical Processes				
Reverse osmosis (RO)	Physical separation	• Commonly used • Effective for short and long-chain PFAS	• Secondary treatment required for high-volume concentrate • Membrane fouling	Dickenson and Higgins (2016), Ross et al. (2018)
Nanofiltration (NF)	Physical separation	• Uses less energy than RO • Effective for short- and long-chain PFAS	• Secondary treatment required	Boo et al. (2018), Dickenson and Higgins (2016)
Ultrafiltration (UF); microfiltration (MF)	Physical separation	Not available	• Not effective for PFAS	U.S. EPA (2020a)
Climatic evaporation; thermal evaporation; mist evaporation	Volume reduction	Limited data available	• Potential secondary emissions	Cerlanek et al. (2024), Goukeh et al. (2025)
Other On-Site Management Methods				
Recirculation	Containment	• Co-location with landfill	• Oversaturation • Potential surface water contamination • Dependent on climate	None identified

Treatment Technology	Treatment Mechanism	Pros for PFAS Treatment	Cons for PFAS Treatment	References
Underground injection	Containment	• Potential solution for PFAS concentrate	• Dependent on site geology • Regulatory approval	ITRC (2018)
Incineration	Thermal destruction	• PFAS destruction	• Potential secondary emissions (incomplete destruction) • Regulatory approval	ITRC (2017), Yamada et al. (2005)
Solidification	Containment	• Co-location with landfill • Reduces PFAS mobility • Could be used in combination with other treatment technologies	• Consumes air space in landfill • Unrealistic for large leachate volume	None identified
Biological Processes				
Activated sludge process sequencing; batch reactor; anaerobic; digestor; membrane bioreactor	Biological processes	Limited data available	• Limited by high concentrations of non-biodegradable organic matter	Ross et al. (2018), Saez et al. (2008), U.S. EPA (2020a)
Natural Processes				
Constructed wetlands; aerated ponds; phytoremediation; land application	Environmental release	Not available	• Direct release of PFAS	U.S. EPA (2020a)

3.b.iii.5.3 Leachate management and treatment technologies

Membrane treatments separate compounds from the leachate using mechanical filtration and pressure. Leachate passes through selective membranes (such as RO, NF, UF, and MF membranes) that divide it into two parts: permeate (which has passed through the membrane) and concentrate (which has not). The permeate and concentrate can then be treated as independent streams. The primary difference between these membranes is the pore size, which in turn affects the operating pressure and removal efficiency for different types of contaminants. RO is the most commonly used type of membrane for leachate treatment, while NF, UF, and MF are generally used in combination with other treatment technologies including RO. Although RO and NF are known to be effective in concentrating some PFAS, UF and MF have pores that are too large to limit the release of most water-bound PFAS across the filtration membrane. Membrane fouling and a large amount of concentrate generation are two of the major drawbacks observed in implementing the membrane treatment system for landfill leachate and

may be further complicated by high concentrations of PFAS (Dickenson and Higgins, 2016; ITRC, 2018; Ross et al., 2018).

An adsorption process with activated carbon is used for targeted removal of organic matter at some landfill sites. Activated carbon is known to be effective at trapping some PFAS, but it may need to be combined with other treatment methods to manage the full range of PFAS found in landfill leachate. Activated carbon is a non-selective treatment method, expected to be less effective in higher strength effluents, such as landfill leachate, that contain nutrients and other compounds that compete for adsorption sites within the carbon. Once saturated, activated carbon needs to be reactivated through a pyrolysis process (see Section 3.a), collected as solid waste, or otherwise treated, with consideration of the PFAS concentration (ITRC, 2017). Leachate also may need to be pretreated before activated carbon treatment to avoid rapidly saturating the carbon.

Methods using ozone, Fenton's reagent, or advanced photocatalytic technologies are used to oxidize organic matter in the leachate. Ozone and hydrogen peroxide (H_2O_2) in combination with other oxidizing agents have been observed to remove up to 99 percent of COD from leachate at different operating conditions (Renou et al., 2008) and may be effective at reducing or modifying certain PFAS in leachate (Ross et al., 2018). Ultraviolet photocatalytic advanced oxidation is known to be capable of destroying PFAS, but additional studies are needed to understand the subsequent products associated with this method (Lockwood, 2018; Ross et al., 2018).

Ion exchange processes using zeolite and magnetic ion exchange resin remove ammonia and organic matter, respectively. Ion exchange can be flexibly designed to address different compounds and may be effective at reducing PFAS in leachate; however, performance data are not currently available. As with activated carbon, the leachate may require pretreatment and the spent media would need to be handled as solid waste or otherwise treated.

Air stripping of landfill leachate is used for ammonia removal. While air stripping could be effective in the treatment pathway of leachate, if it is used before the removal of PFAS, it would likely lead to emissions of more volatile PFAS to air.

Foam fractionation is a water treatment method that takes advantage of the surfactant-like behavior of many PFAS compounds. As air bubbles rise through contaminated water, PFAS molecules attach to their surfaces. These bubbles accumulate and create a surface foam that becomes concentrated with PFAS. By collecting and collapsing this foam, the process separates PFAS into a smaller, more concentrated volume (called foamate), leaving behind treated water with significantly reduced PFAS levels. Foam fractionation is emerging method for removing PFAS from contaminated waters, particularly from sources like AFFF and leachate. Smith et al. (2022) performed a pilot-scale study that evaluated continuous foam fractionation as a treatment for PFAS-contaminated landfill leachate. The process achieved around 60 percent total PFAS removal, with long-chain compounds removed at rates exceeding 90 percent, while short-chain PFAS showed much lower removal efficiencies (less than 30 percent). Operational factors like airflow rate, foam volume, and contact time influenced performance, but differences between batch and continuous modes were minimal. However, further research is needed to test for PFAS aerosolization and volatilization to better understand safety and prevention of PFAS emissions to the atmosphere (Smith et al., 2023).

Natural processes (such as constructed wetlands and phytoremediation) and biological processes (degradation, nitrification, and denitrification) are expected to be ineffective at treating and preventing

release of many PFAS into the environment. Current biological treatment processes such as the activated sludge process and sequencing batch reactor have not been shown to be effective at treating many PFAS, but future research may show biological treatment can play a role in controlling some PFAS or converting them into other types of PFAS. Note that biological treatment does not necessarily result in PFAS releases directly into the environment, because the outputs can be further treated.

Leachate treatment through evaporation reduces the volume of leachate. Open-air evaporation methods may be effective at concentrating leachate but are a pathway for secondary PFAS releases to air. Commercial evaporators operated through the heat generated by the LFG combustion or other fuel sources are sometimes used at landfills. Exhaust gases emitted from the evaporators may be exposed to high temperatures, but those temperatures may not be high enough or last long enough to destroy PFAS (see Section 3.a). Two full-scale thermal landfill leachate evaporation systems were evaluated by Cerlanek et al. (2024). Samples analyzed included the feed leachate, residual evaporated leachate, sludge, and condensed vapor. PFAS concentrations were measured in both the evaporation vapors and residuals. It was estimated that the vapor pathway can emit 9 to 24 percent of feed leachate PFAS mass. Similarly, Goukeh et al. (2025) found that approximately 99.9 percent of FTOHs and between 0.14 to 6.8 percent of PFCAs were lost in a bench-scale rotary evaporator treating three landfill leachates and two synthetic leachates.

3.b.iii.6 Landfill gas emission controls

3.b.iii.6.1 Landfill gas characteristics

Under the anaerobic conditions that dominate landfill environments, organic waste (e.g., food waste, paper, cardboard) decomposes and generates LFG. In MSW landfills, LFG consists mostly of methane and CO_2. In most landfills where gas is collected, it is burned for energy or to destroy the methane and other organic chemicals it contains. Even at sites that actively collect LFG, a fraction (EPA estimates 25 percent, on average; U.S. EPA, 2025) of the LFG is emitted directly to the environment through the landfill surface and other routes. These uncontrolled emissions are referred to as fugitive losses.

Research has found that soluble PFAS with relatively high vapor pressures can be emitted into the atmosphere via the gas generated at landfills (Ahrens et al., 2011; Hamid et al., 2018; Wang et al., 2020; Weinberg et al., 2011). EPA is currently conducting research on direct LFG sample evaluation for PFAS concentrations (see Section 4).

Simulations show that methane, a major component of LFGs, can significantly affect PFAS behavior in landfill settings by competitively adsorbing with vapor-phase PFAS, particularly FTOHs, in montmorillonite-rich clay barriers, potentially leading to their accumulation within the barrier materials (Xu et al., 2025). As moisture content increases, methane's competitive advantage diminishes, allowing PFAS to maintain distinct adsorption regions within unsaturated montmorillonite pores, slowing its mobility, according to Xu et al. (2025). These findings may provide insights to improve landfill barrier soil designs to reduce PFAS fugitive emissions. However, the challenge of effectively destroying PFAS within collected LFG remains unresolved, as discussed in Section 3.b.iii.2.

Unlike waste in MSW landfills, the C&D landfill waste that contributes most to LFG production is generally dominated by gypsum drywall (Yang et al., 2006). Gypsum drywall results in C&D LFG largely consisting of hydrogen sulfide, a highly pungent gas, with a smaller fraction of methane. Because C&D landfills generate a lower volume of gas than MSW landfills, LFG from C&D landfills is typically not collected and is often emitted to the environment without treatment.

3.b.iii.6.2 On- and off-site management of landfill gas

LFG collection and management are regulated under the CAA through New Source Performance Standards (NSPS) and National Emission Standards for Hazardous Air Pollutants (NESHAP) programs. After collection, LFG can be managed on site and burned using a flare. There are two basic types of flares common at MSW sites: open (candlestick) and enclosed flares. LFG can also be managed off site, where it is usually piped from the landfill to a nearby gas-fired system to generate heat or power.

On-site open flares must operate in accordance with key parameters for exit velocity and flare diameter for non-assisted flares (in 40 CFR 60.18). Additionally, a heat-sensing device must be installed to indicate continuous flame presence (but no specific temperature level). A landfill with an enclosed flare must reduce NMOCs to 20 ppmv at the outlet, or reduce NMOCs by 98 percent via a one-time performance test. Lowered emissions are maintained by following operating parameters set during the test for the requisite flare temperature and flow rate.

Combustion temperatures and duration may prove to be critical factors for destruction of PFAS in LFG. While the operating temperature of on-site flare systems averages around 850°C (1,550°F) (U.S. EPA, 2008), power-generating engines and boiler systems may run even cooler. None of these systems operate at the temperature necessary to mineralize PFAS (1,100°C). The use of GAC prior to the combustion of LFG can be effective in removing contaminants of concern from LFG (Smallwood et al., 2024) and could be used to reduce PFAS flows to on-site LFG thermal destruction devices, reducing the potential for PFAS and PICs emissions. See Section 3.a for a more complete discussion on conditions required for PFAS destruction.

Under the CAA regulations, if LFG is treated for sale or use in a beneficial energy recovery device, it must be treated according to a site-specific treatment plan before being utilized on site or piped out of the facility. Like liners, active gas collection systems are not required at all landfills, depending on the landfill size and level of NMOCs in the LFG. The presence or absence of an LFG collection and control system directly affects the release of PFAS via fugitive emissions.

LFG condensate is a liquid that has condensed in the LFG collection system piping during the extraction of gas from the landfill. In gases with high concentrations of water vapor, water condenses in pipes and accumulates in traps staged throughout the collection network. This condensate contains volatile compounds and accounts for a relatively small percentage of flow from a landfill. Gas condensate is commonly collected and managed with the landfill leachate as liquid waste. PFAS has been detected in LFG condensate, with PFBS being the dominant species at a concentration of 1,000 ng/L (Li, 2011) and Chen et al. (2023) finding a maximum total PFAS concentration of 80,900 ng/L ($\sum_{26}$PFAS).

3.b.iv Potential for releases during landfilling

Over time, certain pollutants have increased potential to move into the environment beyond the footprint of the landfill. As water passes through the landfill, it may leach pollutants from the waste—including PFAS—and move them deeper into the waste mass. Controlled landfill leachate is collected and either reinjected, treated on site, or sent for off-site treatment. In the absence of leachate management systems, uncontrolled leachate releases occur when water travels through the waste, out of the landfill, and into groundwater or surface water (see Section 3.b.iii.1).

LFG can also contain heavy metals, organic chemicals, and methane gas and can produce explosive mixtures of gas in the vicinity of the landfill if not properly controlled. LFG capture technologies are

widely used to control gaseous emissions from landfills. However, not all landfills are required to install and operate LFG collection systems. Even when an LFG collection system is installed and properly operated, a fraction of LFG is emitted directly to the environment through the landfill surface and other routes as fugitive losses (see Section 3.b.iii.2).

Even years after landfill closure, direct human and ecological exposure to PFAS is possible if PFAS are emitted through the air or discharged to groundwater or surface water, or if remaining waste is disturbed. Because landfills contain PFAS but are not designed to destroy these compounds, they represent a potential source of PFAS release well beyond the period during which landfills receive waste and the post-closure care period. Ideally, landfill areas could be used for other beneficial purposes after closure; however, this requires that potential risks from landfill contents be adequately managed. Direct exposure to PFAS from landfilled waste is possible for people living or working near landfills due to gaseous or water releases from the site. Additionally, if PFAS-containing wastes are present on trucks and moved to active cells, landfill employees are directly exposed to PFAS on the job. Research has shown elevated concentrations of PFAS in landfill ambient air (Hamid et al., 2018).

Ensuring that PFAS-containing waste is properly disposed of in lined landfills with active gas collection systems where volatile PFAS or MSW landfills are involved is instrumental in reducing PFAS emissions into the environment. Care must also be taken to avoid disposal of PFAS wastes in landfills that are known to have compromised liners, as PFAS in the leachate will migrate and contaminate groundwater.

3.b.v Testing and monitoring

Currently, there are no federal requirements for the monitoring of PFAS in landfill waste, leachate, condensate, or LFG and analyzing for PFAS in LFG may pose a challenge for comparison across destruction/control technologies and types of landfills due to the lack of standardized testing (see Section 4.a for research needs). However, landfill operators should consider including PFAS measurements with the regular leachate monitoring parameters that are regularly evaluated.

EPA and others are conducting studies to evaluate the effectiveness of landfills in containing or managing PFAS (see Section 3.b) and the Agency and collaborators have developed and updated tools for monitoring and testing of landfill PFAS emissions that will provide a better understanding of environmental fate, transport and transformation of PFAs in landfills. EPA published an updated version of Method 1633 (i.e., 1633A) for quantitative analysis of a range of soluble and neutral PFAS in aqueous and solid matrices by liquid chromatography-tandem mass spectrometry (LC/MS/MS), and this method was validated in a variety of matrices including landfill leachate, groundwater, and biosolids. EPA worked with ASTM International to publish ASTM-D8421-11, an additional LC/MS/MS-based analytical method for aqueous matrices that was validated in leachate and groundwater matrices. In collaboration with researchers, EPA also published an integrated, standardized workflow for NTA of PFAS that can be used for identification of non-target PFAS in landfill emissions or in nearby air or groundwater, potentially including novel PFAS precursors for which no certified reference materials are available (Whitehead et al., 2025).

Waste and leachate matrices can present challenges for identification of unknowns due to high levels of background and interferences the limit reliable qualitative identification. This collection of best practices for NTA data acquisition and interpretation will help promote consistency and standardize laboratories' communication of confidence in identification of unknowns.

3.b.vi Uncertainties/unknowns

Additional sampling and analytical methodologies are needed to better characterize the fate, transport, and transformation of PFAS within landfills to provide accurate estimates of PFAS concentrations in waste inputs and landfill emissions and the potential for PFAS releases from leachate or LFG without adequate controls. Standardized analytical methods are needed for volatile PFAS and ultrashort chain PFAS in wastes, leachate and LFG, and aggregate analytical methods such as total organic fluorine and the total oxidizable precursors assay are also needed to simplify testing for a wide range of PFAS precursors and PFAAs.

As with thermal treatment, EPA lacks detailed information on the amounts and concentrations of PFAS and precursor compounds in wastes that are landfilled; however, limited research is providing some information on PFAS fate and partitioning in landfill environments. The bulk of PFAS seems to remain bound with the waste solids, with quantifiable percentages in LFG and leachate. However, there is a high level of uncertainty in these measurements and more data are needed.

A recent study of three MSW landfills in the United States estimated that LFG accounts for approximately 32 to 76 percent of the mass of fluorine/PFAS released from the landfills and 24 to 68 percent via landfill leachate (Lin et al., 2024). Based on data from two MSW landfills, 95 to 97 percent of PFAS leached from MSW was captured by the leachate collection system with 3 to 5 percent found within stormwater and less than 1 percent found in gas condensate and groundwater. These latter data were used in a mass balance to estimate an average mass flux of PFAS leached of 1.67 to 4.21 kg/year, which along with an estimate of the total mass of PFAS within the landfilled waste approximated a 40-year time span for PFAS to be released, assuming constant mass flux (Chen et al., 2024).

EPA has developed peer-reviewed and reliable toxicity data for only a handful of PFAS. Many PFAS precursors and intermediate and terminal degradation products do not have reliable data regarding physicochemical properties that could be used to improve modeling of their fate, transport, and transformation within landfills, or after release in landfill emissions. SFPs can be considered precursors due to their potential to release perfluoroalkyl acid side chains. Much is still unknown about SFP degradation rates in landfills.

Additionally, the efficacy of treatment options for PFAS captured by leachate and LFG collection systems is not well understood and is in some cases intrinsically entwined with TWTDS and thermal treatment options. EPA continues to research these complex and important issues. Refer to Section 4 for a summary of EPA and DoW's planned research activities specific to landfill containment, wastewater treatment, and thermal treatment of PFAS.

Further, current on-site LFG combustion systems—including flares, engines, and boilers—typically operate below the temperatures known to mineralize PFAS compounds (1,100°C and greater). This raises concerns about incomplete destruction and the potential formation of PICs. While GAC pre-treatment may help reduce PFAS concentrations before thermal treatment, the effectiveness of this approach in minimizing PIC formation remains unclear. Further research is needed to evaluate how combustion temperature, residence time, and pre-treatment strategies influence PFAS breakdown and PIC generation in LFG systems, especially under real-world operating conditions.

3.b.vii Summary

Due to widespread use and disposal through typical waste management pathways, numerous PFAS-containing wastes are contained in landfills and some compounds are expected to persist in landfills for many years, given the chemical makeup of PFAS. Though many landfills (except C&D landfills) are designed for permanent waste containment and management of liquid and gas production, it is currently unclear if all landfills used to dispose of PFAS and PFAS-containing materials have controls that are effective for managing PFAS discharges and emissions from waste streams. PFAS-containing waste should not be placed in C&D landfills that do not have liner systems to intercept and manage the leachate. Even with appropriate liners, research has shown an overall collection efficiency of 98 percent for geomembrane and composite liners.

As leachate passes through a landfill, PFAS are released from degrading wastes. PFAS have been detected in the leachate for all types of landfills, and improper management of landfill leachate would result in PFAS releases. To date, research on the efficacy of wastewater treatment technologies in capturing or destroying PFAS in leachate is limited, as most landfills are not currently required to treat leachate for PFAS. The existing data suggest that adsorption and separation treatment mechanisms have been shown to concentrate or capture PFAS from landfill leachate (see Table 3-4). Other leachate management options can control the release of PFAS, including recirculation and solidification, which return PFAS to the landfill. Leachate treatment through natural processes such as constructed wetlands, land application, or ponds is ineffective for preventing the release of PFAS into the environment. More data are needed on the volatilization of PFAS during leachate handling and treatment.

PFAS can be emitted with LFG that is generated as waste decomposes over time. On-site and off-site LFG management commonly uses flares, engines, or boilers to combust LFG. Combustion temperature and duration could be critical factors for the destruction of PFAS in LFG, as discussed in Section 3.a. The use of GAC for treatment of LFG prior to combustion should be explored further for removal of PFAS (Lin et al., 2024).

To varying degrees, hazardous waste or MSW landfills are feasible and effective disposal options for PFAS and PFAS-containing materials. Permitted hazardous waste landfills employ the most extensive set of environmental controls (e.g., double liner systems with leachate collection and leak detection) and practices (e.g., extensive record keeping) that are currently available for the containment of PFAS waste (see Table 3-2) and as a result would be more effective at minimizing PFAS release into the environment than other landfill types. Hazardous waste landfills do not typically accept biodegradable wastes (e.g., biosolids, food scraps), and are not biologically active, so they do not generally need to be equipped to collect and control LFG. Therefore, hazardous waste landfills are not expected to cause PFAS emissions via LFG and may not be appropriate options for biodegradable PFAS-containing wastes.

Modern MSW landfills, when constructed with appropriate controls (e.g., liner system and leachate and gas collection and management systems), can also control the release of PFAS into the environment. Even with these controls in place, the proper management of landfill gaseous and liquid releases needs to be applied to minimize PFAS release into the environment (see Section 3.b.iii). Care must be taken to apply the leachate control technologies that are effective at containing (e.g., solidification, recirculation) or destroying PFAS (see Table 3-4).

Given the high level of uncertainty associated with PFAS behavior in landfills, the effects of PFAS on liner integrity, gaseous emissions from landfills, the effectiveness of leachate treatment for PFAS removal,

and the levels and types of PFAS in landfill leachate, additional research and test data are needed to further evaluate this disposal method for PFAS and PFAS-containing wastes. See Figure 3-2 for a summary of recommended landfill disposal options for PFAS-containing wastes and considerations for selecting the best option based on waste and landfill characteristics.

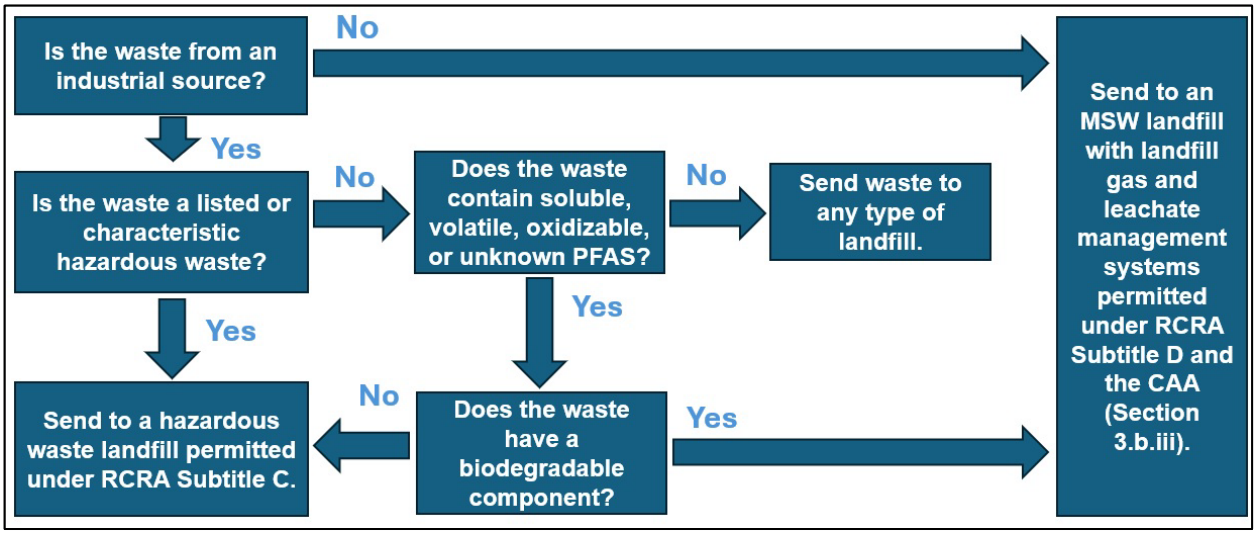

Figure 3-2. Decision framework for selection of landfill disposal for PFAS-containing industrial waste.

3.c Underground injection

Underground injection wells are a feasible and effective disposal option that normally should minimize release of PFAS into the environment. However, underground injection wells are only suited for the disposal of liquids and are restricted to locations with suitable geology. PFAS-containing fluids are currently handled similarly to other waste streams that are injected deep into geologic formations in Class I non-hazardous industrial and hazardous waste disposal wells, while shallow Class V wells would be inappropriate for the management of PFAS-containing fluids. The limited number of wells currently receiving PFAS and accepting off-site waste, well location, and waste transportation logistics may significantly limit the type and quantity of PFAS-containing fluids appropriate for underground injection.

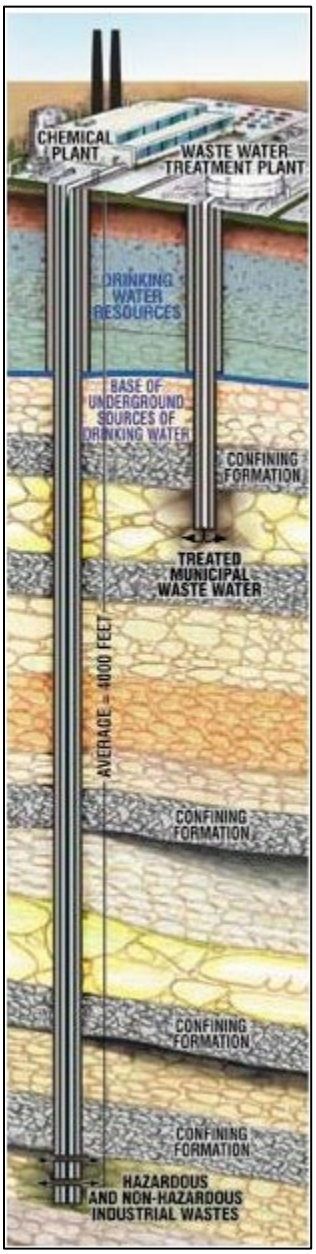

Figure 3-3. Class I wells.

3.c.i Types of wells

Underground injection is generally defined as the subsurface emplacement of fluids through a well. Under the Safe Drinking Water Act (SDWA), EPA is authorized to regulate the permitting of injection wells—including construction, operation, monitoring, and proper closure—for the purpose of protecting USDWs. Underground injection control (UIC) regulations are found in 40 CFR parts 144 to 148.

EPA's UIC program shares information for owners and operators of injection wells, regulators, and the public about safe injection well operations to prevent the contamination of USDWs. Under the UIC program, EPA regulates the permitting of the following well types:

Class I wells inject into geologic formations below the lowermost USDW and are further subdivided into four categories: municipal wastewater, radioactive waste, hazardous waste, and non-hazardous industrial waste disposal wells (see Figure 3-3).

Class II wells are used for injection activities associated with oil and gas production and hydrocarbon storage.

Class III wells are solution mining wells used to inject fluids for the purposes of dissolving and extracting minerals.

Class IV wells, with limited exceptions, have been banned by EPA since 1984 and were used to inject hazardous or radioactive waste into or above geologic formations containing USDWs.

Class V wells include injection wells that are not included in Classes I, II, III, IV, or VI. EPA has identified multiple subtypes, including stormwater drainage wells, septic system leach fields, and agricultural drainage wells.

Class VI wells are used to inject and geologically sequester CO_2.

EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high-concentration liquid PFAS waste has a lower potential for environmental release when compared to other PFAS destruction and disposal options, and there is relatively low uncertainty in this determination. Class I underground injection wells are designed to dispose of and isolate liquid waste below the land surface and beneath USDWs. The standards associated with the construction, operation, and monitoring of Class I wells are designed to ensure protection of USDWs. These standards include at least one confining layer between the zone in which the fluid will be emplaced and the lowest USDW. While Class I wells are an option for managing PFAS-containing fluids, this technology may not be appropriate everywhere. The suitability of a site for injection is dependent on the geologic formations in the area. Sites need to be evaluated to ensure that there is an appropriate confining zone and that there are geologic formations that can receive fluids.

Class I wells for non-hazardous industrial and hazardous waste are currently being used for disposal of PFAS-containing fluids and are the focus of this section. PFAS-containing fluids that may be disposed of via Class I underground injection wells may originate from industrial activities such as chemical production (e.g., products and byproducts) and waste management operation (e.g., landfill leachate).

The standards associated with the permitting, construction, operation, and monitoring of Class I hazardous waste wells, which are regulated under RCRA and SDWA, are more stringent than for non-hazardous industrial waste disposal wells.

3.c.ii Siting, engineering, and operational controls

3.c.ii.1 Overview of the regulatory framework

Underground injection through Class I non-hazardous industrial and hazardous waste wells is a long-standing, well-regulated disposal technology. Underground injection has been used as a waste disposal practice in the United States since the 1930s, beginning with disposal of brines from oil production activities. Underground injection of wastewater from industrial facilities has been in practice since the 1950s. In response to concerns around underground injection activities and incidents of well failure, in 1974 (the same year the SDWA was enacted), "EPA issued a policy statement in which it opposed underground injection without strict control and clear demonstration that the wastes will not adversely affect groundwater supplies" (U.S. EPA, 2001).

Final UIC regulations were published six years later, and federal and state regulation and oversight has been informed by extensive reviews of injection practices and the associated risks over time (U.S. EPA, 2001). The requirements for Class I wells under 40 CFR part 146 and 40 CFR part 148 (which applies to hazardous waste wells only) are designed to ensure that injected fluids cannot migrate into USDWs through either of two potential pathways: (1) loss of waste confinement, or (2) "improperly plugged or completed wells or other pathways near the well" (U.S. EPA, 2001). These requirements include, but are not limited to:

- Proper siting.
- Conducting geologic and hydrogeologic studies that demonstrate that injected fluids will not endanger USDWs.
- Implementing specific design, construction, and operation requirements.
- Implementing continuous monitoring and periodic monitoring and testing requirements.
- Performing appropriate well closure and plugging activities.

Specific components of these requirements are discussed further below.

3.c.ii.2 Class I non-hazardous industrial and hazardous waste wells

Underground injection to Class I non-hazardous industrial and hazardous waste wells reduces the potential risks of human exposure to injected materials, avoiding discharge to surface and shallow groundwater and generating little or no air emissions. When injected into non-hazardous industrial or hazardous waste Class I wells, fluids are placed below the lowermost USDW. The area into which waste is injected is referred to as the injection zone, which for Class I wells, typically range from 1,700 to more than 10,000 feet in depth (U.S. EPA, 2001). Injection zones are porous and permeable geologic formations and they are separated from USDWs by one or more confining layers of impermeable rock. The confining layers prevent injected fluids from migrating vertically into a USDW.

Class I wells are sited in geological areas that are conducive to injection operations. Siting considerations include ensuring that injected fluids will not migrate through natural fractures and faults from the injection zone into USDWs. Likewise, well operators are required to demonstrate the absence of non-natural pathways (e.g., abandoned wells) or other nearby active wells that could allow for movement of injected fluids into USDWs within a prescribed area surrounding the well (known as the area of review). In addition to the safeguards offered by siting, engineering, and operating requirements, well design and construction requirements incorporate redundant safety features, and construction materials are "corrosion-resistant and compatible with the wastewater and the formation rocks and fluids into which they come in contact" (U.S. EPA, 2001). Class I wells might also use multiple strings of well casing, inject through tubing set on a packer, and be constructed with adequate cement alongside the entire well string to protect any USDWs.

3.c.ii.3 Potential for Release

Permitted underground injection of fluids through Class I non-hazardous industrial and hazardous waste wells ensures that injected fluids are confined and cannot enter USDWs—the pathway of concern for this waste disposal technology. In its 2001 study of risks associated with Class I wells, EPA stated that the "probability of Class I well failures, both non-hazardous and hazardous, has been demonstrated to be low. In the unlikely event that a well would fail, the geology of the injection and confining zones serves as a final safety net against movement of wastewaters to USDWs" (U.S. EPA, 2001).

Injection well operators invest millions of dollars in the permitting, construction, and operation of wells. Development of Class I non-hazardous industrial and hazardous waste wells is a resource-intensive process, with the geologic limitations noted previously. In addition, siting requirements limit the areas in the country where Class I wells can be located (see Section 3.c.iii). Routine operation and maintenance include addressing requirements for extensive mechanical integrity testing, monitoring, and periodic submission of permit/no-migration petitions.

3.c.ii.4 Additional requirements for Class I hazardous waste wells

Class I hazardous waste wells are highly protective of USDWs and include additional requirements beyond those of Class I non-hazardous industrial waste wells. The 1984 Hazardous and Solid Waste Amendments to RCRA prohibited land disposal of hazardous waste, including via underground injection, with limited exceptions. Hazardous waste disposal via Class I injection wells is permitted if the operator can demonstrate that the waste will remain where it has been injected for as long as it remains

hazardous (defined under regulation as a period of up to 10,000 years). To demonstrate this, Class I hazardous waste well operators must receive approvals of "no-migration petitions" from EPA.

No-migration petitions present information and modeling results using data on local and regional geology, waste characteristics, geochemical conditions of the well site, injection history, and many other factors, which EPA reviews to determine whether the petitioner has adequately demonstrated that the waste will not migrate from the disposal site for as long as it remains hazardous. Furthermore, Class I hazardous waste well facilities are subject to inspections and well operators must conduct annual testing and analysis to demonstrate they are meeting the conditions of the permit and that all assumptions, projections, and models are still appropriate and valid. This includes performing mechanical pressure tests and geophysical logging tests to assess well integrity, both internally and externally, to ensure injected fluids are being emplaced and are remaining within the injection zone.

3.c.iii Availability

Currently, the United States has 886 Class I wells. Approximately 50 percent of Class I wells are permitted for non-hazardous industrial waste injection and approximately 16 percent are permitted for hazardous waste disposal. The remainder are permitted for municipal wastewater disposal. EPA is aware of both non-hazardous industrial and hazardous Class I wells that manage PFAS-containing fluids. However, there is currently no national information on the number and location of Class I non-hazardous industrial or hazardous waste wells that could accept PFAS-containing waste or are willing to accept waste not generated on site.

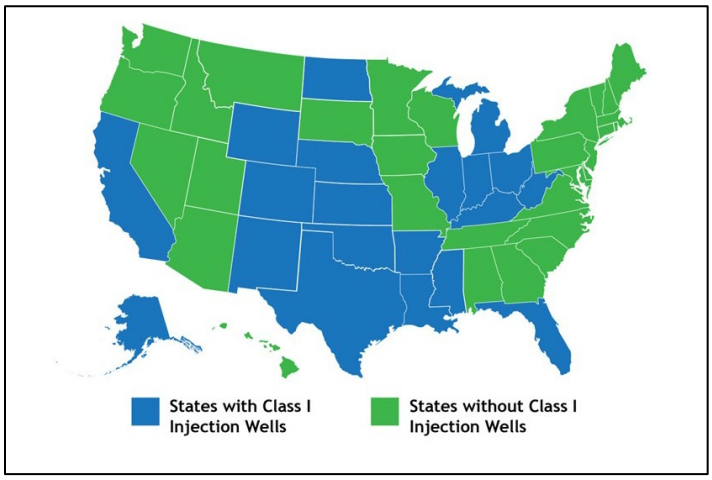

Figure 3-4. States with Class I non-hazardous or hazardous waste injection wells.

Figure 3-4 shows all states that currently have at least one permitted Class I injection well of any type (non-hazardous industrial or hazardous waste). Table 3-5 provides a more detailed breakdown of the number of permitted Class I wells by state.

Table 3-5. Inventory of Permitted Class I Non-Hazardous and Hazardous Waste Wells in the United States (FY 2023; Source: EPA)[26]

Location of Wells		Number of Wells	
EPA Region	State/Tribe	Class I Non-Hazardous	Class I Hazardous
3	West Virginia	1	-
4	Florida	302	-
	Kentucky	2	-

[26] EPA's inventory of Class I non-hazardous waste wells consists of all non-hazardous waste wells, including municipal and industrial waste wells. However, the municipal waste wells are located exclusively in Florida.

Location of Wells		Number of Wells	
EPA Region	State/Tribe	Class I Non-Hazardous	Class I Hazardous
	Seminole Tribe	3	-
	Mississippi	4	4
5	Illinois	5	2
	Indiana	12	4
	Michigan	46	7
	Ohio	9	10
6	Arkansas	8	4

	New Mexico	-	6
	Oklahoma	6	-
	Osage Nation	1	-
	Texas	82	78
7	Kansas	58	7
	Nebraska	11	-
8	Colorado	13	-
	North Dakota	8	-
	Wyoming	85	-
9	California	47	-
10	Alaska	25	-
Total		**745**	**141**

3.c.iii.1 Class I non-hazardous industrial waste wells

Non-hazardous industrial waste wells are currently located across 19 states and two Tribal lands, though the majority are in five states—Wyoming, Texas, Kansas, California, and Michigan. There are currently no Class I non-hazardous waste wells in EPA Regions 1 or 2 (see Figure 3-4 and Table 3-5). Disposal to this type of well requires well operators to apply for and receive a permit for specific waste streams. Current Class I injection wells may have limited capacity for PFAS-containing fluids, as many of them are used for specific purposes and disposal of waste generated on site. To begin accepting PFAS-containing fluids, existing well permits would have to be modified to recognize that the facility is accepting waste from other entities and to authorize the facility to inject modified waste streams.

Well operators must also consider the well's capacity to accept additional volumes of waste and the compatibility of the PFAS-containing fluids with the well material, the geochemistry of the injection formation and formation fluids, and the properties of other injected wastes.

3.c.iii.2 Class I hazardous waste wells

Hazardous waste wells are currently located in 10 states; however, most are in Texas and Louisiana. Most Class I hazardous waste wells are sited at industrial facilities and dispose of waste generated on site (U.S. EPA, 2016). There are currently no Class I hazardous waste wells in EPA Regions 1, 2, 3, 8, 9, or

10 (see Figure 3-4 and Table 3-5). Because of this geographic concentration of Class I hazardous waste wells, waste producers may face transportation and logistical challenges.

EPA anticipates the number of current Class I hazardous waste wells that would begin accepting new sources of PFAS-containing waste to be very limited due to the necessary modifications of Class I hazardous waste well permits (e.g., increased injection volumes, changes to waste streams, no-migration petitions). These modifications would involve engineering and scientific evaluations, modeling, and public hearings.

3.c.iv Testing and monitoring

Class I non-hazardous industrial waste and hazardous waste disposal wells are subject to extensive testing and monitoring requirements established under federal regulations. Requirements for hazardous waste wells are more stringent than for non-hazardous industrial waste wells. Additionally, by law, states with primary enforcement authority for Class I wells may have more stringent testing and monitoring requirements. Class I monitoring and testing requirements are designed to ensure there are no leaks within or out of the well and that all injected fluid is contained in the injection zone.

Broadly, Class I well operators must:

- Analyze characteristics of injected fluids at a frequency that results in representative data.
- Continuously monitor and record injection pressure, annulus pressure, flow rate, and volume.
- Conduct internal and external mechanical integrity testing.
- Monitor for fluid release into the USDW within the area of review.

Class I hazardous waste wells operators must conduct mechanical integrity testing more often than Class I non-hazardous industrial waste operators. They also must establish and follow additional procedures for reporting and correcting mechanical integrity problems. Operators of Class I hazardous waste wells must also develop and follow a waste analysis plan and conduct annual tests of cement at the base of the well (U.S. EPA, 2015).

Additional information on testing and monitoring requirements, including mechanical integrity testing, is included in EPA's summary document *Requirements for All Class I Wells and Class I Hazardous Waste Wells*[27] and EPA Region 5's guidance on *Determination of the Mechanical Integrity of Injection Wells*[28].

3.c.v Uncertainties/unknowns

The fate and transport of PFAS in the subsurface depends on the chemical and physical properties of specific PFAS and the geochemical properties of the injection zone. Understanding of the long-term fate and transport properties of PFAS (including precursors) in the injection zone is currently limited. Studies have shown wide ranges in PFAS properties, and these can be altered by mixture effects and interactions with co-contaminants. This creates uncertainty in predictions of PFAS contaminant release

[27] Available at: *https://www.epa.gov/sites/production/files/2015-10/documents/page_uic-class1_summary_class1_reqs_508c.pdf*.

[28] Available at: *https://www.epa.gov/sites/production/files/2015-09/documents/r5-deepwell-guidance5-determation-mechanical-integrity-200802.pdf*.

and longevity in the injection zone. These uncertainties need to be considered in the development of the required no-migration petition for disposal of PFAS in Class I hazardous waste wells.

3.c.vi Summary

EPA has determined the use of Class I non-hazardous industrial waste and hazardous waste wells for high-concentration liquid PFAS waste has a lower potential for environmental release when compared to other PFAS destruction and disposal options. Permitted underground injection of fluids through Class I non-hazardous industrial and hazardous waste wells ensures that injected fluids are confined and cannot enter USDWs—the pathway of concern for this waste disposal technology. Additional Class I wells may need to be constructed where geologically suitable, and existing well permits may require modification to meet the capacity needs for PFAS disposal. Research on the long-term fate and transport of PFAS (including precursors) to predict release potential in the injection zone could support future permits.

See Appendix D for a summary of costs and considerations.

4. Research Needs and Data Gaps for Destruction and Disposal Technologies

EPA's understanding of potential PFAS releases from destruction and disposal activities continues to evolve as the results of testing and ongoing research activities become publicly available, but more research is needed to refine EPA's non-binding, interim guidance on the destruction and disposal of PFAS and PFAS-containing materials. This section identifies and prioritizes research needs that, if addressed, are expected to help EPA provide meaningful updates on effective destruction and disposal practices for PFAS-containing materials in future iterations.

What's New in Section 4 of the 2026 Guidance Document?

- Revised Table 4-1 based on new information presented in this document and public comments received on the 2024 interim guidance.
- Replaced discussion of current research efforts with links to ongoing, relevant federal research activities.

Addressing the research needs described in Section 4.a will require sustained effort across government, academic, and private institutions. Within the federal government, EPA, and DoW have been leaders in supporting the research, development, and demonstration of PFAS destruction and disposal technologies. Information on these activities can be found at:

- EPA's PFAS Innovative Treatment Team – Section 5.a
- EPA's Research on PFAS[29]
- DoW's Strategic Environmental Research and Development Program (SERDP) and the Environmental Security Technology Certification Program (ESTCP) PFAS Projects[30]
- DoW's Defense Innovation Unit Prototype Projects[31]

Colleges and universities, who are the recipients of federal and other research funding, conduct cutting-edge research related to PFAS destruction and disposal. These institutions often bring together expertise from many disciplines which enables the rapid development of innovative approaches for managing the constantly changing set of PFAS-containing materials.

Other entities have strong interests in expanding into the area of PFAS material management, disposal, and destruction. These entities include private industry, the operators of waste disposal technologies, municipal water utilities, professional and trade associations, and relevant research foundations. These organizations are actively developing and marketing solutions to address PFAS material management, disposal, and destruction.

[30] Available at: *https://www.serdp-estcp.org/Featured-Initiatives/Per-and-Polyfluoroalkyl-Substances-PFASs*.

[31] Available at: *https://www.diu.mil/pfas*.

EPA encourages all entities conducting PFAS destruction and disposal research to do so in a manner that is consistent with the tenets of gold standard science established in Executive Order 14303 (*Restoring Gold Standard Science*[32]) and further defined in a memorandum from the *Office of Science and Technology Policy dated June 23, 2025*[33].

4.a Research needs to inform future guidance updates

EPA has translated the uncertainties and data gaps identified throughout this interim guidance into research needs, which are presented in Table 4-1. The research needs in Table 4-1 are focused on advancing our ability to measure PFAS in materials and releases from destruction and disposal technologies and improving our understanding of the performance of thermal treatment units, landfills, and underground injection control wells for managing PFAS and PFAS-containing materials. Individually, the research needs identified in Table 4-1 are complex to address because of the variety of substances within the PFAS class, the range of PFAS-containing materials discussed in this interim guidance, and the variability in technology designs and operating conditions. Collectively, some of the research needs identified in Table 4-1 are dependent upon other research needs. For example, fully characterizing PFAS releases from destruction and disposal technologies is dependent upon the availability of methods for measuring PFAS in air, water, and solids. Because of the complexity of the research needs and their inter-dependence, EPA anticipates that it will take years for the research needs in Table 4-1 to be fully addressed.

EPA has also prioritized the research needs in Table 4-1 as either high, medium, or low based on the potential for results to inform future versions of this interim guidance. In general, EPA designated the characterization of potential PFAS releases from thermal treatment units and landfills as high priority because these data are essential for determining whether nearby populations living near destruction and disposal sites could be exposed to PFAS at unreasonable levels from these facilities. At the same time, EPA recognizes that current laboratory methods for identifying and quantifying PFAS are limited. As such, the Agency also considers the development of sampling and analytical methods to be medium or high priority. EPA does not, however, believe that characterizing PFAS releases from PFAS destruction and disposal activities should wait until additional analytical methods are available. Rather, EPA expects that characterizing PFAS releases from destruction and disposal sites will be iterative and that future characterization efforts will be informed and guided by past efforts and the availability of new methods. EPA also expects that data on PFAS releases from PFAS destruction and disposal technologies will be used to inform and prioritize future research efforts.

EPA designated research needs associated with the underground injection of PFAS and PFAS-containing materials via Class I wells as a low priority. The Agency made this designation because the standards associated with the construction, operation, and monitoring of Class I wells are designed to isolate liquid wastes deep below the land surface and ensure protection of USDWs. While data on the performance of Class I wells for managing liquid PFAS waste would be informative, the highest priority continues to be on characterizing PFAS releases from thermal treatment units and landfills.

Table 4-1. Prioritized Research Needs to Inform Future Guidance Updates

Topic	Research Needs	Priority
Thermal Treatment	Methods for sampling and analyzing PFAS in solid-, liquid-, and gas-phase waste streams from thermal treatment units:	
	• Organic fluorine (all phases).	Low
	• Targeted methods for non-polar, semivolatile PFAS (gas-phase).	High
	• Targeted methods for polar, volatile PFAS (gas-phase).	High
	• Targeted methods for cationic, zwitterionic, and nonionic PFAS (solid- and liquid-phase).	High
	Full-scale performance testing—following the parameters and procedures suggested in Appendix A—at:	
	• Hazardous waste combustors:	
	○ Commercial hazardous waste incinerators (HWI).	High
	○ Hazardous-waste-burning cement kilns.	High
	○ Hazardous-waste-burning lightweight aggregate kilns (LWAK).	Medium
	• Carbon regeneration and reactivation units.	High
	• Non-hazardous waste combustors:	
	○ Sewage sludge incinerators.	High
	○ Municipal waste combustors.	Medium
	○ Thermal oxidizers.	High
	Characterization of PFAS releases from thermal treatment units operating under different conditions/designs:	
	• Gas-phase emissions.	High
	• Air pollution control device (APCD) discharges.	High
	• Bottom ash.	High
	• Biosolids, remediated soil.	High
Landfills	Methods for sampling and analyzing PFAS to better characterize PFAS loading to and fate in landfills and releases from landfills to air, municipal WWTPs, and groundwater:	
	• "Aggregate" measurements that capture target and non-target PFAS (e.g., total organic fluorine, total oxidizable precursors).	Medium
	• Non-targeted analysis to better characterize occurrence and prevalence of novel PFAS.	High
	• Quantitative analytical methods for a wider array of precursors and intermediate and terminal transformation products:	Medium
	○ Volatile PFAS (e.g., FTOHs, FTACs).	
	○ PFAA precursors, including cationic, zwitterionic and non-ionic species.	
	○ Ultrashort chain PFAS (e.g., PFPrA).	
	Approaches for solidification and stabilization of PFAS-containing materials:	
	• Effectiveness of differing solidification and stabilization techniques.	High
	• Performance over time.	High
	Fate and transport of PFAS—including modeling transformation processes and partitioning between solid-, liquid-, and gas-phases in:	
	• Hazardous waste landfills.	High
	• Industrial waste landfills.	High
	• Municipal solid waste landfills.	Medium
	• Ash monofill landfills.	Low
	• Construction and demolition (C&D) landfills.	High
	Full-scale performance testing of engineered landfill components:	

Topic	Research Needs	Priority
	• Bottom liner and leachate collection systems. • On-site leachate treatment systems. • Gas collection and emission control systems. • Final cover systems.	Low High Low Low
	Characterization of PFAS releases from landfills operating in different regions and under different conditions/designs: • Gas-phase emissions, including PICs from flaring or incineration of MSW LFG. • Emissions in leachate collected in lined landfills. • Data on groundwater contamination from infiltration at unlined landfills or from permeation through liners at lined landfills.	 High High High
	Efficacy of PFAS removal during LFG and leachate treatment: • Conventional technologies. • Emerging technologies.	 High Medium
Underground Injection (Class I)	Performance data from wells that are managing PFAS-containing liquids: • Surface management practices. • Effects on injection performance.	 Low Low
	Long-term fate and transport of PFAS in injection zones of Class I wells: • Mixture effects. • Interactions with co-contaminants.	 Low Low
	Data on the presence/absence of PFAS in groundwater near Class I wells receiving PFAS-containing liquids and data on known failures or leaks from Class I wells receiving PFAS-containing liquids.	Low
Emerging Technologies	Lab-, pilot-, and field-scale research to test the effectiveness of emerging technologies for different PFAS-containing materials and to characterize the outputs for PFAS and non-PFAS constituents.[a]	High

[a] See Section 5 for discussion of emerging technologies. EPA encourages technology developers to generate and publicly release data that can be used to answer the questions presented in the technology evaluation framework in Section 5.b.

5. Emerging Technologies for PFAS Destruction and Disposal

What's New in Section 5 of the 2026 Guidance Document?

- Added information on remaining PITT outputs in Section 5.a.
- Revised information on the technology evaluation framework in Section 5.b to incorporate suggestions from public comments received on the 2024 interim guidance.

Because of their chemical and physical properties, PFAS can pose unique challenges for end-of-life materials management. As described in Section 3, the effectiveness of commonly used waste management technologies, such as thermal treatment and landfilling, for managing PFAS materials can vary. Additionally, current operating conditions and practices at some thermal treatment facilities and landfills may not be sufficient to limit releases of PFAS to the environment. Concerns about the effectiveness of widely-used technologies for managing PFAS materials call for innovative research and development efforts toward new technologies, as well as testing to apply existing destruction technologies to PFAS materials at various scales.

Development of new technologies typically involves the following stages:

- Technology development often starts with exploring and understanding the basic scientific principles and processes that underly the technology. At this early stage, the primary focus is on gaining understanding of how the process works and whether it shows promise for a particular application (e.g., PFAS destruction).
- If the results of early experiments are promising, the next stage of development generally focuses on prototype development and testing under controlled conditions. This stage allows developers to better understand whether the technology is practical and effective at larger scales. It also provides developers with information on costs associated with manufacturing and operating units.
- In the final stage of development, the focus generally shifts to field-scale demonstration projects that allow developers to test the technology under a variety of real-world conditions and to develop better cost estimates for operation and maintenance. During this stage, developers may identify the best and most cost-effective applications for the technology. In the case of PFAS destruction and disposal, this may include identifying the types of PFAS materials best suited for the technology (e.g., high-concentration materials versus low-concentration materials).

At any stage of the technology development process, developers may determine that the technology is not applicable or is not cost-effective and development can stop.

In addition to research to identify and develop novel technologies for PFAS destruction, efforts are underway to apply existing destruction technologies—other than thermal treatment—to PFAS materials. In these cases, the scientific principles and processes underlying a technology may already be understood, but there is little information on the performance of the technology or its applicability to

PFAS materials. Evaluating the applicability of an existing technology to PFAS materials can occur at various scales:

- Laboratory- and pilot-scale studies can be used to evaluate the effectiveness of a technology under controlled conditions and to determine how operating conditions can affect PFAS destruction.
- Field studies can provide data from full-scale applications that reflect the variability seen in real-world operating conditions.

The purpose of this section is to: (1) provide an overview of EPA efforts to identify and test emerging technologies for PFAS destruction, and (2) outline the PFAS destruction and disposal technology evaluation framework, which provides a transparent, consistent approach for evaluating destruction and disposal technologies for PFAS materials. In addition to the EPA-investigated emerging technologies discussed in this section, the Agency is aware of other emerging technologies that are at various stages of development and implementation, such as smoldering combustion, hydrothermal alkaline treatment (HALT), advanced reducing processes (ARP), and non-thermal plasma technologies. For an additional, separate discussion of current PFAS treatment technologies, including emerging technologies, managers of PFAS-containing materials can refer to Section 12 of the *ITRC PFAS Technical and Regulatory Guidance Document*[34].

EPA encourages continued collaboration with other government, academic, and private institutions to continue conducting research to better understand destruction and disposal of waste containing PFAS, and to be potentially included in future iterations of this guidance. EPA encourages that technology developers generate and publicly release data that can be reviewed, and that data are consistent with the tenets of gold standard science established in Executive Order 14303 (*Restoring Gold Standard Science*[35]).

5.a EPA's PFAS Innovative Treatment Team

EPA initiated the PITT in 2020 as a short-term, dedicated, cross-office effort to identify, review, and conduct preliminary research on potential treatment technologies. Over six months, the multi-disciplinary PITT conducted state-of-the-science reviews of proposed methods to dispose and/or destroy PFAS in media and wastes. Several criteria were evaluated using available information, including efficacy, feasibility, performance, and costs of each technology, while also considering potentially hazardous byproducts. The PITT partnered with other agencies and states to conduct a competitive public challenge to identify solutions that were potentially overlooked and to encourage further development of potential technologies.

The PITT chose to focus on the effectiveness of a few technologies, such as mechanochemical degradation, gasification and pyrolysis, and supercritical water oxidation. These technologies showed theoretical promise of the sought-after criteria: PFAS destruction, production of few to no hazardous residuals or byproducts, commercial availability, and cost effectiveness for various contaminated matrices. References and discussion for each technology can be accessed in the PITT Research Briefs at

[34] Available at: *https://pfas-1.itrcweb.org/*.

[35] Available at: *https://www.govinfo.gov/content/pkg/FR-2025-05-29/pdf/2025-09802.pdf*.

PITT Research Briefs[36]. The identification of these technologies by the PITT should not be considered an endorsement or recommendation to use these technologies to destroy PFAS. Additional research is needed to determine the effectiveness of these technologies for different PFAS-containing materials and to characterize the outputs for PFAS and non-PFAS constituents. An overview of the results of the PITT's state-of-the-science review is available in *Developing Innovative Treatment Technologies for PFAS-Containing Wastes* (Berg et al., 2022).

After the state-of-the-science reviews, the PITT selectively encouraged development and research of the four chosen emerging technologies to better understand the potential for PFAS destruction, specifically AFFF, while avoiding creation or transfer of environmental hazards. The PITT conducted in-house research and partnered with industry and academia to collect data regarding the technologies and to encourage further development of the methods required to ascertain PFAS destruction efficacy. Additionally, during the PITT effort, a subsection of the team developed an innovative technology for a thermomechanochemical (TMC) waste treatment processing device. The TMC methodology and apparatus were patented by the U.S. Patent and Trademark Office in 2024 and 2025 (Whitehill et al., 2024; Whitehill et al., 2025).

Although the effort originally was allotted six months in 2020, the work initiated by the PITT results beyond the initial six-month timeframe. The sections below describe some of the results from this work.

5.a.i PITT-investigated emerging technologies

To further explore the potential for mechanochemical degradation of PFAS, EPA scientists partnered with colleagues in New Zealand to conduct a proof-of-concept case study using a benchtop ball mill, AFFF-spiked sand, and AFFF-contaminated soil (Gobindlal et al., 2023). Mechanochemical degradation is a treatment technology that uses a high-energy, ball-milling device (with the option of co-milling reagents) to produce highly reactive conditions to degrade contaminants. Results from the AFFF-spiked sand showed a 99.99-percent destruction efficiency for the sum of all measured PFAS after 960 minutes, and results from the AFFF-contaminated soil indicate that measured PFAS were below the limit of detection after 1,440 minutes. Because this study analyzed PFAS in the solids after different ball-milling time intervals, from 15 to 1,440 minutes, the authors were able to identify increases in some of the measured PFAS before concentrations decreased, indicating the transformation of PFAS during ball milling. An extractable organic fluorine method was also used to determine the reduction in extractable organic fluorine before and after ball milling. In the case of AFFF-spiked sand, the authors reported a 97.8-percent reduction in extractable organic fluorine. A 53.5-percent reduction in extractable organic fluorine was reported for the AFFF-contaminated soil. Air emissions were not characterized as part of this study, making it difficult to determine whether full mineralization of PFAS occurred, and more work is needed in this regard. As noted in the study, more work is also needed to identify primary operations variables to inform the scalability of mechanochemical destruction.

In 2020, EPA conducted a pilot study at a biosolids treatment facility using pyrolysis (Thoma et al., 2022). Pyrolysis is a process that decomposes materials at moderately elevated temperatures in an oxygen-free environment. During the pilot study, dried biosolids were fed into a pyrolysis reactor operating at approximately 610 °C (1,100 °F). The dried biosolids and the resulting biochar were sampled and tested for 41 target PFAS. Twenty-one PFAS were detected in the input biosolids, and none of the target PFAS were detected in the biochar. The pyrolysis system's target PFAS removal efficiencies were estimated to

[36] Available at: *https://www.epa.gov/chemical-research/pfas-innovative-treatment-team-pitt*.

range between greater than 81.3 percent and greater than 99.9 percent. The pilot study also included limited analysis of the air emission control system, with results indicating no transmission of the target PFAS to the air. It is important to note, however, that full characterization of PFAS using non-targeted methods was not performed and more work is needed to understand PFAS transformations and the destruction mechanism.

EPA also completed studies to test the effectiveness of supercritical water oxidation for treating AFFF. Supercritical water oxidation is a process that occurs when the temperature and pressure of water is above the critical point. Above the critical point, oxidation processes are accelerated. In 2020, EPA partnered with three companies to perform tests of their supercritical water oxidation systems on dilute, PFOS-based AFFF (Krause et al., 2022). During these demonstration tests, each system was operated under slightly different conditions, and each company analyzed samples of the influent and effluent for slightly different PFAS. The overall destruction efficiency of each system was calculated by summing the concentrations of the measured PFAS. In all cases, the overall destruction efficiency was found to be greater than 99 percent. It is important to note, however, that the sum of the PFAS measured in the effluent ranged from approximately 10 µg/L to approximately 100 µg/L, suggesting that further treatment of the effluent may be necessary. It is also important to note that non-targeted analysis was not conducted and air emissions were not monitored, making it difficult to assess the fate, transport, and transformation of PFAS with the supercritical water oxidation systems.

In 2021, EPA also partnered with a company to conduct tests at industrial-scale supercritical water oxidation system (Sahle-Demessie et al., 2022). These tests used a dilute, FTS-based AFFF. The primary objective of the study was to determine the destruction efficacy of the PFAS in the input material. Analysis of the influent and effluent showed greater than 99.99-percent destruction of the total PFAS measured. The average sum of the targeted PFAS in the effluent was approximately 55 µg/L, but PFAS were also detected in the tap water used as quench water in the system, suggesting that the overall performance of the system could be improved if non-PFAS-contaminated water is used in the system. A secondary objective of the study was to characterize degradation products using non-targeted analysis and stack sampling for nonpolar volatile fluorochemicals. Non-targeted analysis of the effluent tentatively identified the shorter carbon-chain PFAS on the targeted analyte list, and the authors suggested a possible destruction mechanism that would be consistent with this result. Further work is needed, however, to determine the destruction mechanism. The air emissions sampling did not detect targeted PFAS in air emissions above background levels; further work with finalized air methods (e.g., OTM-50) is needed to confirm this observation.

At this time, EPA is neither recommending nor discouraging the use of any emerging technology for managing PFAS-containing materials, including the technologies studied by the PITT. While the PITT studies generally indicated potential for PFAS destruction, further work using newly available methods is needed to more fully characterize the outputs of these processes and to evaluate their performance for PFAS-containing materials beyond AFFF.

5.b PFAS Destruction and Disposal Technology Evaluation Framework

Researchers have proposed metrics to evaluate PFAS destruction and disposal technologies, including technology readiness levels (TRLs), DREs of target compounds, fluorine mass balances, and others (Berg et al., 2022; Deeb et al., 2021; Krause et al., 2021). When used individually, these metrics fail to accurately capture comprehensive system performance or provide a holistic understanding of the potential for PFAS transformation and/or release to the environment. For example, DREs calculated

from targeted analyses using existing methods can result in underreporting of the total PFAS in a matrix because existing detection methods can only measure a fraction (e.g., 50 individual PFAS) of the total number of PFAS that may be present in a sample. Similarly, TRLs can fail to accurately reflect the current development stage of a technology by either reporting the overall maturity of the technology, instead of its specific PFAS application, or by relying on a niche, small-scale application to justify an overall readiness level.

These limitations drive the need for a comprehensive framework for evaluating a technology and its application to PFAS-containing materials. Such a framework should allow the user to prioritize the collection and consideration of different pieces of information. To meet these needs, EPA developed a technology evaluation framework that uses a multiple-lines-of-evidence approach to evaluate a technology/PFAS material combination (Table 5-1). The framework provides a transparent approach for evaluating and selecting a technology to reduce PFAS releases to the environment. EPA recommends that managers of PFAS-containing materials use the framework to evaluate emerging technologies, and to inform decisions about destruction and disposal of PFAS-containing materials.[37] EPA encourages technology developers to generate and publicly release data that can be used to answer the questions presented in the framework.

The framework comprises several topical sections: technology, material, analytical methods, disposal/destruction efficacy, community considerations, and regulatory requirements. Within each section, EPA has identified key pieces of information that, when considered together, provide a more holistic evaluation of a technology and its applicability for PFAS disposal or destruction.

The framework is intended to be an adaptable tool that allows the user to prioritize the collection and consideration of different pieces of information via the "priority" column in the framework. This allows users to address questions most relevant to their priorities and with respect to their decision context and the shared priority of preventing and mitigating potential exposures. Users may also choose to prioritize addressing certain questions before others to streamline their evaluation of a technology/material combination. For example, if a user of the framework is evaluating the performance of a destruction technology, the questions in the disposal efficacy section of the framework are not needed and could be removed from the framework. As another example, a user may prioritize answering questions under the technology section of the framework because those questions may rule out a technology for a particular application (e.g., the technology may not be available at the scale needed to process the PFAS-containing material of interest). Once a technology is ruled out, lower priority questions do not need to be answered. For further adaptability, if a user has particular needs or concerns that go beyond those currently identified in Table 5-1, the user may decide to add other categories and questions to the framework. For example, a user may want to add a category for pollution prevention and waste minimization considerations, if that is a relevant priority (e.g., Does the technology use toxic chemicals? Is the technology energy or resource intensive; or Does the technology produce large amounts of waste?). While users may not answer each question in the framework or may choose to add other questions according to their needs, EPA encourages users of the framework to

[37] The Interstate Technology and Regulatory Council (ITRC) PFAS Team developed the *PFAS Technical and Regulatory Guidance Document* (available at *https://pfas-1.itrcweb.org/*) to support state and federal environmental staff, as well as others, to gain a working knowledge of the current state of PFAS science and practice. Section 12 of the ITRC guidance document provides information on PFAS treatment technologies, including destruction technologies. Managers of PFAS-containing materials may find this resource useful when completing Table 5-1.

address as many questions as possible to inform decisions about the destruction and disposal of PFAS materials.

Table 5-1 shows this approach, followed by more detailed considerations for each question.

Table 5-1. Framework for Evaluating Destruction/Disposal Technologies for PFAS-Containing Materials

Category of Information	Key Questions	Priority[a]	Answer and Associated Notes for PFAS Material of Interest
Technology	If available, what is the TRL for the technology/material combination of interest?		
	Is the technology of interest available at the scale needed for the intended application?		
	Is a treatment train needed to meet the desired destruction/disposal outcome?		
Material	What PFAS-containing material has been used to test the performance of the technology of interest?		
	Which PFAS, and at what concentration ranges, have been used to test the performance of the technology of interest?		
	Are there non-PFAS constituents that may affect the performance of the technology of interest?		
Analytical methods	Which standardized or validated targeted analytical methods (e.g., OTM-45, EPA Method 1633A) have been used to characterize the performance of the technology for the PFAS-containing material of interest?		
	Has non-targeted analysis been performed on waste streams from the technology/material combination of interest? If so, are there other PFAS detected that should be considered when assessing this technology?		
	What other analytical approaches have been used to characterize the performance of the technology for the PFAS-containing material of interest?		
	Was the study design and the quality of the data generated during testing appropriate to evaluate the technology?		
Disposal efficacy	Have potential transformation and partitioning pathways been identified for the technology/material combination of interest?		
	Are engineering controls in place to prevent or minimize release of PFAS to the environment?		
	What is the longevity of the disposal technology?		

Category of Information	Key Questions	Priority[a]	Answer and Associated Notes for PFAS Material of Interest
	Has a fluorine mass balance been determined?		
	Does the disposal of the PFAS-containing material contribute to the potential release of non-PFAS constituents to the environment?		
Destruction efficacy	Is the mechanism of destruction understood?		
	Have all process inputs and outputs been characterized for PFAS to the extent possible given current analytical methods?		
	What is the reported destruction efficiency?		
	Have any PIDs (or PICs) been identified?		
	Has a fluorine mass balance been determined?		
	Have all process outputs been characterized for non-PFAS constituents to the extent possible given current analytical methods and understanding of the composition of the PFAS-containing material?		
Community Considerations	Has a destruction/disposal site been identified?		
	What are the characteristics of the surrounding community?		
	Are PFAS releases anticipated from the technology/material combination of interest?		
	Has the surrounding community been engaged?		
Regulatory requirements	Are there state or federal regulations that control emissions or releases from the technology of interest?		
	Are there state or federal regulations that control the management of the PFAS-containing material of interest?		

[a] Users can prioritize key questions using a variety of approaches. For example, questions could be labeled as *high, medium*, or *low* priority. Questions could also be prioritized using a numerical ranking system with *1* indicating questions to answer first, *2* indicating questions to answer second, and so forth.

5.b.i Key questions for technology evaluation

Technology. The first section of the framework focuses on the destruction or disposal technology. Key questions include:

If available, what is the TRL for the technology/material combination of interest? TRLs are generally assigned using the *definitions developed by NASA*[38] (NASA, 2023), where level 1 corresponds to observation and reporting of basic scientific principles and level 9 corresponds to "flight proven"

[38] Available at: *https://www.nasa.gov/directorates/heo/scan/engineering/technology/technology_readiness_level*.

technologies. TRLs may be determined through technology readiness assessments[39] or through other methods. If other methods are used, EPA recommends that users consider the source of reported TRLs and prioritize TRLs determined through independent technology readiness assessments over TRLs assigned by the technology developer.

- **Is the technology of interest available at the scale needed for the intended application?** Some technologies may only be available as mobile, containerized units, which may be suitable for high-concentration, low-volume materials. These units may not be appropriate for low-concentration, high-volume materials where a stationary treatment unit with greater capacity is needed.
- **Is a treatment train needed to meet the desired destruction/disposal outcome?** If so, describe the treatment train needed and whether such technology is available and effective for the PFAS-containing material of interest. Note that treatment trains may produce materials that will also need to be managed.

Material. The second section of the framework focuses on the PFAS-containing material of interest. The six types of PFAS-containing materials discussed in this interim guidance vary in terms of phase, PFAS composition and concentration, physical and chemical properties, and overall composition (e.g., the presence of other contaminants). To understand the performance of a technology across the range of variations within a material type, the following key questions should be addressed:

- **What PFAS-containing material has been used to test the performance of the technology of interest?** The description of the material(s) used to evaluate a technology/material combination of interest should be specific as possible (e.g., 3M Light Water™ versus AFFF), and links to bulk material characterization should be included, if available. If the material evaluated is artificially contaminated (i.e., spiked with known PFAS species and concentrations), that should be noted because it may not be an accurate reflection of the performance of the technology for the intended application.
- **Which PFAS, and at what concentration ranges, have been used to test the performance of the technology of interest?** To best inform decisions on technology use, the PFAS and concentrations used to test performance should match the PFAS and concentrations anticipated for the intended application.
- **Are there non-PFAS constituents that may affect the performance of the technology of interest?** This could include constituents in the original PFAS-containing material or constituents that may be created or introduced during a treatment train or by the technology of interest. For example, hydrofluoric gas may be produced during PFAS destruction, which may cause corrosion.

Analytical methods. PFAS are a large class of substances, and there are various approaches for identifying and measuring PFAS. EPA recommends using a combination of approaches to characterize the performance of the technology for the PFAS-containing material of interest, including characterizing PFAS in emissions or waste streams from the technology of interest. Key questions to be addressed under this section include:

[39] See the *Technology Readiness Assessment Guide* for best practices for evaluating technology maturity. The guide, developed by the U.S. Government Accountability Office and released in January 2020, provides organizations with best practices for conducting high-quality assessments.

- Which standardized or validated targeted analytical methods (e.g., OTM-45, EPA Method 1633A) have been used to characterize the performance of the technology for the PFAS-containing material of interest? When possible, EPA recommends the use of standardized and/or validated methods for targeted analysis.
- Has non-targeted analysis been performed on waste streams from the technology/material combination of interest? If so, are there other PFAS detected that should be considered when assessing this technology? Non-targeted analysis is an important tool for characterizing PFAS in waste streams from a technology/material combination of interest because it can tentatively identify PFAS beyond those measured using targeted analytical methods.
- What other analytical approaches have been used to characterize the performance of the technology for the PFAS-containing material of interest? Other analytical approaches may include total oxidizable precursor assays and total organic fluorine assays for PFAS and analysis for non-PFAS substances (e.g., HF).
- **Was the study design and the quality of the data generated during testing appropriate to evaluate the technology?** For any quality assurance/quality control concerns identified, the user should determine whether it is appropriate to use the data to inform decisions about destruction and disposal of the PFAS-containing material using the technology of interest.

Disposal efficacy. Effective disposal of PFAS-containing material should prevent or minimize re-release of PFAS to the environment. Key questions for evaluating the efficacy of a disposal technology for a particular PFAS-containing material are identified below. (Questions included in this section should be skipped when evaluating a destruction technology.)

- **Have potential transformation and partitioning pathways been identified for the technology/material combination of interest?** The fate and transport of PFAS within a disposal technology can help inform whether PFAS may be present in emissions or releases from the technology. Note that the characteristics of the receiving matrix and environmental conditions can affect the fate and transport of PFAS within the disposal technology.
- **Are engineering controls in place to prevent or minimize release of PFAS to the environment?** If so, is there a monitoring system in place to evaluate the performance of the engineering controls?
- **What is the longevity of the disposal technology?** Because of the strength of the C-F bond, PFAS are persistent. It is important to consider the lifespan of the disposal technology and whether the technology can contain PFAS for very long timeframes.
- **Has a fluorine mass balance been determined?** If so, is there fluorine that is unaccounted for? In some cases, a fluorine mass balance may be impractical.
- Does the disposal of the PFAS-containing material contribute to the potential release of non-PFAS constituents to the environment? PFAS-containing materials may contain other, non-PFAS constituents. Depending on the identity of those constituents and their potential to impact human health and the environment, it may be important to consider whether appropriate engineering controls are in place to prevent or minimize releases of non-PFAS constituents.

Destruction efficacy. Destruction of PFAS should result in breaking C-F bonds without reforming PFAS and releasing PFAS to the environment. Key questions for evaluating the efficacy of a destruction technology for a particular PFAS-containing material are identified below. (Questions included in this section should be skipped when evaluating a disposal technology.)

- **Is the mechanism of destruction understood?** If so, has the destruction mechanism been experimentally confirmed, and have the reaction kinetics been determined? A thorough understanding of the destruction mechanism improves confidence in the performance of the technology of interest for PFAS.
- Have all process inputs and outputs been characterized for PFAS to the extent possible given current analytical methods? If not, what information may be missing?
- **What is the reported destruction efficiency?** Destruction efficiencies (or DREs) are generally reported for specific PFAS (e.g., PFOA or PFOS). As noted earlier, the destruction efficiency (or DRE) alone may not be sufficient to determine whether other PFAS may be released to the environment during the destruction process.
- **Have any PIDs (or PICs) been identified?** If so, which PFAS have been detected and at what levels? Are those PFAS regularly detected for this technology/material combination?
- **Has a fluorine mass balance been determined?** If so, is there fluorine that is unaccounted for? In some cases, a fluorine mass balance may be impractical.
- Have all process outputs been characterized for non-PFAS constituents to the extent possible, given current analytical methods and understanding of the composition of the PFAS-containing material? The destruction of PFAS-containing materials is expected to result in non-PFAS products. Depending on the identity of those products and their potential to impact human health and the environment, it may be important to consider whether appropriate engineering controls are in place to prevent or minimize releases of non-PFAS constituents. It may also be important to consider the effect of the destruction process on non-PFAS constituents in the PFAS-containing material of interest. Thus, the characterization of process outputs beyond PFAS may be warranted.

Community considerations. When considering destruction and disposal technologies for PFAS-containing materials, it is important to consider the community that may be exposed to potential PFAS releases from intended destruction or disposal. Key questions to consider include:

- **Has a destruction/disposal site been identified?** Some destruction technologies may be mobile, allowing for treatment and destruction to occur where PFAS-containing materials are generated or stored. Other technologies may be stationary, requiring PFAS-containing materials to be brought on site for destruction or disposal.
- **What are the characteristics of the surrounding community?** Different factors can influence the potential magnitude of community exposures, such as the size and distribution of the community near the destruction/disposal site, the proximity of the community to the destruction/disposal site, geographical characteristics where the community is located, and other considerations.
- **Are PFAS releases anticipated from the technology/material combination of interest?** If so, describe which PFAS may be released, at what levels, and over what duration. Also note whether there are controls in place to mitigate releases to avoid or minimize potential impacts to surrounding communities.
- **Has the surrounding community been engaged?** Sharing information about planned destruction or disposal activities for PFAS-containing materials allows community members to take actions to address concerns they may have. There may also be opportunities to collaborate with government officials and community leaders on engagement activities.

Regulatory requirements. Regulations regarding the destruction or disposal of PFAS-containing materials can vary from state to state and may change over time. Key questions to consider include:

- **Are there state or federal regulations that control emissions or releases from the technology of interest?** Such regulations may limit the amount of PFAS or other pollutants present in emissions or other releases from the technology of interest.
- **Are there state or federal regulations that control the management of the PFAS-containing material of interest?** Such regulations may specify or restrict destruction or disposal options for the PFAS-containing material of interest.

Appendix A: EPA Guidance to Conduct PFAS Emissions Field Testing at Commercial Thermal Destruction Sources

The U.S. Environmental Protection Agency (EPA) is conducting per- and polyfluoroalkyl substances (PFAS) thermal destruction emissions characterization research to improve our understanding of the behavior of PFAS with respect to waste incineration and thermal treatment (e.g., hazardous waste, municipal waste, biosolids, contaminated soils, spent media), as well as thermal destruction emissions control technologies (e.g., afterburners, thermal and catalytic oxidizers). The following could be used by any entity evaluating thermal treatment of PFAS-containing materials either in collaboration with EPA or independently.

Overall goals of the field tests are as follows:

- Confirm/determine if thermal treatment under representative conditions can result in the thermal destruction of PFAS as defined by conventional destruction and removal efficiency (DRE) testing.
- Characterize potential products of incomplete combustion/destruction (PICs/PIDs) and evaluate the use of alternative, or surrogate, indicators of destruction performance.
- Confirm that any treated material is appropriate for any defined beneficial reuse (e.g., treated soils, reactivated granular activated carbon [GAC]).

To achieve these goals, it is necessary to determine the specific conditions (i.e., temperature, residence time, and turbulence) required to maximize DRE, minimize PICs/PIDs, and produce products appropriate for beneficial reuse. Because bench- and pilot-scale testing have limitations, actual test data under full-scale thermal treatment conditions are necessary to determine if representative thermal processes can achieve these goals.

Sampling Details:

- EPA is available to collaborate with the host site on the technical approach for source characterization. Testing would require multiple stack sampling methodologies performed by commercial stack testing companies, including the host's regular tester, if desired.
- All gas, liquid, and solid inlet, intermediate, and outlet streams would be collected and analyzed. This includes:
    - At the stack and including all air pollution control devices (APCDs).
    - All inlet streams (e.g., materials to be thermally treated, air or gas inlets, water), including samples taken prior to testing.
    - All process materials (e.g., water used for spray dryers and/or scrubbers, carbon, high pH solution for scrubbers) as they may contain PFAS and affect the results, if unknown.
    - All residual streams (e.g., bottom ash, baghouse and/or electrostatic precipitator [ESP] solids, scrubber effluent, spent carbon).
    - All final products (e.g., reactivated carbon, soils), if applicable.
- A comprehensive air emission source characterization would include:

- Samples would be collected for semivolatile polar PFAS using method OTM-45 and analyzed for targeted (known) PFAS. Samples would be collected for nonpolar volatile fluorinated compounds (VFCs) and PFAS using method OTM-50 and analyzed for targeted (known) fluorinated compounds and the identification of unknown detected volatile fluorinated compounds.
- Samples would be collected for other semivolatile nonpolar target compounds using methods SW-846 Methods 0010/3542/8270 with the inclusion of the Method 8270 procedure.
- Carbon hexafluoride (C_2F_6) and carbon tetrafluoride (CF_4) could be injected during one day of testing, ideally at multiple injection locations, as a surrogate measure of destruction efficiency if appropriate and permitted.
- Samples would be collected for other semivolatile target compounds using methods SW-846 Methods 0010/3542/8270 with the inclusion of the Method 8270 procedure.
- Hexafluoroethane (C_2F_6) could be injected during testing, ideally at the location most PFAS would be injected, or multiple injection locations if possible, as a surrogate measure of destruction efficiency if appropriate and permitted. Tetrafluoromethane (CF_4) can also be injected separately, if FTIR is being used, to ensure the injection system is working and to establish the gas residence time of the system to aid in the sampling of C_2F_6.

- Tests would be run under a single, representative process condition including the waste that would be co-fired with PFAS-containing material.
- EPA would prioritize testing several PFAS-containing materials, including but not limited to:
  - Incineration of aqueous film forming foam (AFFF).
  - Incineration of wastewater sludges.
  - Reactivation of spent GAC.
  - Incineration of municipal solid waste.
  - Thermal treatment of contaminated soils.
  - Incineration of spent ion exchange resins and their concentrated regeneration liquids.
- All sampling would be conducted under a well-documented sampling plan and quality assurance project plan.
- Final testing results would be shared with EPA, the state, local authorities.

Additional details on emission testing approaches can be provided upon request.

Supplemental Information

Emissions sampling and analytical approaches

Emissions samples would be collected for nonpolar, volatile, and polar and non-polar semivolatile PFAS compounds and analyzed for both targeted PFAS compounds, or method established endpoints.

EPA's Other Test Method 45 (OTM-45) would be used to collect polar semivolatile PFAS compounds for targeted analyses. The method's 50+ target analytes include many PFAS commonly found in AFFF. This would enable DE, DRE, and emission rate determination as appropriate for a known list of PFAS compounds along with identifying potential PFAS PICs/PIDs.

The OTM-50 canister sampling method would be used to collect nonpolar volatile PFAS compounds for targeted compound analyses. The current target list includes CF_4 and C_2F_6 as well as a procedure to identify unknown volatile fluorocarbons.

Non-targeted analyses (NTA) are an optional analytical tool for characterizing potential PICs/PIDs. HRMS, combined with chromatographic separation and multiple ionization techniques, is used to identify compounds present in collected samples. NTA could be performed on the OTM-45 samples. FTIR spectroscopy would be used to measure a variety of compounds in real-time, including HF, HCl, CO_2, and water; multiple PFAS compounds including CF_4 and C_2F_6; and multiple known PICs/PIDs. FTIR is particularly useful during injection of a surrogate compound.

EPA research questions

The following section describes detailed elements of the research questions EPA will ultimately work to address, as well as the input information that is needed. EPA requests an opportunity to engage with the host facility prior to developing a full sampling plan to better understand site-specific conditions and requirements.

Process characterization

Question: How does the process operation affect the destruction and removal of PFAS compounds present in the feed?

- Requires understanding of waste feed (e.g., description, concentration, other wastes), feed approach (e.g., liquid feed, through flame/post flame, co-fired, drums/barrels), and feed rate.
- Requires data on combustor operations and conditions (e.g., temperature, residence time).
- Requires data on air pollution control devices (APCDs) and their operation: configuration, operating parameters (e.g., temperature, pressure drop, pH of scrubbing liquid, gas velocity).

Determine destruction removal efficiency (DRE)

Question: What is the DRE and emission rate of the specific PFAS compounds present in the feed material?

- Requires known input rate and identity of PFAS compounds in waste.
- Requires evaluation of the extent of PFAS mineralization.
- Requires replicate sampling of polar semivolatile organics using OTM-45 for quantitative measurement of feed PFAS compounds in emissions.
- Requires sampling across multiple APCDs.

Products of incomplete combustion/destruction (PICs/PIDs)

Question: Are PICs/PIDs formed during thermal treatment and measured by OTM-50 present and, if so, what are they and under what conditions?

- Requires replicate sampling of polar, nonpolar, semivolatile, and volatile organics for non-targeted compound analysis using OTM-45, OTM-50, and Method 0010/3542/8270.
- Requires sampling across multiple APCDs.

Alternative indicators of destruction performance

Question: Can easily measured/monitored, hard-to-destroy compounds serve as alternative (surrogate) indicators for PFAS adequate destruction or PID formation conditions?

- Requires injection of known concentrations/masses of C_2F_6 (approximately 10 to 30 parts per million by volume (ppmv) stack equivalent) at representative waste injection locations (CF_4 can be used as a tracer gas to assist in the process).
- The evaluation is greatly benefitted by on-line FTIR monitoring of the surrogate compounds, PICs, HF, HCl, and other compounds of interest.
- Requires initial background signal baseline, normal operation without the addition of the perfluorocarbons.
- Requires concurrent OTM-50 sampling for analysis of surrogate compounds and known PICs.

Analysis of fluorinated compounds in waste/effluent streams

Question: What is the fate of PFAS compounds across the entire thermal system?

- Requires sampling of all discharges:
  - Gas sampling prior to and after APCDs (e.g., spray dryer, wet scrubber, baghouse and/or ESP, activated carbon injection).
  - Sampling of solid and liquid discharges (e.g., bottom ash, baghouse and/or ESP solids, scrubber effluent analyses, spent carbon).

Analysis of fluorinated compounds in final product materials, where applicable

Question: What PFAS remain in the material treated, such as reactivated GAC or treated soils?

- Requires sampling of influent and effluent materials:
  - Sampling of solid materials (e.g., spent carbon and reactivated carbon).

Appendix B: Summary of the 2021 and 2022 Clean Harbors Test Data

Summary

Two testing campaigns were conducted at the Clean Harbors Environmental Services (CHES) hazardous waste combustor (HWC) located in Aragonite, Utah. Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented Per- and Polyfluorinated Alkyl Substances (PFAS) Feed (Condition 2, where known amounts of four or five target PFAS were fed to the incinerator), and Post-spiking Normal Operations (Condition 3, where aqueous film-forming foam [AFFF] was included in the incinerator feed). Clean Harbors used the Other Test Method 45 (OTM-45) Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources (OTM-45) from the U.S. Environmental Protection Agency (EPA) for stack gas samples. The 49 targeted PFAS analytes were measured using liquid chromatography/tandem mass spectrometry (LC/MS/MS) with isotope dilution. The tests appear to demonstrate that the primary objective, "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," was achieved for the five selected PFAS compounds that were subjects of these studies.

Introduction

Two testing campaigns were conducted at CHES HWC located in Aragonite, Utah. The first campaign was conducted from June 17 to 19, 2021, and the second from February 17 to 19, 2022. The stated principal objective of the test program was to "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," with secondary objectives of conducting a mass balance of PFAS in process streams and demonstrating high hydrogen fluoride (HF) removal that would be associated with a high destruction of PFAS. This summary presents a high-level overview of both tests' final reports as well as a third-party review of the 2021 test performed by Dr. Philip H. Taylor under contract to CHES.

General Process Description

The HWC tested at the CHES Aragonite facility consists of a slagging rotary kiln incinerator followed by an afterburner. Solid waste materials and containerized wastes are fed into the rotary kiln only, while liquid wastes may be injected directly into rotary kiln or the afterburner. The air pollution control device (APCD) system for the HWC as tested[40] consists of a spray dryer/gas quench followed by activated carbon injection upstream of a fabric filter (particulates, dioxin/furan, and mercury control). Following the fabric filter, the gases enter a sodium carbonate saturator/wet scrubber (sulfur dioxide, hydrogen chloride, hydrogen fluoride control) with TMT-15 (1,3,5-triazine2,4,6(1H,3H, 5H)-trithione, trisodium salt, used for additional mercury and metals control) injection.

[40] Stack testing was performed in the exit duct of the wet scrubber instead of at the stack for safety reasons (lack of scaffolding). The HWC is equipped with a wet electrostatic precipitator (WESP) following the wet scrubber and prior to the stack, but the WESP was decommissioned in 2004 and is no longer in service. These tests were conducted prior to the WESP although the stack location is the test location for compliance performance tests for the facility.

Operational Description

Each test campaign was divided into three test conditions: Baseline (Condition 1), Augmented PFAS Feed (Condition 2), and Post-Spiking Normal Operations (Condition 3), with the waste feed matrices as follows:

1. **Condition 1.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes). Following the 2021 testing, CHES determined that the sludge stream fed to the kiln during all three conditions included some AFFF. During the first run of the 2022 testing, CHES determined that AFFF was inadvertently being fed into the afterburner's corrosive waste port. The testing team decided to be consistent with runs 2 and 3 and continued the AFFF feed, with additional amounts of AFFF fed during Condition 3.
2. **Condition 2.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes), with the addition of augmented feed rates of four (2021) or five (2022) PFAS (or their equivalent potassium salt). The four PFAS are perfluorooctanioic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorohexane sulfonic acid (PFHxS), hexafluoropropylene oxide-dimer acid (HFPO-DA), and perfluorobutanesulfonate (PFBS, 2022 only). The target feed rate of the PFAS was estimated to be 0.0816 pounds per hour or around 0.62 grams per minute in 2021 for all PFAS, but the HFPO-DA was increased to 2.2 grams per minute in the 2022 testing to reflect the method detection limit (MDL) for this compound. Similarly, the PFBS feed rate was 0.33 grams per minute on average to reflect the MDL. The PFAS were fed in boxed containers to the rotary kiln via the containerized solid conveyor in approximately 10-gram portions of all PFAS compounds about every 15 minutes for the duration of these test runs.
3. **Condition 3.** Normal matrix of liquid materials (waste fuel, clean fuels, sludge, and aqueous wastes) and solid waste materials (containerized, shredded, and bulk solid wastes). For this test condition, AFFF concentrate was also fed (neat) to the incinerator. In 2021, the AFFF was fed via the containerized solids in 5-gallon buckets at a rate of 176 pounds per hour. During the 2022 test, the AFFF was labeled as Ansulite and was fed through the educt station to the incinerator directly from a tote bin. The AFFF feed rate ranged from 244 pounds per hour to 316 pounds per hour during the 2022 test.

The rotary kiln was operated in a temperature range between 1,893°F and 2,008°F for the 2021 test and between 1,949°F and 2,219°F for the 2022 test. The afterburner was operated at 2,052°F to 2,110°F during the 2021 test and 2,048°F to 2,075°F for the 2022 test. Oxygen content (free) at the exit of the rotary kiln was maintained between 8 and 9 percent and ranged from 6 to 7 percent for the afterburner for both test campaigns. Clean Harbors estimates that non-combustible material is retained within the combustor for approximately 60 minutes, while combustion gas residence time of the afterburner is two to three seconds.

For the 2021 test, the temperature of the flue gas was reported as 369°F following the spray dryer; between 341°F and 343°F following the fabric filter; between 166°F and 168°F at the saturator outlet; and 148°F to 153°F at the stack. For the 2022 test, the temperature of the flue gas was reported as 363°F following the spray dryer; between 168°F and 170°F at the saturator outlet; and 149°F to 151°F at the stack. The following table lists the APCD operational parameters during the testing campaigns.

Test Campaign	Stack Gas Flow (actual cubic feet per minute [acfm])	Soda Ash Flow (lb/hr)	Carbon Injection (lb/hr)	TMT-15 Flow (lb/hr)
2021	66,793–68,761	452–789	30.7–31.5	3.95–4.48
2022	51,053–53,640	411–1594	32.0–33.1	3.64–4.00

Test Methods and Scope

During both testing campaigns, samples of stack gases and process streams were taken and analyzed for 49 PFAS target compounds, with the stated analytical objective of characterizing as many streams entering or exiting the incinerator as possible. Clean Harbors used EPA's Other Test Method 45 (OTM-45), *Measurement of Selected Per- and Polyfluorinated Alkyl Substances from Stationary Sources*, for stack gas samples (as noted earlier, "stack" meaning the exit duct from the wet scrubber as it was deemed a safer sampling location than the actual stack). The 49 targeted PFAS analytes were measured using LC/MS/MS with isotope dilution.

Process streams sampled included waste fuels, clean fuels, waste feeds, process water, and residuals (liquids and solids), as well as some pre-test sampling of chemical inputs (soda ash, activated carbon, and TMT-15). As noted in the reports, however, due to the waste profile matrix complexity and the heterogeneity of all three solid waste streams, they were not sampled or analyzed for PFAS. Absent any final EPA-approved methods for media other than drinking water, LC/MS/MS analysis was used to measure the targeted PFAS compounds in the process stream samples.

In addition to the 49 PFAS analytes, the HF concentration of the stack gas was measured using EPA Method 26A. The AFFF-containing material in the 2021 test was analyzed for the 49 target PFAS both before and after chemical oxidation as a total oxidizable precursor assay (TOPA). During the 2022 test, a TOPA and total organic fluorine assay (TOFA) were performed on the AFFF-containing materials. The objective of performing TOPA is to "reveal perfluoroalkyl acid (PFAA), fluorotelomer sulfonate (FTS), and possibly other precursors that are not identifiable with targeted PFAS analysis." TOFA, as described in the 2022 report, identifies the mass of compounds containing carbon-fluorine bonds, and was performed using combustion ion chromatography following a laboratory in-house method for adsorbable organo-fluorine.

Results

According to the tests and third-party review, the primary objective of determining the destruction and removal efficiency (DRE) of each of the spiked (augmented feed) PFAS was achieved. The calculated DREs for each test (triplicate test run average) and PFAS compound are as follows:

PFAS Analyte	2021 Test DRE (%)	2022 Test DRE (%)
PFOA (perfluorooctanioic acid)	99.999943	99.99990
PFOS (perfluorooctanesulfonic acid)	99.999955	99.99977
PFHxS (perfluorohexane sulfonic acid)	99.999977	99.99996
HFPO-DA (hexafluoropropylene oxide – dimer acid)	99.999979	99.99984
PFBS (perfluorobutanesulfonate)	Not available	99.99997

Both test reports note that none of the other 45 (or 44, in 2022) target PFAS analytes were present in the waste feed at levels sufficient to demonstrate 99.9999-percent DRE without spiking, even though stack gas concentrations were non-detect in many cases. According to the 2021 test report, there were three other PFAS present in the waste feeds at sufficient mass feed rate without spiking to enable demonstration of DRE's exceeding 99.999 percent. These included PFOS, 6:2 fluorotelomer sulfonate (FTS), and 8:2 FTS. The report stated that the FTS compounds are common constituents of AFFF.

As for the secondary objectives, the results are, as stated within Dr. Taylor's review, "most difficult to achieve as they involve more complex sampling issues." With respect to the secondary PFAS mass balance objective, he notes that "some of the PFAS that was not sampled in the infeed may have been more difficult to gasify and burn, contrary to the assertions in the report." However, he concurs with the report statements that the PFAS DRE is conservative.

The objective of demonstrating high HF removal that would be associated with a high destruction of PFAS is seemingly not achieved, primarily due to analytical issues. Dr. Taylor notes that "the sinks for the HF were not accurately quantitated leading to some questions about the validity of the reported HF removal efficiency." He further notes that the assumption that all fluorine in the waste if converted to HF is challenged, as there would be a required excess of hydrogen to fluorine to be demonstrated, which are not provided for in the data. Further, he stated that there is a "demonstrated lack of accuracy of the analytical methods for measuring inorganic fluorine in the residual streams," which, in his opinion, leads to a very low fluorine recovery mass balance. He concluded that, "development of better analysis methods for complex matrices for inorganic fluorine are needed before high HF removal efficiencies can be reported at full scale.[41]

Conclusions

The tests appear to demonstrate that the primary objective, "demonstrate the ability of the high-temperature incineration system at Aragonite to effectively destroy PFAS in the waste feed during normal process operating conditions," was achieved for the five selected PFAS compounds that were subjects of these studies. However, this study did not evaluate the formation of PICs due to previous methodology limitations. Dr. Taylor, in his review, noted this as well: "The larger question from an environmental viewpoint is the complete mineralization of these substances and prevention of emission of highly stable C_1-C_2 PFCs (perfluorocarbons)." Dr. Taylor concludes that CHES' results, although promising and demonstrating reduction of a limited selection of specific PFAS compounds, did not support complete mineralization.

EA Engineering, Science, and Technology, Inc., PBC. (2022). Report on PFAS destruction testing results at Clean Harbors' Aragonite, Utah hazardous waste incinerator (Final).

[41] Although not stated by Dr. Taylor in his assessment, another possible reason for lack of finding inorganic fluorine (HF) could be the result of poor conversion (mineralization) of PFAS to HF and carbon dioxide during incineration. This may indicate formation of non-target PFAS or fluorocarbons during incineration that were not measured by these tests.

Appendix C: Summary of the Chemours Thermal Oxidizer Test Data

Introduction

Chemours Company FC, LLC, located in Fayetteville, North Carolina, manufactures chemicals and plastics and was required to install a thermal oxidizer to control per- and polyfluoroalkyl substances (PFAS) emissions. Tests have been conducted annually since installation. The objective of the tests was to determine how "the Thermal Oxidizer and 4-stage Scrubber system will achieve the emission reduction [of 99.99 percent], including the use of a surrogate for all PFAS, such as the hexafluoropropylene oxide (HFPO)." This summary presents a high-level review of the two tests' reports.

General Process Description

The thermal oxidizer at the Chemours facility operates at 10 million British thermal units (BTUs) per hour and is powered by natural gas. Waste gases from both polymer and monomer production are fed into the thermal oxidizer. The gaseous emissions from the oxidizer are fed into the four-stage packed bed column scrubber system while solid calcium fluoride (CaF_2) is removed, collected, and disposed of at an off-site location. The scrubber has three water scrubbing stages and one caustic scrubbing stage and is stated to remove hydrogen fluoride (HF) from the final emissions.

Operational Description

Test Methods and Scope

The tests done on the thermal oxidizer focused on five PFAS compounds: HFPO, hexafluoropropylene oxide-dimer acid (HFPO-DA), hexafluoropropylene oxide-dimer acid fluoride (HFPO-DAF), carbonyl fluoride (COF_2), and Fluoroether E-1. These compounds were selected because they are handled and used at the Fayetteville facility. The compounds have varying chemical structures and properties and cannot be sampled and tested in the same manner.

Modified Method 18 sampling was used to capture the PFAS compounds. This method uses six fluoropolymer (PFA) impingers charged with methanol arranged in a series and captures the compounds using chemical reactions and condensation.

To capture HFPO-A, the facility needed to use Modified Method 0010 sampling with a heated probe and filter, condenser coil, XAD-2 resin cartridge, deionized water impingers, and a silica gel impinger. In addition to the normal Modified Method 0010 sampling process, this test added a second XAD-2 resin cartridge to monitor possible target PFAS breakthrough.

Three compounds (HFPO, HFPO-DAF, and COF_2) were sampled by chemical reaction. The sample gas was passed through the series of methanol impingers. The compounds then react with methanol, and each produced unique ether compounds that were monitored and quantified using SW-846 Method 8260.

The strategy used to sample Fluoroether E-1 and HFPO-DA was to capture the compounds through condensation and dissolution in the same methanol impingers. The volatile organic compound, Fluoroether E-1, was then quantified using SW-846 Method 8260b. The semivolatile organic compound HFPO-DA was quantified using EPA Method 537.

Samples were taken from the polymer production and monomer production waste gas feed lines to capture the initial amount of PFAS compounds they produced as waste and to provide a baseline concentration of PFAS prior to treatment. The other sampling location was in the stack after the thermal oxidizer and scrubber. This location would show how effective the process was at destroying the targeted PFAS compounds.

The sampling and testing methods only captured the amount of target PFAS compounds and did not measure any products of incomplete combustion (PICs). Although the four-stage scrubber was implemented to reduce the possible HF emissions, there was no sampling of HF.

Results

The results of the tests showed that the mandated 99.99 percent destruction of targeted PFAS compounds had been achieved. In both testing years the average PFAS destruction and removal efficiency (DRE) was above 99.999 percent with no result being lower than 99.999 percent. Results were presented as a total FPAS destruction efficiency with the amount of each target PFAS compound summed to provide an aggregate destruction efficiency. The total PFAS destruction efficiencies for each run and each year are as follows:

Year	Run 1	Run 2	Run 3	Average
2020	99.99982%	99.99974%	99.99986%	99.99981%
2021	99.99920%	99.99968%	99.99963%	99.99951%
2022	99.99951%	99.99966%	99.99967%	99.99961%
2023	99.99951%	99.99964%	99.9972%	99.9988%
2024	99.99934%	99.99964%	99.99934%	99.99944%

Conclusions

The test reports demonstrate a PFAS destruction efficiency above the 99.99-percent level that was mandated for the Chemours facility for the specific compounds that were tested. HFPO was tested as a surrogate for all species of PFAS, but there are no definitive data showing the performance of the thermal oxidation process for PFAS species outside of the compounds tested. There was also no discussion of possible PICs in the reports. The thermal oxidizer at the Chemours facility appropriately destroys the five PFAS compounds of interest that have been identified at the facility. However, removal processes for PICs or products of incomplete destruction of potential compounds not studied but potentially found in the facility waste streams are still unclear.

Appendix D: Summary of Costs and Considerations

Introduction

This appendix provides some estimates of costs for end-of-life management of PFAS materials by thermal treatment, landfilling, and underground injection. The cost information presented has limitations and is highly variable and is likely most suitable to make comparisons between techniques.

The cost to destroy or dispose of PFAS and PFAS-containing materials can vary widely depending on a number of factors. Waste management infrastructure's design and operation are heavily influenced by regional needs, local regulations, and technological advancements. As a result, waste management costs vary by the type of waste and by location due to factors like availability and transportation costs. In addition, technological advances specifically related to the management of PFAS-containing materials can potentially reshape the cost and operational landscape of PFAS waste management. Multiple factors and limitations contribute to cost variability and should be considered when using the information in this appendix.

- Market conditions such as supply and demand and macroeconomics change frequently, resulting in fluctuating costs.
- Location of destruction and disposal options and transportation affect case-by-case costs.
- Transportation costs or any special handling costs for accepting and treating additional waste are not included in most of these estimates, thus actual costs would vary.
- Costs may be affected by permitting and state/local requirements for PFAS-containing material, which vary depending on state/local regulations, public input, and geographic location.

Thermal Treatment

Hazardous Waste

Table D-1. Estimated Costs to Incinerate Different Types of Hazardous Waste (U.S. EPA, 2005a)

Hazardous Waste Type	Estimated Thermal Treatment Cost per Ton[a]
Liquids, sludges, solids (halogenated)	$1,221-1,774
Liquids, sludges, solids (non-halogenated)	$358-976
Laboratory packs	$6,054
Containerized gases	$2,929

[a] Costs were developed for hazardous waste combustors (HWC) that were affected by the 2005 National Emission Standards for Hazardous Air Pollutants (NESHAP), including commercial incinerators, cement kilns, lightweight aggregate kilns, and commercial HWC boilers. Cost per ton is assumed to be in 2002 dollars, the same year basis of the regulation from which these costs were obtained. Costs were normalized to 2024 dollars using the Bureau of Economic Analysis (BEA) gross domestic product (GDP) deflator (U.S. BEA, 2025) for waste management and remediation services using a base year of 2002. Note that applying the BEA GDP deflator for this industry sector is a top-down approach. For regulatory purposes, a bottom-up approach is typically used, accounting for capital costs based on the Chemical Engineering Plant Cost Index (CEPCI), energy prices typically based on Energy Information Administration (EIA) data, and labor costs based on industry segment indices using Bureau of Labor Statistics (BLS) data.

Limitations:

- Costs have likely changed since 2002 and scaling costs to 2024 contributes to uncertainty.
- Does not include transportation costs or any special handling costs for accepting and treating additional waste materials.

Table D-2. Example Disposal/Reactivation Costs for Drinking Water Treatment Residuals (Derived from U.S. EPA, 2020a)

Method	Cost of Disposal ($/lb of Media)	Estimated Cost of Disposal Plus Replacement Media ($/lb of Media)[a]
Reactivated GAC—off-site	$0	$1.63
Disposal via landfill	$0.06	$2.21
Disposal via incineration	$1.20	$3.35

[a] Cost per pound is in 2024 dollars. For GAC, on-site reactivation is possible. However, the utility or site would have to have ample workforce, managerial, and financial (both capital and operating) resources to justify this choice. It is likely to be cost-effective only for very large facilities and would require consideration of other factors including availability of land and public opinion. Due to the complex analysis needed, a full comparison of off-site versus on-site is beyond the scope of this document.

Limitations:

- These estimates are presented as examples only to illustrate tradeoffs. Actual site-specific costs are likely to vary based on factors including the quantity of media reactivated/replaced and are used as an example of trends. In this example, reactivated GAC and virgin GAC are estimated to be $1.42 per pound and $2.15 per pound, respectively.
- All unit costs assume 21,000 lbs of GAC reactivated/replaced.
- For reactivated GAC, it is assumed that the "replacement" media is the returned reactivated media plus the replacement of the GAC lost during reactivation with virgin media (assumed to be 30 percent).
- Disposal costs assume 10 miles of transportation to the disposal site.
- Incineration costs are based on incineration of ion exchange resin media. Incineration of GAC could be somewhat more expensive, depending on the relative fuel value of the spent media.
- The analysis is complex and a number of issues need to be considered at the site level, such as those that affect costs (cost of energy, shipping, labor, construction, operation, sampling, etc.) and those that affect other matters (practicality, public versus private ownership, contract availability, regional reactivation availability, off-gas permitting, public opinion, etc.).

Landfills

Hazardous Waste

Table D-3. Estimated Costs to Landfill a Representative Type of PFAS-Containing Material (Defense Logistics Agency (DLA), 2023)

Hazardous Waste Type	Estimated Cost per Ton of Waste (2024$)
Aqueous film-forming foam (AFFF) and other PFAS-related Solids/Debris, Non-RCRA, >100 parts per million (ppm) PFAS for direct disposal at RCRA Subtitle C Landfill (e.g., contract line item number (CLIN) PF06B1)	$1,301-3,664 ($0.65-1.83/lb)

Limitations:

- The DLA pricing web application lists current government contracts for destroying or disposing of PFAS and PFAS-containing materials and may be useful for government contract cost estimates. The estimated cost per ton of waste appears to include removal and disposal costs for the specific material, although a portion of transportation costs may be attributed to other cost elements of each respective contract so transportation costs may not be fully reflected in these costs.
    - **Per the DLA pricing web application:** The prices contained in the database were awarded based on contract terms and conditions, procurement requirements, and price reasonableness determinations. The prices and contract information in the database are for reference only.
- Users of the DLA pricing web application are cautioned that each contract was developed to meet specific requirements for specific geographic regions or military installations. There are multiple variables that result in the pricing information displayed, including contract award date, proximity to DLA-approved disposal facilities, quantities of PFAS material estimated for disposal in proportion to other hazardous waste on the contract, reoccurring need for services, and whether PFAS material is disposed of in bulk or whether there are small, limited quantities.
- Pricing is provided here for bulk waste types for disposal at a Subtitle C hazardous waste landfill. Pricing for multiple waste types with varying units of measure for disposal, including containerized waste, are provided in the DLA pricing web application.
- The estimated cost in the table above only applies to a limited number of military installations and only considered bulk pricing from 600 to 10,000 pounds. Pricing is expected to differ for containerized waste and should be considered when relying on this cost information.

Non-Hazardous Waste (Municipal solid waste)

Table D-4. Average MSW Tipping Fees per Ton by U.S. Region (EREF, 2022)

Region	Average Tipping Fee (2024$/ton)	Region	Average Tipping Fee (2024$/ton)
Pacific	$64.81	Northeast	$71.28
Mountains/Plains	$47.74	Southeast	$45.73
Midwest	$58.23	South Central	$47.74

Limitations:

- MSW landfills emit more PFAS than originally thought in 2020. Research estimates that although MSW landfills contain PFAS for the most part, up to 5 percent of the PFAS may be released in the landfill gas (LFG) and, 11 percent may be released in the leachate annually (Tolaymat et al., 2023). Thus, MSW tipping fees may not be a relevant data point for cost information.

Non-Hazardous Waste (Liquid waste)

Table D-5. Average Industrial Wastewater Rates by U.S. Region (Unger et al., 2023)

Region	$/1,000 gallon	Region	$/1,000 gallon
Pacific	$11.64	Northeast	$4.71
Mountains/Plains	$3.05	Southeast	$7.35
Midwest	$4.66	South Central	$5.08

[a] Data are consolidated by region and the number of data points varies by region. Cost per gallon is expressed in 2024 dollars. American Water Works Association (AWWA) water and wastewater rate surveys were used to gather historical rate data for water and wastewater utilities in the United States. These datasets were compiled and assessed to produce a single dataset of time series rate data for 112 water utilities and 76 wastewater utilities located throughout the United States.

Limitations:

- These data do not include specific information on extra treatment considerations that may be required by a national pollutant discharge elimination system (NPDES) permit or by an industrial user permit for a discharge into a POTW to control the release of PFAS. Thus, similar to the cost of landfilling PFAS waste, the associated treatment of PFAS-laden leachate is difficult to assess because the available data are associated with typical industrial wastewater generators or typical landfill leachate.

One report examined the cost to manage landfill leachate on site (U.S. EPA, 2021). Based on review of the treatment processes and technologies that are currently used, the cost to manage leachate on site is highly variable but generally ranges between $10.78-161.77/1,000 gallons ($0.01-0.16/gallon). Capital costs can range from hundreds of thousands to several million dollars. The report lists multiple limitations and does not specify treatment for PFAS.

Underground Injection

Class I Wells (hazardous and non-hazardous)

Table D-6. Estimated Costs for Class I Wells

Description	Underground Injection Cost ($/1,000 gallon)[a]
Deep well injection	$178-254 (deSilva, 2019)
Trucking costs	$9-188 (McCurdy, 2011)

[a] Costs were normalized to 2024 dollars using the Bureau of Economic Analysis (BEA) gross domestic product (GDP) deflator (U.S. BEA, 2025) for waste management and remediation services using a base year of 2019.

Limitations:

- Class I well capacity is limited, which may affect the costs associated with deep well injection.
- Because of the geographic concentration of Class I wells, waste producers may face transportation and logistical challenges.
- To begin accepting PFAS-containing fluids, owners/operators of existing Class I wells may incur costs to modify their permits to accept waste from other entities or new waste streams.

Another source includes costs for disposing of sewage sludge and indicates that among fees and transportation costs is a fee ($40.44 per ton) for deep well injection of leachate (CDM Smith, 2020).

The prices and contract information in the database apply to DoW requirements and are for reference only.*

Appendix E: Fact Sheet for the 2026 Interim Guidance on the Destruction and Disposal of PFAS

U.S. Environmental Protection Agency has issued an update to the *Interim Guidance on the Destruction and Disposal of Perfluoroalkyl and Polyfluoroalkyl Substances and Materials Containing Perfluoroalkyl and Polyfluoroalkyl Substances (PFAS)*[42].

The non-binding, interim guidance provides recommendations for managers of PFAS and PFAS-containing materials to protect human health and the environment. It also contains a new technology evaluation framework to help analyze the safety and effectiveness of new destruction and disposal (D&D) technologies. The interim guidance does not establish requirements for destruction or disposal of PFAS materials. For more information about PFAS and what EPA is doing to address PFAS, visit EPA's *PFAS website*[43].

The interim guidance summarizes scientific information on current understanding of PFAS and focuses on three widely used and commercially available D&D technologies[44]:

1) Underground injection.
2) Landfills.
3) Thermal treatment under certain conditions, which includes incineration.

The interim guidance summarizes research needs and data gaps and calls for increased collaboration with EPA to collect data and enhance decision-making, as well as describes new EPA test methods.

Key Updates in 2026:

Updated information on destruction and disposal technologies

EPA is not endorsing any technology, but is presenting the technologies' relative potential to minimize PFAS release. As a general approach, EPA encourages managers of PFAS and PFAS-containing materials to consider site-specific conditions and to use D&D options that have a lower potential for releasing PFAS to the environment as described in Section 1 of the interim guidance. In general, the following technologies (in no relative order) have a lower potential for environmental release of PFAS compared to other technologies or operating conditions within the categories of storage, underground injection, landfilling, and thermal treatment:

- **Underground injection–Permitted Class I non-hazardous industrial or hazardous waste injection wells:** The standards associated with the construction, operation, and monitoring of these Class I wells are designed to isolate liquid wastes deep below the land surface and ensure protection of underground sources of drinking water. While Class I wells are an option for managing PFAS-containing fluids, this technology may not be appropriate or available everywhere (Section 3).

[42] Available at: *https://www.epa.gov/pfas/interim-guidance-destroying-and-disposing-certain-pfas-and-pfas-containing-materials-are-not*.

[43] Available at: *http://www.epa.gov/pfas*.

[44] For general information on these technologies, see EPA websites for *incineration*, *landfills*, and *underground injection*. Please note that these resources are not specific to PFAS and not all information in them may be relevant to PFAS D&D.

- **Landfills–Permitted RCRA Subtitle C hazardous waste landfills:** When landfill disposal is selected and PFAS concentration of the waste is relatively high, EPA recommends using a hazardous waste landfill. These types of landfills have the most stringent engineering controls and practices for minimizing environmental release of PFAS from leachate and landfill gas. These controls are especially important for certain types of PFAS-containing materials that break down more easily in landfill conditions. However, for all landfill types, new information demonstrates landfilling could result in higher PFAS releases to the environment than previously thought in 2024 (Section 3).
- **Thermal treatment–Permitted hazardous waste combustors that operate under certain conditions:** New research since 2024 indicates that thermal treatment units operating under certain conditions are more effective at destroying PFAS and minimizing environmental releases or human exposures. Certain hazardous waste combustors and certain granular activated carbon (GAC) reactivation units may operate under these conditions, but uncertainties remain. For example, more information is needed to determine whether harmful products of incomplete combustion (PICs) or PFAS air emissions are formed by units operating at lower temperatures (e.g., municipal waste combustors). EPA's new analytical methods for a targeted list of polar semivolatile PFAS (Other Test Method 45 [*OTM-45*[45]]) and volatile fluorinated compounds (*OTM-50*[46]) that, as well as additional EPA methods under development for evaluating treatment of hard-to-destroy PFAS will allow better characterization of PICs which will help to address some of these uncertainties. The updated interim guidance encourages testing with a range of methods at thermal treatment facilities before accepting large quantities of PFAS-containing materials (Section 3 and Appendix A).
- The interim guidance discusses these and other PFAS D&D technologies, plus testing and research needs to improve technology performance, improve understanding of PFAS behavior, and reduce uncertainties (Section 4).

Emerging Destruction and Disposal Technologies

Federal entities and many companies and researchers are developing and testing new PFAS D&D technologies (e.g., the *PFAS Technical and Regulatory Guidance Document*[47] developed by the Interstate Technology and Regulatory Council, and the Department of War's *Strategic Environmental Research and Development Program (SERDP) and the Environmental Security Technology Certification Program (ESTCP) PFAS Projects*[48] website). EPA encourages technology developers to generate and publicly release data that can be reviewed, and to ensure the data are consistent with the tenets of gold standard science established in Executive Order 14303 (*Restoring Gold Standard Science*[49]). The guidance provides a technology evaluation framework to help analyze the safety and effectiveness of new D&D technologies, and notes the need for innovation, research, and validation (Section 5).

Public Input and Participation

EPA has opened a *docket*[50] to take input on the interim guidance. We welcome public input on how to improve the interim guidance and this fact sheet.

Public Feedback and Next Steps

EPA and other government, academic, and private institutions will continue to conduct research to better understand PFAS destruction and disposal (see Section 4). EPA will consider public comments it receives on this version of the guidance, as well as additional advancements in PFAS research and science to publish annual updates[51]. This guidance will be published with a 60-day comment period. EPA will publish a Federal Register Notice with instructions on how to submit comments. During the public comment period, EPA encourages the public to submit studies and data related to management of the PFAS-containing waste described in Section 2. Additionally, continued collaboration with industry and researchers is encouraged to conduct emissions testing of PFAS treatment devices, including evaluation of PICs and products of incomplete destruction (PIDs).

[50] Available at: *https://www.regulations.gov/document/EPA-HQ-OLEM-2020-0527-0003*.

[51] On April 28, 2025, the EPA Administrator committed to providing more frequent updates to the interim guidance—changing from every three years to annually.

Environ. Sci. Technol. **2001**, *35,* 1339−1342

Global Distribution of Perfluorooctane Sulfonate in Wildlife

JOHN P. GIESY* AND
KURUNTHACHALAM KANNAN

Department of Zoology, National Food Safety and Toxicology Center, Institute for Environmental Toxicology, Michigan State University, East Lansing, Michigan 48824

Here we report, for the first time, on the global distribution of perfluorooctanesulfonate (PFOS), a fluorinated organic contaminant. PFOS was measured in the tissues of wildlife, including, fish, birds, and marine mammals. Some of the species studied include bald eagles, polar bears, albatrosses, and various species of seals. Samples were collected from urbanized areas in North America, especially the Great Lakes region and coastal marine areas and rivers, and Europe. Samples were also collected from a number of more remote, less urbanized locations such as the Arctic and the North Pacific Oceans. The results demonstrated that PFOS is widespread in the environment. Concentrations of PFOS in animals from relatively more populated and industrialized regions, such as the North American Great Lakes, Baltic Sea, and Mediterranean Sea, were greater than those in animals from remote marine locations. Fish-eating, predatory animals such as mink and bald eagles contained concentrations of PFOS that were greater than the concentrations in their diets. This suggests that PFOS can bioaccumulate to higher trophic levels of the food chain. Currently available data indicate that the concentrations of PFOS in wildlife are less than those required to cause adverse effects in laboratory animals.

Introduction

Research investigating the environmental fate of halogenated compounds has focused largely on chlorinated and brominated compounds. Fluorinated organic compounds (FOCs) have received less attention because their measurement is more difficult. Because they have surface-active properties, FOCs are more difficult to separate from tissues than the more classical neutral residues that have been studied. Also, because they are nonvolatile and have relatively high molecular weights, they require specialized liquid chromatography/mass spectrometry methods for analysis. Because much of the FOCs were incorporated into polymers, they are perceived as more biologically inert and therefore, less likely to have an impact on human health or the environment.

FOCs have been manufactured for over 50 years. FOCs are used as refrigerants, surfactants, and polymers, and as components of pharmaceuticals, fire retardants, lubricants, adhesives, cosmetics, paper coatings, and insecticides (*1*). Because of their many useful properties, since the 1970s there has been a steady increase in the use of FOCs for a variety of industrial applications.

Although partially fluorinated hydrocarbons may undergo chemical breakdown at functional group bonds (*2*), given the high energy of the carbon−fluorine bond (known to be the strongest of covalent bonds), some perfluorinated compounds are very stable in the environment (*3*). Even though FOCs could be persistent, the magnitude and extent of distribution of FOCs in the environment was unknown. However, the occurrence of FOCs in human blood sera was reported as early as 1968 (*4*). Further reports of FOCs in human sera from various locations in the U.S., South America, and Japan appeared over the next several decades (*5*−*8*). These reports would indicate a relatively widespread distribution of these materials in human sera and would suggest the potential for distribution in the environment. However, no compound-specific information on the extent of the distribution of FOCs in the environment or in wildlife was available. This was due, in part, to the lack of a practical compound-specific method of analysis that could be applied to a wide range of sample types with sufficient sensitivity to measure ecologically relevant concentrations of specific compounds. Recent development of a compound-specific method for the analysis of some FOCs using high-performance liquid chromatography−negative ion electrospray tandem mass spectrometry (*9*) permitted the survey of four FOCs in liver and blood plasma of wildlife on a global scale.

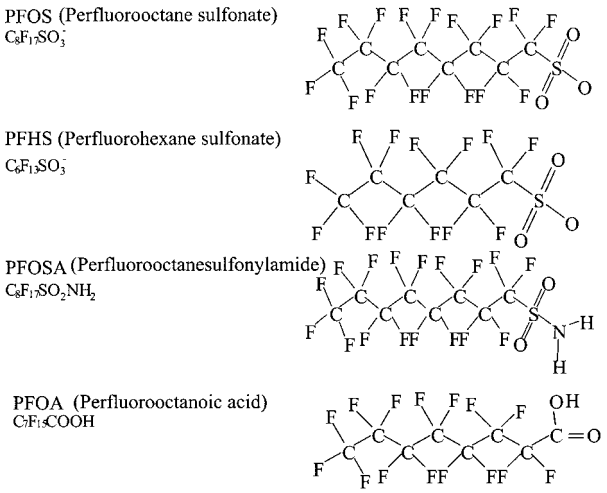

FIGURE 1. Structures of target fluorinated organic compounds.

The number of synthetic FOCs has increased over the past few years. Among them, sulfonyl-based fluorochemicals have been produced and used for over 40 years. Perfluorooctanesulfonyl fluoride (POSF) is the basic building block of a series of perfluorinated alkyl sulfonates that are used as surface protectors in carpets, leather, paper and packaging, fabric, and upholstery. It has been hypothesized that, during their life cycles, POSF and some POSF-based products could ultimately degrade to other fluorochemicals including perfluorooctane sulfonate (*10*) (PFOS; Figure 1).

The studies on which we report here are part of a larger, ongoing, comprehensive program of investigation of global distribution and fate of PFOS in the environment. The objectives of this study were to elucidate the current environmental distribution of PFOS by use of biomonitoring and to evaluate bioaccumulation and biomagnification potential in aquatic and terrestrial food webs. Tissues of a variety of wildlife species, living near urban areas and in more remote areas, including the Arctic and the Antarctic, were studied to monitor for the presence of PFOS. In addition, species from different trophic levels with different feeding

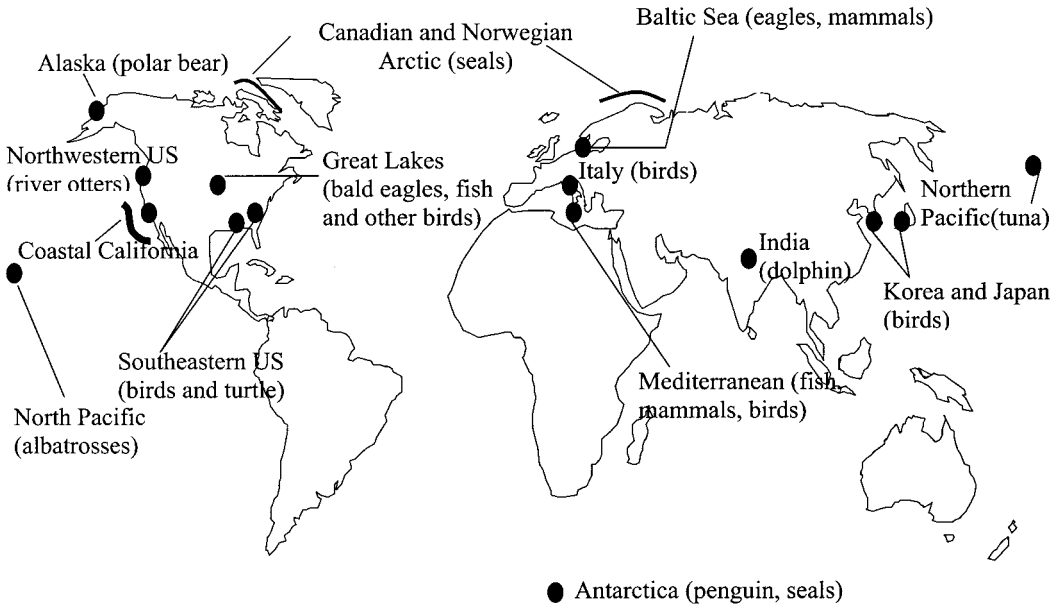

FIGURE 2. Sampling locations of wildlife to monitor fluorinated organic compounds.

strategies were selected to provide some insight into potential environmental pathways.

Materials and Methods

Tissues of various species of aquatic mammals, birds, fish, and amphibians were collected as part of earlier monitoring studies conducted by Michigan State University, East Lansing, Michigan. Samples were collected under permits from state and federal agencies. Tissues of most individuals of aquatic mammals were obtained from stranded dead animals. Samples were also obtained from archived tissues from federal and state agencies. Samples collected in the 1990s were used. Samples were obtained to represent various geographical locations including the Arctic and the Antarctic Oceans (Figure 2).

Concentrations of PFOS and other FOCs in liver, egg yolk, muscle, or blood plasma were determined by use of high-performance liquid chromatography (HPLC) with electrospray tandem mass spectrometry (*9*). The PFOS used as standards and for matrix spikes was purchased as the potassium salt (Fluka, Milwaukee, WI). The purity of the PFOS standard was 86%. The reported concentrations were not corrected for the purity. The internal standard, 1*H*,1*H*,2*H*,2*H*-perfluorooctane sulfonate (THPFOS) was purchased from ICN (Costa Mesa, CA). One mL of sera, 5 μL of internal standard (250 ng), 1 mL of 0.5 M tetrabutylammonium hydrogen sulfate (TBA) solution, and 2 mL of 0.25 M sodium carbonate buffer (adjusted to pH 10) were added to a 15-mL polypropylene tube for extraction. After the solution was thoroughly mixed, 5 mL of methyl-*tert*-butyl ether (MTBE) was added, and the mixture was shaken for 20 min. The organic and aqueous layers were separated by centrifugation, and an exact volume of MTBE (4 mL) was removed from the solution. The aqueous mixture was rinsed with MTBE and separated twice; all rinses were combined in a second polypropylene tube. The solvent was allowed to evaporate under nitrogen before being reconstituted in 1 mL of methanol. The extract was vortex mixed for 30 s and passed through a 0.2-μm nylon mesh filter into an autosampler vial. For the extraction of liver samples, a liver homogenate of 1 g of liver in 5 mL of purified (milli-Q) water was prepared. A 1-mL aliquot of the homogenate was added to a polypropylene tube, and the sample was extracted according to the procedure described above.

Analyte separation was performed using a Hewlett-Packard HP1100 liquid chromatograph modified with low dead-volume internal tubing. Extract (10 μL) was injected onto a 50 × 2 mm (5 μm) Keystone Betasil C_{18} column with a 2 mM ammonium acetate/methanol mobile phase starting at 45% methanol. At a flow rate of 300 μL/min, the gradient was increased to 90% methanol before reverting to the original conditions after 9 min. Column temperature was maintained at 25 °C. The HPLC system was interfaced to a Micromass (Beverly, MA) Ultima or Quattro II atmospheric pressure ionization tandem mass spectrometer operated in the electrospray negative ion mode. In all cases, the capillary was held between 1.6 and 3.2 kV. Cone voltage was 20−60 v and collision energy was 30−45 v. The source temperature was maintained at 250 °C. Instrumental parameters were optimized to transmit the [M-H], [M-K], or [M-NH_4] ion for analytes. When possible, multiple daughter ions were monitored, but quantitation was based on a single product ion. In the electrospray tandem mass spectrometry (ESMSMS) system, the 499 Da → 80 Da transition can be optimized to provide a stronger signal than the 499 Da → 99 Da transition of PFOS. However, in the analysis of tissue samples collected from some species of animals, an unidentified interferent was present in the 499 Da → 80 Da transition. Although this interferent was rarely observed, to ensure complete selectivity, quantitation was based on the 499 Da → 99 Da transition. To further ensure that no interferent compromised the quantitation of PFOS, the transitions 499 Da → 80 and 499 → 99 were compared. If a quantitative deviation of >20% was observed, a third transition, 499 Da → 130 was also monitored. In all cases, the validity of the 499 Da → 99 transition was confirmed by one of the other transitions. Samples were evaluated versus an averaged $^1/_x$ weighted, unextracted external calibration curve. Because of the variety of matrices analyzed, with respect to both species and tissues, and because of evolving analytical methods, the limit of quantitation (LOQ) was variable. Data quality assurance and quality control protocols included matrix spike, surrogate spike, laboratory blank, surrogate matrix blanks, and continuing calibration verification. Recoveries of target analytes spiked to rabbit sera or liver and passed through the analytical procedure ranged from 85 to 101% (*9*). Concentrations of target analytes were not corrected for recoveries of the surrogate standard or matrix spike recoveries.

TABLE 1. Ranges of Concentrations of PFOS (ng/g, wet wt, for Liver and Muscle Tissues and ng/mL for Blood Plasma) in Wildlife; Mean Concentrations Are Given in Parentheses

species	location	tissue	n	PFOS
	Aquatic Mammals			
ringed seal	Canadian Arctic	plasma	24	<3−12
ringed seal	Baltic Sea	plasma	18	16−230 (110)
ringed seal	Norwegian Arctic	plasma	18	5−14 (9)
gray seal	Baltic Sea	plasma	26	14−76 (37)
gray seal	Canadian Arctic	plasma	12	11−49 (28)
California sea lion	Coastal California	liver	6	<35−49
elephant seal	Coastal California	liver	5	<35
harbor seal	Coastal California	liver	3	<35−57
river otter	Northwestern USA	liver	5	34−990 (330)
sea otter	Coastal California	liver	8	<35
northern furseal	Coastal waters of Alaska	liver	14	<35−120
polar bear	Alaska, USA	liver	17	180−680 (350)
mink	Midwestern USA	liver	18	970−3680 (2630)
bottlenose dolphin	Mediterranean Sea	liver	5	170−430 (270)
striped dolphin	Mediterranean Sea	liver	4	65−160 (100)
weddel Seal	Terra Nova Bay, Antarctica	liver	1	<35
Ganges river dolphin	Ganges River, India	liver	2	<35−81
	Birds			
double-crested cormorant	Lake Huron, Great Lakes	plasma	6	1−270 (170)
herring gull	Lake Huron, Great Lakes	plasma	2	66−79 (73)
polar skua	Terra Nova Bay, Antarctica	plasma	2	<1−1.4
black-tailed gull	Hokkaido, Japan	plasma	24	2−12 (6)
double-crested cormorant	Lake Winnepeg, Canada	egg yolk	4	130−320 (210)
ring-billed gull	Lake Huron, Great Lakes	egg yolk	3	<35−150
Laysan and black-footed albatrosses	Midway Atoll, North Pacific	liver	9	<35
common loon	North Carolina, USA	liver	8	35−690 (290)
brown pelican	Mississippi, USA	liver	2	290−620 (460)
common cormorant	Italy	liver	12	33−470 (96)
black-tailed gull	Korea	liver	15	70−500 (170)
Laysan and black-footed albatrosses	Midway Atoll, North Pacific	plasma	3	9−26 (18)
double-crested cormorant	Lake Huron, Great Lakes	plasma	3	110−430 (260)
herring gull	Lake Huron, Great Lakes	plasma	2	280−450 (370)
bald eagle	Midwestern USA	plasma	26	1−2570 (360)
Laysan and black-footed albatrosses	Midway Atoll, North Pacific	plasma	10	3−39 (9)
	Fish			
lake whitefish	Michigan waters, USA	eggs	2	150−380 (260)
brown trout	Michigan waters, USA	eggs	3	49−75 (64)
Chinook salmon	Michigan waters, USA	liver	6	33−170 (110)
lake whitefish	Michigan waters, USA	liver	5	33−81 (67)
brown trout	Michigan waters, USA	liver	10	<17−26
yellow-fin tuna	Northern North Pacific Ocean	liver	12	<7
blue-fin tuna	Mediterranean Sea	liver	8	21−87 (48)
carp	Saginaw Bay, Michigan, USA	muscle	10	60−300 (120)
Chinook salmon	Michigan waters, USA	muscle	6	7−190 (110)
lake whitefish	Michigan waters, USA	muscle	5	97−170 (130)
brown trout	Michigan waters, USA	muscle	10	<6−46
	Turtles and Frogs			
yellow-blotched map turtle	Mississippi, USA	liver	6	39−700 (190)
green frogs	Southwest Michigan, USA	liver	4	<35−290
snapping turtle	Lake St. Clair, Michigan, USA	plasma	5	1−170 (72)

Results and Discussion

Samples were scanned for four FOCs: PFOS, perfluorooctane sulfonylamide (PFOSA), perfluorohexane sulfonate (PFHS), and perfluorooctanoate (PFOA). However, all concentrations of PFHS were less than the LOQ (LOQ range = 1 to 86 ng/g, wet wt) and only a few samples contained PFOA or PFOSA at levels greater than the LOQ of 2.5 to 180 ng/g, wet wt, and 1 to 38 ng/g, wet wt, respectively. Therefore, only the results for PFOS are presented (Table 1).

When a method detection limit of 1 ng/g, wet wt, was attained, PFOS was detectable in most samples including those from remote marine regions. Concentrations of PFOS in the blood of ringed and gray seals from the Canadian and Norwegian Arctic were in the range of 3 to 50 ng/mL. PFOS concentrations were 2−10 times greater (14−230 ng/mL) in seals from relatively more urbanized locations,such as the Baltic Sea, than those from the Arctic Ocean. Blood plasma of Laysan and black-footed albatrosses collected from remote oceanic locations, such as Midway Atoll in the North Pacific Ocean, contained concentrations of PFOS ranging from 3 to 26 ng/mL. PFOS concentrations in the blood of cormorants and herring gulls from the Great Lakes were approximately 10-fold greater than those in albatrosses from Midway Atoll. Although the liver of yellow-fin tuna from the northern North Pacific did not contain quantifiable concentrations of PFOS (<7 ng/g, wet wt), blue-fin tuna from the Mediterranean Sea contained up to 87 ng/g, wet wt, PFOS in the liver. Livers of polar bears from Alaska contained concentrations of PFOS between 180 and 680 ng/g, wet wt. Although PFOS is distributed in remote marine environments including polar regions, concentrations of PFOS in these regions were severalfold less than those from relatively more industrialized

KD2154

locations such as the Baltic Sea and the Great Lakes.

Among various bird species analyzed, blood plasma of bald eagles from the midwestern U.S. contained PFOS concentrations of up to 2570 ng/mL (mean: 360). All plasma samples were obtained from bald eagle chicks less than 200 days old. Other fish-eating water birds such as common loons and brown pelicans contained quantifiable concentrations of PFOS in the liver. All the bird tissues from Canada, Italy, Japan, and Korea contained quantifiable concentrations of PFOS. PFOS concentrations in the blood of black-tailed gulls (2−12 ng/mL) from Hokkaido in Japan were less than those found in albatrosses from Midway Atoll. Occurrence of PFOS in these birds suggests that their potential source of exposure is the fish diet. Tissues of fish from the Great Lakes and the Mediterranean Sea contained measurable concentrations of PFOS. The highest PFOS concentrations observed in fish (300 ng/g, wet wt) were in the muscle of carp from Saginaw Bay, Michigan.

Mink from the midwestern U.S. contained significant concentrations of PFOS in their livers (970−3680 ng/g, wet wt). Mink are opportunistic predators but do eat fish as part of their diet. When mink were fed carp from Saginaw Bay, Michigan, containing an average concentration of 120 ng PFOS/g (wet wt), under laboratory conditions, the estimated biomagnification factor based on the concentrations of PFOS in livers of mink was approximately 22.

Although the results of this study have demonstrated for the first time that PFOS is widely distributed on a global scale and can be persistent and bioaccumulative in various food chains, little information is available on possible toxic effects of PFOS to wildlife. PFOS and related perfluorinated compounds have been shown to affect cell−cell communication, membrane transport and process of energy generation, and proxisome proliferation (*11*, *12*). Currently available data (unpublished reports to U.S. EPA; Docket No. FYI-0500-01378) indicate that concentrations of PFOS in wildlife are less than those required to cause significant adverse effects in laboratory animals. However, as more species-specific information becomes available, a more refined assessment of the risks to wildlife will be possible.

GREENHOUSE GAS PROTOCOL

Global Warming Potential Values

The following table includes the 100-year time horizon global warming potentials (GWP) relative to CO_2. This table is adapted from the IPCC Fifth Assessment Report, 2014 (AR5)[i]. The AR5 values are the most recent, but the second assessment report (1995) and fourth assessment report (2007) values are also listed because they are sometimes used for inventory and reporting purposes. For more information, please see the IPCC website (www.ipcc.ch). The use of the latest (AR5) values is recommended. Please note that the GWP values provided here from the AR5 for non-CO_2 gases do not include climate-carbon feedbacks.

ABSTRACT

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are a class of global environmental pollutants whose environmental fate and adverse effects are of concern. However, data on the basic physicochemical properties of PFASs are scarce. To fill part of the data gaps, improved quantitative structure–property relationship (QSPR) models for prediction of PFAS properties are developed based on the correlation between reported experimental data and molecular descriptors (fluorine number, molar volume and total surface area). Properties include vapor pressure, aqueous solubility, octanol/water partition coefficient, air/water partition coefficient and octanol/air partition coefficient. The fluorine number-descriptor model is based on good statistical results. However, this model cannot distinguish among PFASs with the same number of attached fluorines. Setting aside the fluorine number-descriptor models, models based on molar volume are statistically better than those based on total surface area. Therefore, The PFAS data obtained from the molar volume descriptor model are more reliable than from fluorine number and total surface area descriptor models. These results are intended to improve the understanding of the behavior and fate of PFASs in the environment, at contaminated sites and during remediation.

1. Introduction

Perfluoroalkyl and polyfluoroalkyl substances (PFASs) are aliphatic materials containing one or more carbon atoms, on which all the hydrogen substituents present in the nonfluorinated analogs from which they are notionally derived have been replaced by fluorine atoms, in such a manner that PFASs contain the perfluoroalkyl moiety C_nF_{2n+1} (Buck et al., 2011). They have been manufactured since the 1950s for use as refrigerants, surfactants, fire retardants, and stain-resistant coatings for fabrics, carpets and paper (Kissa, 2001). Given their high electronegativity and the small size of the fluorine atom, the carbon–fluorine bond possesses strong polarity and large bond energy. The strength of the carbon–fluorine bond, together with the presence of three pairs of non-bonding electrons around each fluorine atom, as well as effective shielding of the carbon atom by fluorine atoms, render PFASs relatively stable. Consequently, PFASs are non-flammable and resist degradation by acids, bases, oxidants, photolytic processes, microbes and metabolic processes (Giesy and Kannan, 2002; Kissa, 2001).

Because of their persistence, PFASs can be detected in all environmental media and in biological samples. Environmental monitoring studies have reported the presence of PFASs in lakes (De Silva et al., 2009), rivers (Eschauzier et al., 2012), precipitation (Kwok et al., 2010), sea sediment (Gomez et al., 2011) and even the Arctic atmosphere (Shoeib et al., 2006). In addition, it has been reported that PFASs are highly accumulated in fish in different countries such as Germany (Schuetze et al., 2010) and Spain (Llorca et al., 2009), as well as different regions of North America (De Silva et al., 2009). In view of their persistence and widespread occurrence in the environment, perfluorooctane sulfonate (PFOS), its salts and perfluorooctane sulfonyl fluoride were added to Annex B of the International Stockholm Convention treaty on Persistent Organic Pollutants (POPs) in May 2009, resulting in global restrictions on production and use of these compounds.

To understand and model how PFASs migrate through the global environment and their potential for multi-media fate and transport, it is necessary to know their fundamental physicochemical properties. Important properties in this regard include: vapor

KD2160

pressure and aqueous solubility, as well as their air/water, octanol/water and octanol/air partition coefficients (Wang et al., 2011). Long-range transport of PFASs is strongly affected by vapor pressure and partitioning between air and water (Schenker et al., 2008). The solubility and octanol/air partition coefficient is also useful for predicting the potential for bioaccumulation and toxicity of chemicals in the environment and biota, such as soil, vegetation and humans (Boethling et al., 2004).

Despite their importance, few experimental measurements of physicochemical properties have been reported, with the result that some property values of PFASs are missing (Dreyer et al., 2009; Liu and Lee, 2007; Shoeib et al., 2004; Steele et al., 2002ab). Also, fundamental thermodynamic relationships between the reported properties are commonly not satisfied because of errors and inconsistencies in experimental measurements and predictions. For example, fluorotelomer alcohol (FTOH) and sulfonamide congeners have shown substantial differences (up to 10 orders of magnitude) between experimental and predicted partitioning data (Arp et al., 2006). The calculated concentrations of perfluorooctylsulfonyl fluoride (POSF-based precursors) in air deviate from levels measured in the environment (Schenker et al., 2008). Henry's law constant is often estimated as the ratio of saturation vapor pressure and aqueous solubility, but measured or estimated data are not fully consistent (Beyer et al., 2002).

To fill the gaps, QSPR models have been utilized as powerful tools to predict properties of other compounds (Li et al., 2008; Mansouri et al., 2012). QSPR studies are based on the correlation between the experimental values and different molecular descriptors such as the number of specific atoms, molecular volume, molecular surface area, molecular connectivity indexes and relative retention time. Among the most commonly used molecular descriptors are the number of specific atoms, molar volume and total surface area (Yue and Li, 2013) which are related to the chemical's hydrophobicity, aqueous solubility and octanol/water partitioning (Amidon and Anik, 1981; Gobas, 1991; Mailhot and Peters, 1988).

This paper aims to: (i) review available experimental and estimated data for key basic physicochemical properties of PFASs (vapor pressure (P_L), aqueous solubility (S_L), air/water partition coefficient (K_{AW}), octanol/water partition coefficient (K_{OW}) and octanol/air partition coefficient (K_{OA})). (ii) Evaluate QSPR models based on fluorine number (F_N), molar volume (V_M) and total surface area (TSA) and select the best ones to estimate complete sets of data for PFASs. (iii) Check for internal consistency based on fundamental thermodynamic relationships. With the aid of these steps, more reliable data can be utilized for environmental modeling, and for assessment and remediation of PFAS-contaminated sites.

2. Methodology

2.1. Collection of experimental and estimated data

Experimental and estimated property values of PFASs which include perfluorinated carboxylic acids (PFCAs), perfluorinated sulfonic acids (PFSAs), perfluoroalkane sulfonamide substances (FASAs) and fluorotelomer alcohols (FTOHs) were selected from the literature. These four classes of PFASs have elicited considerable attention because of toxic effects of their degradation products or manufacturing residuals of fluorinated polymers and PFAS precursors (Giesy and Kannan, 2002; Halldorsson et al., 2012). For this reason, a total of 23 PFASs encompassing 10 PFCAs, 3 PFSAs, 6 FASAs and 4 FTOHs congeners were selected for our study (Table 1). Molecular structures of these 23 PFASs are represented in Supplementary information (Table S1). For the selection of reliable data, Yue and Li (2013) critically review properties data and assign values of PBDEs based on several criteria. In this study, the same criteria were applied to filter available data for PFASs physicochemical properties: (i) The available property values were obtained from measured and estimated data at the same conditions (298 K and 760 mm Hg). (ii) Where multiple data were available from the same research group, the most recent values were

assigned. (iii) Where data were available from different research groups and it was unclear which are more reliable, those based on what appeared to be the more acceptable method were chosen. (iv) Obviously dubious values were excluded. Data were converted to a log scale for modeling.

2.1.1. Vapor pressure

Selected experimental log P_L values (hereafter labeled Ext-Sel. log P_L, with pressure units in Pa) were collected from measured data based on indirect and direct measurement methods. Steele et al. (2002a, b) determined the vapor pressures of perfluoroheptanoic acid (PFHpA) and perfluorobutanoic acid (PFBA) using a twin ebulliometric apparatus. Kaiser et al. (2005) obtained the vapor pressures of perfluorooctanoic (PFOA), -nonanoic (PFNA), -decanoic (PFDA), -undecanoic (PFUnA) and -dodecanoic (PFDoA) acids using a dynamic method developed by Scott (1986). Lei et al. (2004) estimated the liquid-phase vapor pressures of FTOHs and ethyl perfluorooctane sulfonamidoethanol (EtFOSE) as a function of temperature, based on a gas chromatographic retention time (GC-RT) technique which utilizes the consistent retention time of a compound in a GC column at a given temperature. The above methods were successfully employed for reference compounds. The resulting data sets are used for QSPR analysis of PFAS properties.

2.1.2. Aqueous solubility

Experimental data from U.S. EPA (2003), Kaiser et al. (2006) and Liu and Lee (2007) were selected to predict the solubility of all PFASs in this study (Ext-Sel. log S_L, with S_L units in mol L^{-1}). The solubility data reported in the references were determined by the method incorporated as a standard by the Organization for Economic Co-operation and Development. The solubility is affected by the intermolecular forces between solute and solvent, as well as the melting point and enthalpy of the solute. Subcooled liquid solubility is a function of both molecular size and melting point, while solid solubility is a function of only molecular size (Yue and Li, 2013). Therefore, to overcome the difference between congeners due to the melting-point effect, aqueous solubility (S_S, in mol L^{-1}) for solid substances have to be converted into the subcooled liquid using the fugacity ratio (F).

$$1/F = \exp\left[\Delta S_{\mathrm{fus}}/R \times (T_{\mathrm{m}}/T - 1)\right] \quad (1)$$

$$S_{\mathrm{L}}/S_{\mathrm{S}} = P_{\mathrm{L}}/P_{\mathrm{S}} = 1/F \quad (2)$$

where ΔS_{fus} is the entropy of fusion (J K^{-1} mol^{-1}), R the universal gas constant (8.314 J K^{-1} mol^{-1}), T_m the normal melting point (K), and T is the absolute temperature of interest (here 298.15 K). Based on Hinckley et al. (1990), Bidleman and Harner (2000) and Shoeib et al. (2004), ΔS_{fus} = 56.45 J K^{-1} mol^{-1} was adopted in this study. T_m for PFASs was obtained from U.S.EPA's EPI (Estimations Programs Interface) Suite.

2.1.3. Octanol/water partition coefficient

PFASs tend to form three immiscible layers when they are added to an octanol/water mixture because PFASs are simultaneously hydrophobic and lipophobic. Therefore, it is impossible to determine directly their K_{OW} values using 'regular' methods that are common for organic chemicals. Jing et al. (2009) determined K_{OW} of a homologous series of perfluoroalkyl and alkyl carboxylates using ion-transfer cyclic voltammetry. In this study, the selected experimental octanol/water partition coefficient data (Ext-Sel. log K_{OW}) were obtained from Jing et al. (2009).

2.1.4. Air/water partition coefficient

The Air/Water partition coefficient, K_{AW}, which is the concentration ratio of a substance in equilibrium between air and water phases, can be expressed either in dimensionless form or with the same units as the Henry's law constant (H) (Ding and Peijnenburg, 2013; Shiu and Ma, 2000). Because the information on K_{AW} for PFASs was extremely limited, values of K_{AW} (Ext-Sel. log K_{AW}) are estimated from the dimensionless Henry's law constant (H′) according to the equation

$$K_{\mathrm{AW}} = H/RT = H' \quad (3)$$

$$H = P_L/S_L \quad (4)$$

where, P_L and S_L represent Ext-Sel. log P_L and Ext-Sel. log S_L respectively.

2.1.5. Octanol/air partition coefficient

Experimental log K_{OA} (Ext-Sel. log K_{OA}) data for PFASs were selected from Shoeib et al. (2004), Goss et al. (2006) and Dreyer et al. (2009). Shoeib et al. (2004) and Dreyer et al. (2009) measured K_{OA} for perfluoroalkyl sulfonamides (FASAs) and perfluoroalkyl sulfonamidoethanols (FASEs) using a modified generator column. Goss et al. (2006) determined K_{OA} of FTOHs based on the method described by Shoeib et al. (2004). These results were supported by data reported by Thuens et al. (2008).

2.2. Correlations with molecular descriptors

Selected PFAS property data were correlated to F_N, V_M and TSA. F_N is a constitutional descriptor derived from atomic composition, whereas V_M and TSA are geometric descriptors derived from 3-D structures. These molecular descriptors were gathered from the ACD/Labs' ACD/PhysChem Suite and are listed in Table 1.

The single descriptor models correlated with selected molecular descriptors were evaluated from the statistical values of significance test (F), significance level (P), squared correlation coefficient (r^2), and standard error (S.E.) of the estimate and cross-validated coefficient (Q^2 or Rcv^2) (Li et al., 2008; Sabljic et al., 1993; Yue and Li, 2013). Cross-validated coefficients using the leave-one-out technique (LOO-Rcv^2) were calculated from the equation: LOO-Rcv^2 = 1 − PRESS/TSS, where PRESS is the prediction error sum of squares and TSS is the total sum of squares (Gramatica and Pilutti, 2004; Li et al., 2011). Statistical significance was set at $P < 0.05$, and linear regression was performed using Sigmaplot 10 (Systat Software Inc, Point Richmond, CA).

2.3. Incorporating reliability

Basic constraining equations exist for the air, water and octanol system, as described by Cole and Mackay (2000). For internal consistency, all property data from available single-descriptor models were checked against the following basic equations (Beyer et al., 2002; Yue and Li, 2013):

$$\log K_{\mathrm{AW}} = \log S_A - \log S_W \quad (5)$$

$$\log K_{\mathrm{OA}} = \log S_O - \log S_A \quad (6)$$

$$\log K_{\mathrm{OW}} = \log S_{\mathrm{OW}} - \log S_{\mathrm{WO}} \quad (7)$$

$$\log S_O/S_W = \log S_O - \log S_W \quad (8)$$

KD2162

where the subscripts A, W and O designate air, water and octanol, respectively. OW and WO denote octanol saturated with water and water saturated with octanol, respectively. S_O/S_W is regarded as the partition coefficient between pure octanol and pure water. However, S_O/S_W is not necessarily equal to K_{OW} because S_O is not equal to S_{OW}, nor is S_W equal to S_{WO} (Harner and Mackay, 1995; Kömp and McLachlan, 1997; Pinsuwan et al., 1995). In addition, Eqs. (5), (6) and (8) can be combined to give;

$$\log S_O/S_W - \log K_{OA} = \log K_{AW} \quad (9)$$

Eq. (9) can be used to determine the deviation (ε) from the ideal relationship when only K_{OW}, K_{AW} and K_{OA} are available, where ε from the ideal relationship ($\log K_{AW} - \log S_A + \log S_W = 0$) is calculated by

$$\log K_{AW} - \log S_A + \log S_W = \varepsilon \quad (10)$$

In the procedure for internal consistency, an uncertainty factor is assigned to each property ranging from 0 (highest accuracy) to 5 (lowest accuracy). This assignment is subjective, based on judgment through proposed model statistical results. This methodology was described in greater detail by Beyer et al. (2002).

In addition, to evaluate the consistency of QSPR models related to molecular descriptor and faulty adjusted property values, estimated data (Est'd-Sel. property) from QSPR models were compared with those from Ext- Cal data. Est'd-Sel. properties of PFASs were

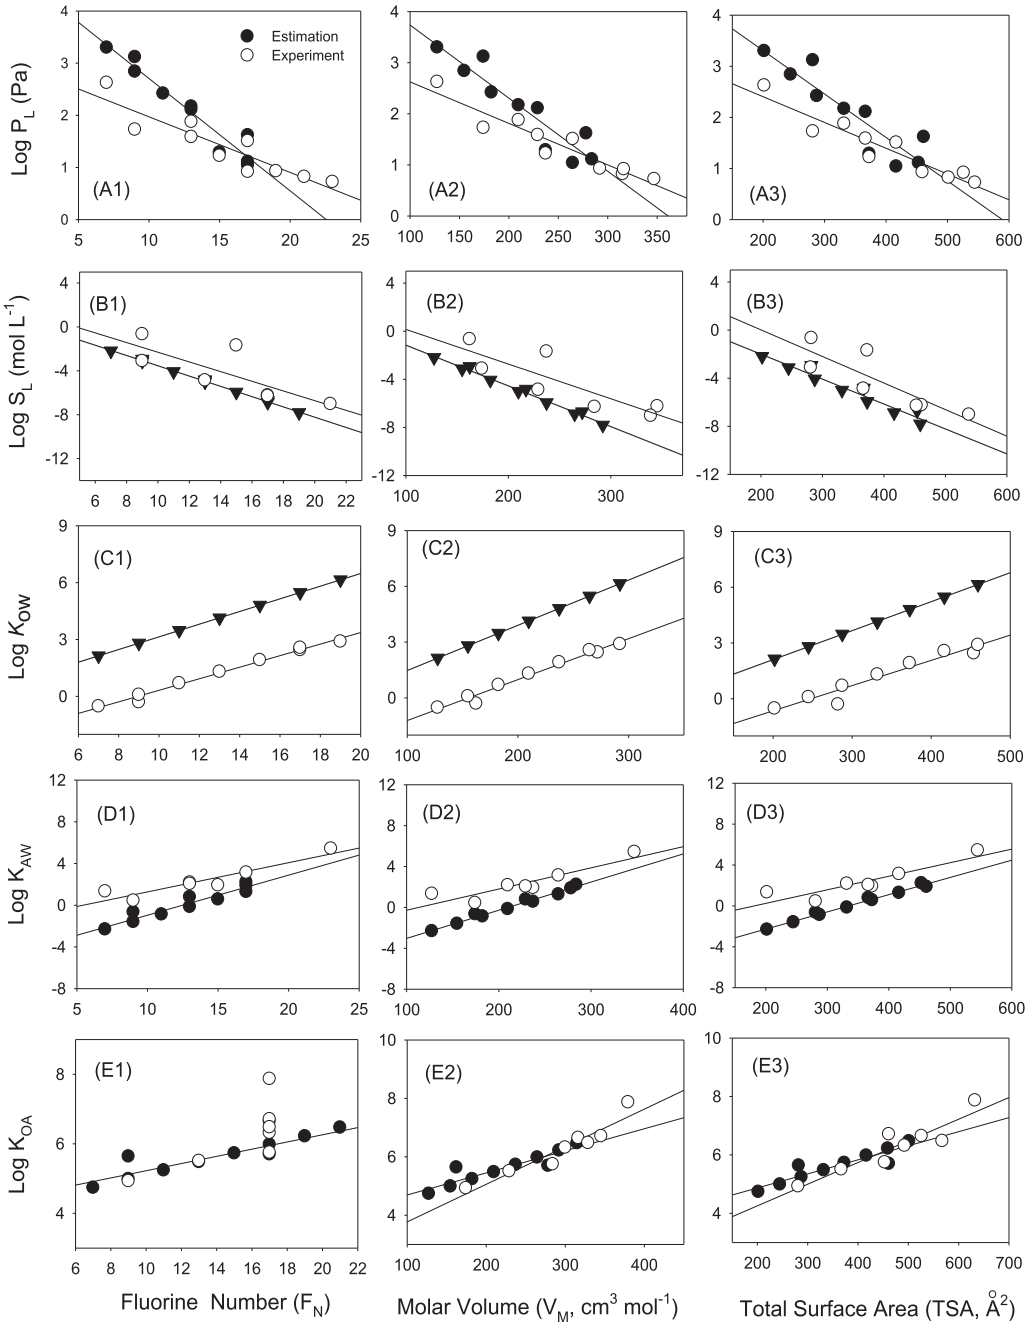

Fig. 1. Correlations between PFASs properties ((A) vapor pressure, (B) aqueous solubility, (C) octanol/water partition coefficient (D) air/water partition coefficient and (E) octanol/air partition coefficient) and molecular descriptors ((1) Fluorine number, (2) molar volume and (3) total surface area).

KD2163

obtained from U.S. EPA's EPI. EPI Suite, a set of computer programs for physical property estimations developed by the US EPA's Office of Pollution Prevention Toxics and Syracuse Research Corporation. These programs are useful for QSPRs and prediction of partition parameters (K_{OW}, K_{AW} and K_{OA}), with values available (Dearden and Schuurmann, 2003; Meylan and Howard, 1995).

3. Results and discussion

3.1. Vapor pressure

Vapor pressure determines the exchange rate of compounds across an air/water interface, volatilization from water, soil or plants, and transport of trace organics throughout the global environment. The volatility parameter, log P_L, is plotted against F_N, V_M and TSA of PFASs in Fig. 1. The Ext-Sel. log P_L, correlation equations and statistical results appear in Table S2 of the Supplementary information, with P_L in units of Pa. In the statistical results, the P values of all single descriptor models based on F_N, V_M and TSA were all significant at the <0.05 level of significance for their respective regression models. In the single descriptor models obtained from experimental data, the model based on V_M was statistically better than those based on F_N and TSA because it has the highest Q^2 (0.8597), largest r^2 (0.8981) and smallest S.E. (0.2006). The single descriptor model with V_M is then

$$\log P_L = -0.0081 \times V_M + 3.4361 \text{ with } n = 10,\ r^2 = 0.8981,\ F = 70.48,\ \text{S.E.} = 0.2006,\ Q^2 \text{ or LOO} - \text{Rcv}^2 = 0.8597 \quad (11)$$

Bhhatarai and Gramatica (2011) also provided an equation to estimate the vapor pressure for 20 PFASs and obtained a number of statistical parameters.

$$\log P_L = 7.97(\pm 1.26) - 0.16(\pm 0.02)F03[C-F] - 3.16(\pm 0.92)\text{AAC} - 0.64(\pm 0.40)n\text{DB} \quad (12)$$

with $n = 35$, $r^2 = 0.9093$, $F = 103.6$, S.E. = 0.883, $Q^2 = 0.8821$.

The model consisted of 2D frequency fingerprint descriptor, F03 [C–F], 2D information indices, AAC, and 0D constitutional descriptor, nDB, which represent the frequency of C–F bonds at three distant linkages, the average atomic composition index and the number of double bonds, respectively. This correlation is based on experimental data of Arp et al. (2006). It can be seen that the model based on Eq. (12) has higher $r^2$and more experimental data (35) than the one based on Eq. (11). However, Arp et al. (2006) only compared the estimated P_L (e.g., COSMOtherm., Sparc. and EPI Suite) with experimental data obtained by Krusic et al. (2005), Kaiser et al. (2005) and Shoeib et al. (2004). These gathered experimental data were determined using different methods and were not tested for internal consistency. In addition, the vapor pressures of FTOHs determined by Krusic et al. (2005) were significantly lower than those reported by Lei et al. (2004) and Stock et al. (2004). For these reasons, the descriptor model (Eq. (12)) of Bhhatarai and Gramatica (2011) cannot be used directly to estimate P_L for PFASs. Based on the descriptor model based on V_M (Eq. (11)), the calculated log P_L values (Ext-Cal. log P_L) of all PFASs are compiled in Table S2 of the Supplementary information, and are subjected below to an internal consistency check.

3.2. Aqueous solubility

Aqueous solubility plays an important role when water ecosystems are involved in chemical transport. Aqueous solubility of PFASs is a useful property on its own, but it can also be used to calculate other physicochemical properties such as K_{AW} and Henry's law constant, which can be estimated together with vapor pressure (Staudinger and Roberts, 1996). In our study, Ext-Sel. log S_L values of PFASs were found from U.S. EPA (2003), Kaiser et al. (2006) and Liu and Lee (2005), as recorded in the Supplementary information, Table S3. Single descriptor models were obtained based on F_N, V_M and TSA (Fig. 1). Although all single descriptor models have similar statistics, the model based on TSA,

$$\log S_L = -0.0221 \times \text{TSA} + 4.4391 \text{ with } n = 7,\ r^2 = 0.7313,\ F = 13.6071,\ \text{S.E.} = 1.4095,\ Q^2 \text{ or LOO} - \text{Rcv}^2 = 0.9305 \quad (13)$$

has higher r^2 and lower S.E than those based on F_N and V_M, as shown in Table S3 of the Supplementary information. Bhhatarai and Gramatica (2011) developed QSPR for the aqueous solubility of PFASs based on experimental data for 20 PFASs. The aqueous solubility of PFASs using both molecular descriptors which are bi-dimensional was predicted by

$$\log S_L = -0.418\left(\pm 1.940\right) - 0.003\left(\pm 0.001\right)T\left(\text{F..F}\right) + 5.185\left(\pm 3.849\right)\text{SIC1 with } n = 20, r^2 = 0.7631,\ F = 27.38,\ \text{S.E.} = 0.91,\ Q^2 = 0.6913 \quad (14)$$

where T(F..F), a topological descriptor, represents the sum of distances between pairs of fluorine atoms. SIC1 is a descriptor based on neighbor degrees and edge multiplicity, mainly related to the structural symmetry of the molecule. It can be seen that Eq. (14) is statistically better than Eq. (13), except for Q^2, with higher r^2 and F, lower S.E. and more experimental data. However, the data from Bhhatarai and Gramatica (2011) were not obtained from similar experimental measurements and were not tested for internal consistency. For these reasons, Eq. (13) is used to estimate the solubilities of 25 PFASs. The calculated log S_L values (Ext-Cal. log S_L) are compiled in Table S3 of the Supplementary information.

3.3. Octanol/water partition coefficient

The octanol/water partition coefficient is the ratio of the concentrations of organic compounds in n-octanol and water phases at equilibrium. The octanol/water partition coefficient is the best-known environmental parameter used to characterize the lipophilicity of compounds to evaluate the tendency of compounds to partition between an organic phase (e.g., fish tissue or soil organic matter) and an aqueous phase (Ding and Peijnenburg, 2013). Arp et al. (2006) calculated K_{OW} values from experimental K_{AW} and K_{OA} data of FTOHs. However, Schwarzenbach et al. (2002), and Carmosini and Lee (2008) suggested that the K_{OW} values calculated by Arp et al. (2006) were not obtained with water molecules in the octanol phase and octanol molecules in the water phase at phase equilibrium. Therefore, K_{OW} values from Arp et al. (2006) were excluded in our study. Jing et al. (2009) reported the first experimental K_{OW} for several representative straight-chain PFCA and PFSA congeners. Their data provided the opportunity to assess the predictive abilities of various software programs (e.g., SPARC and ALOGPS 2.1) using the SMILES molecular formula language to predict K_{OW} of PFASs. Based on the experimental data collected by Jing et al. (2009) (Table S4 of the Supplementary information), correlation equations were obtained for three molecular descriptors (Fig. 1):

KD2164

$$\log K_{OW} = 0.3047 \times F_N - 2.7258 \quad (15)$$

with $n = 9$, $r^2 = 0.9876$, $F = 557.76$, S.E. $= 0.1548$, LOO-Rcv$^2 = 0.9800$

$$\log K_{OW} = 0.0220 \times V_M - 3.4264 \quad (16)$$

with $n = 9$, $r^2 = 0.9768$, $F = 294.63$, S.E. $= 0.2119$, LOO-Rcv$^2 = 0.9635$

$$\log K_{OW} = 0.0136 \times TSA - 3.3683 \quad (17)$$

with $n = 9$, $r^2 = 0.9322$, $F = 96.17$, S.E. $= 0.3623$, LOO-Rcv$^2 = 0.9031$

Of these, the F_N descriptor model (Eq. (15)) is chosen as the best model because it has the highest r^2 (0.9876), highest LOO-Rcv^2 (0.9800) and smallest S.E. (0.1548). Recently, de Voogt et al. (2012) discussed the relationship between hydrophobicity and number of fluorine-substituted carbon atoms in perfluoros. The contribution of each CF_2 group to the increase in hydrophobicity is equal to 0.66, a value that is close to the values of 0.50 and 0.80 estimated by earlier model calculations using COSMOtherm and SPARC models (Arp et al., 2006) and again close to the value of 0.62 calculated with COSMOtherm (Wang et al., 2011). However, the value in Eq. (15) (F_N correlation) is 0.3047, which is close to half values from previous reports (de Voogt et al., 2012; Jing et al., 2009) because the number of fluorines is equal to nearly twice the number of CF_2 groups. Therefore, values of K_{OW} calculated (Ext-Cal. log K_{OW}) from the F_N descriptor model (Eq. (15)) are provided in Table S4 of the Supplementary information.

In addition, Endo and Goss (2014) predicted log K_{OW} of PFASs using poly-parameter linear free energy relationships (PP-LFER). These equations are

$$\log K_{OW} = c + sS + aA + bB + vV \quad (18)$$

$$\log K_{OW} = c + eE + sS + aA + bB + lL \quad (19)$$

$$\log K_{OW} = c + sS + aA + bB + vV + lL \quad (20)$$

based on three major forms, where, the descriptors are E, excess molar refraction; S, dipolarity/polarizability parameter; A, solute H-bond acidity; B, solute H-bond basicity; V, McGowan's molar volume with units of (cm^3 mol^{-1})/100 and L, the logarithmic hexadecane-air partition coefficient. However, the PP-LFER model cannot respect the K_{OW} for all PFASs because K_{OW} values were only predicted based on experimental FTOH data (4:2 FTOH, 6:2 FTOH and 8:2 FTOH). Therefore, these models are not suitable when selecting the best model in this study.

3.4. Air/water partition coefficient

The air/water partition coefficient is useful for predicting vapor exchange rates between air and water interfaces (Burkhard et al., 1985). Lei et al. (2004) and Goss et al. (2006) measured K_{AW} for the FTOHs (4:2 FTOH, 6:2 FTOH and 8:2 FTOH) using static headspace. However, Lei et al. (2004) were unable to account fully for the intermolecular interaction between target molecules and the water phase because of the limited number of experimental temperatures. Goss et al. (2006) found that the experimental values from Lei et al. (2004) contradicted thermodynamic theory, and the 8:2 FTOH result raised some questions. Therefore, because there is little information on different K_{AW} values for FTOHs and none for PFCAs, PFSAs and FASAs, Ext-Sel. log K_{AW} values were calculated from Ext-Sel. log P_L and Ext-Sel. log S_L in our study.

To select a QSPR model with respect to the log K_{AW} of PFASs, Ext-Sel. log K_{AW} was correlated with single molecular descriptors (Fig. 1) leading to:

$$\log K_{AW} = 0.2804 \times F_N - 1.5251 \quad (21)$$

with $n = 7$, $r^2 = 0.8692$, $F = 33.23$, S.E. $= 0.6284$, LOO-Rcv$^2 = 0.8295$

$$\log K_{AW} = 0.0207 \times V_M - 2.3439 \quad (22)$$

with $n = 7$, $r^2 = 0.8223$, $F = 23.13$, S.E. $= 0.7325$, LOO-Rcv$^2 = 0.7583$

$$\log K_{AW} = 0.0133 \times TSA - 2.4051 \quad (23)$$

with $n = 7$, $r^2 = 0.8103$, $F = 21.35$, S.E. $= 0.7568$, LOO-Rcv$^2 = 0.7493$

Eq. (21) is chosen as the best of these models because it has the highest r^2 (0.8692) and LOO-Rcv^2 (0.8295), as well as the smallest S.E. (0.6284). Calculated K_{AW} values (Ext-Cal. log K_{AW}) are given in Table S5 of the Supplementary information.

3.5. Octanol/air partition coefficient

The octanol/air partition coefficient is a key property when assessing partitioning between the atmosphere and organic phases, such as for organic films on aerosols, organic carbon in soil, the waxy cuticle and lipid portions of vegetation (Ding and Peijnenburg, 2013). However, application of K_{OA} is based on the assumption that interactions between organic chemicals and environmental organic phases closely resemble the interaction between the chemical and octanol (Wania et al., 2002). Shoeib et al. (2004) measured K_{OA} for methyl perfluorooctane sulfonamidoethanol (MeFOSE), EtFOSE and methyl perfluorooctane sulfonamidethylacrylate (MeFOSEA) using a modified generator column method at different temperatures. Goss et al. (2006) estimated K_{OA} of FTOHs as a function of temperature using the identical method. Since then, Thuens et al. (2008) agreed with K_{OA} values for FTOHs published by Goss et al. (2006). Dreyer et al. (2009) determined K_{OA} of methyl perfluorooctane sulfonamide (MeFOSA), ethylperfluorooctane sulfonamide (EtFOSA), MeFOSE and EtFOSE. In our study, K_{OA} data for FASAs and FTOHs are obtained from Shoeib et al. (2004), Goss et al. (2006) and Dreyer et al. (2009). However, log K_{OA} values for PFCA and PFSA are limited, and the QSPR model has never been applied to estimate K_{OA} of all PFASs. Based on Ext-Sel. log K_{OA}, correlation equations with F_N, V_M and TSA were obtained (Fig. 1, Supplementary information Table S6);

$$\log K_{OA} = 0.2234 \times F_N + 2.8150 \quad (24)$$

with $n = 8$, $r^2 = 0.5537$, $F = 7.44$, S.E. $= 0.6447$, LOO-Rcv$^2 = 0.5114$

$$\log K_{OA} = 0.0129 \times V_M + 2.4847 \quad (25)$$

with $n = 8$, $r^2 = 0.8989$, $F = 53.36$, S.E. $= 0.3068$, LOO-Rcv$^2 = 0.8716$

$$\log K_{OA} = 0.0074 \times TSA + 2.7736 \quad (26)$$

with $n = 8$, $r^2 = 0.8485$, $F = 33.60$, S.E. $= 0.3756$, LOO-Rcv$^2 = 0.8133$

Of these correlations, Eq. (25) has the largest r^2 (0.8989) and LOO-Rcv^2 (0.8716), as well as the smallest S.E. (0.3068). Calculated K_{OA} (Ext-Cal log K_{OA}) values from this model are provided in Table S6 of the Supplementary information.

3.6. Reliability based on fundamental thermodynamic relationships

Internal consistency of all Ext-Cal. data was evaluated through fundamental thermodynamic relationships. For reliability or

KD2165

uncertainty of all Ext-Cal. values, uncertainty factors of 1 and 4 were assigned to the K_{OW} model and S_w model respectively. The K_{AW} model was assigned an uncertainty factor of 3. Other properties were given an uncertainty factor of 2. The adjusted experimental property data (Ext-Adj. data) based on these uncertainty factors are listed in Supplementary information, Table S7. The Ext-Adj. property data are compared in Fig. 2 with Ext-Cal. property data to evaluate the accuracy of these proposed models for PFAS properties (Table S9 and S10 of the Supplementary information).

Of the PFASs, three classes, PFCAs, PFSAs and FTOHs, showed close linearity between Ext-Adj. data and Ext-Cal. data for all properties of interest (i.e., P_L, S_L, K_{OW}, K_{AW} and K_{OA}). In the case of

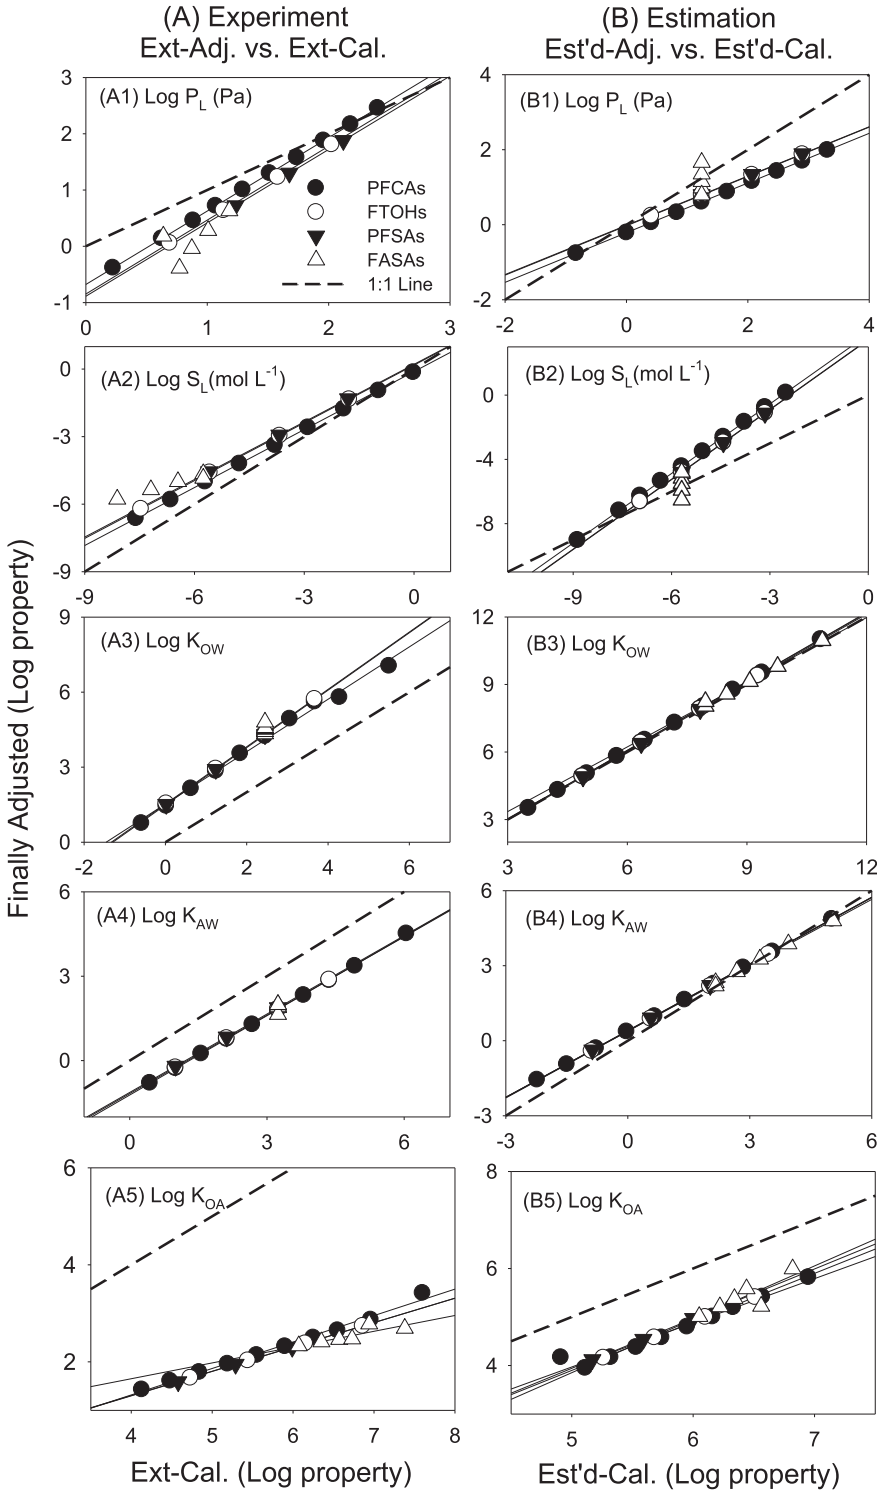

Fig. 2. Relationship between finally adjusted properties and calculated properties of PFASs (PFSA, PFCA, FASA and FTOH) from experimental and estimated data. Calculated properties were obtained by single descriptor model, selected based on statistical results. Adjusted properties were obtained based on fundamental thermodynamic relationships (Beyer et al., 2002).

KD2166

FASAs, except for log P_L, log S_L and log K_{OA}, the Ext-Adj. data and the Ext-Cal. data for FASAs (MeFOSA, EtFOSA, EtFOSE, MeFOSE and MeFOSEA) are not described well by linear fits (Fig. 2). The different trend of the dependence of FASAs on K_{OW} and K_{AW} could arise from either: (i) The proposed model related to the molecular descriptor or (ii) Faulty adjusted property values.

In order to determine the reason for this FASA lack of agreement between Ext-Adj. data and Ext-Cal. data, the Est'd-Cal. data from available property models obtained from estimated property data

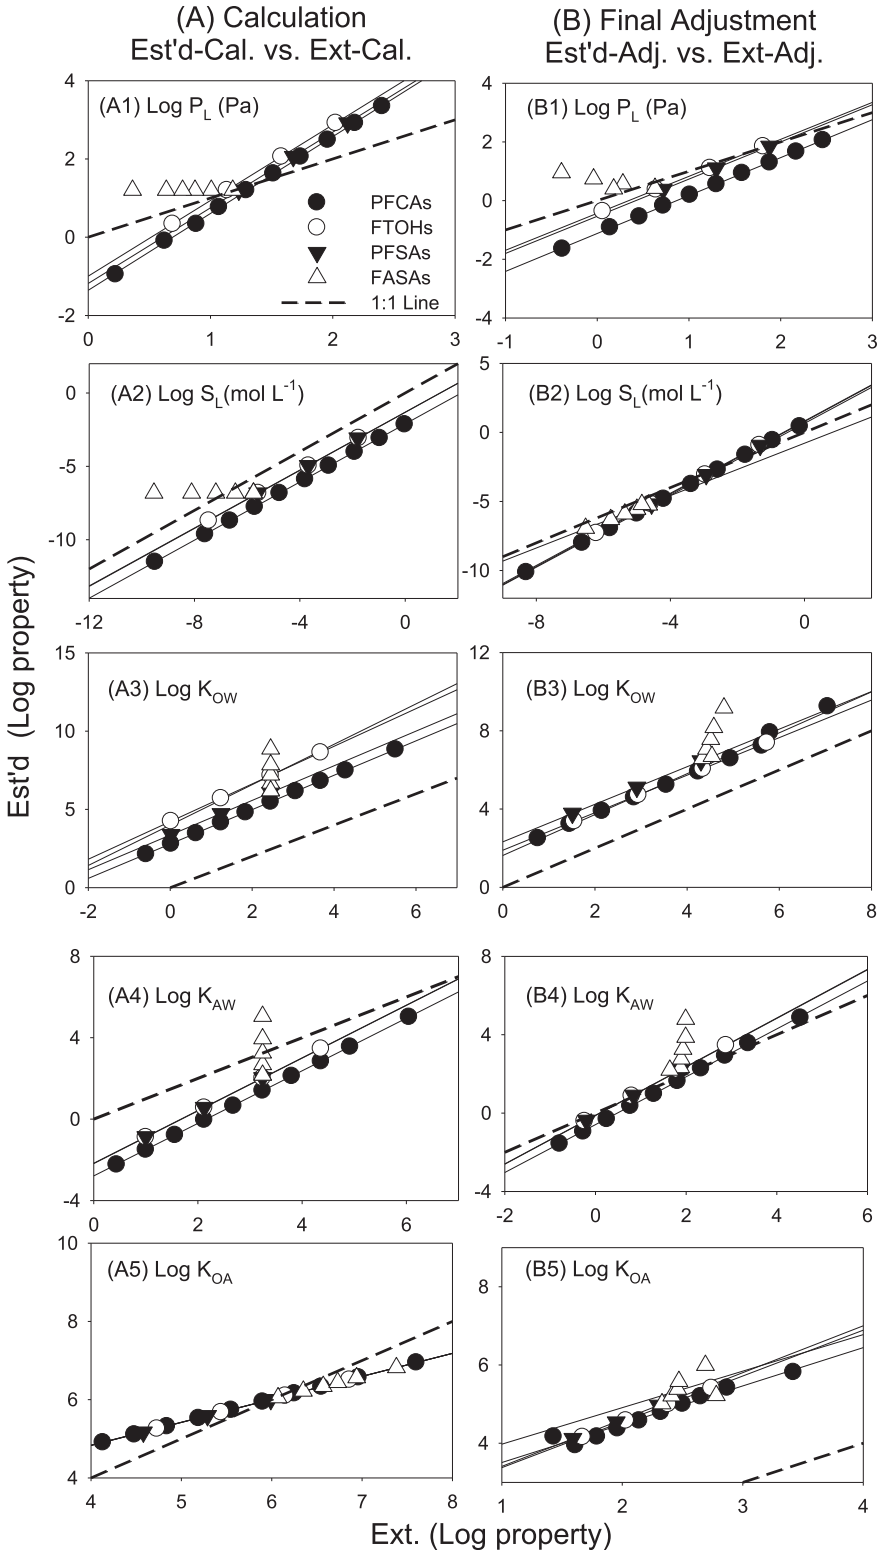

Fig. 3. Comparison of relationship between experimental calculated data and estimated calculated data ((A) Ext-Cal. vs. Est'd-Cal.) and that between finally adjusted experimental data and finally adjusted estimated data ((B) Ext-Adj. vs. Est'd-Adj.).

KD2167

Table 2
Quantitative structure property relationships between logarithm of properties (298 K and 760 mmHg) and molar volume (V_M, $cm^3\ mol^{-1}$) for PFASs.

Property	Single molecular model	r^2
Vapor pressure (P_L)	$\log (P_L/Pa) = -0.0081 \times V_M + 3.4361$	0.8981
Water solubility (S_L)	$\log (S_L/mol\ L^{-1}) = -0.0288 \times V_M + 3.0364$	0.7229
Octanol/water partition coefficient (K_{OW})	$\log K_{OW} = 0.0220 \times V_M - 3.4264$	0.9768
Air/water partition coefficient (K_{AW})	$\log K_{AW} = 0.0207 \times V_M - 2.3439$	0.8223
Octanol/air partition coefficient (K_{OA})	$\log K_{OA} = 0.0129 \times V_M + 2.4847$	0.8989

(Est'd-Sel. data) are compared with adjusted estimation data (Est'd-Adj. data) based on the identical procedure. The Est'd.-Cal data and Est'd-Adj. data sets are compared in Fig. 2. The degree of linearity between the Est'd-Adj. log data and Est'd-Cal. log data for FASAs differs significantly from that of the Ext-Adj. data and Ext-Cal. data. log P_L and log S_L do not show a linear relationship. The results suggest that non-linear relationships of the properties are driven by the proposed model with F_N because the FASA family consists of an eight-carbon backbone, fully surrounded by ten fluorines and a terminal sulfonamide functional group. Therefore, although the F_N descriptor model displayed good statistical results, this descriptor model cannot distinguish among PFASs with the same number of fluorines (i.e., FASA).

The relationship between Ext-Cal. data and Est'd-Cal. data is compared with that of Ext-Adj. data and Est'd-Adj. data in Fig. 3. The correlation equations and statistical results for each relationship appear in Tables S11 and S12 of the Supplementary information. Except for FASAs data obtained from the F_N molecular descriptor models, the correlation coefficient of the log–log linear relationship between two sets (i.e., Ext-Cal. data and Est'd-Cal) of data was >0.83. However, linear relationships differ from the ideal relationship (1:1 Line). This could be due to different methods of estimation and unmatching experimental conditions.

The relationship between Ext-Adj. data and Est'd-Adj. data (Ext-Cal. data and Est'd-Cal. data) for FASA tends to be non-linear when the Ext-Cal. data or Est'd-Cal. FASA data are obtained from the F_N molecular descriptor models, indicating that the non-linearity between Ext-Adj. data and Est'd-Adj. data for FASA is driven by faulty Ext-Cal. data and Est'd-Cal. data from the F_N descriptor model. Thus, it is clear that this F_N model, which is constitutional descriptor model derived from fluorine atom composition, is not very accurate for prediction. Meanwhile, V_M and TSA, which are geometric descriptors derived from 3-D structures, are highly correlated with the properties of PFASs (PFCA, PFSA, FASA and FTOH). V_M and TSA have been used mostly as bulk/cavity terms. There is no unique way to define V_M or TSA, but most approaches try to define a surface contour similar to the van der Waals volume. Therefore, V_M and TSA have often been used in QSPR studies to model molecular properties (e.g., Shiu et al., 1988; Valvani et al., 1976). In order to obtain reasonable estimates of the experimental properties for PFASs, simple QSPRs are suggested on the basis of V_M for the PFASs, including the same number of fluorine atoms because, setting aside the F_N descriptor models, models based on V_M are statistically better than those based on TSA. Hence V_M is the most important descriptor for QSPR of PFAS properties (Table 2). The calculated property values from the descriptor model based on V_M are given in Table 3.

4. Conclusion

To narrow physicochemical property data gaps, predictive models for P_L, S_L, K_{OW}, K_{AW} and K_{OA} of PFASs are developed based on molecular descriptors (F_N, V_M and TSA). Properties were calculated from single descriptor models selected by statistical results and checked for internal consistency. Each of these properties for PFCAs, PFSAs and FTOHs showed good linearity between finally adjusted properties and calculated properties.

On the other hand, log K_{OW} and log K_{AW} for FASAs do not show a linear relationship. The results were driven by the proposed model with F_N because the FASA families all consisted of an eight-carbon backbone fully surrounded by ten fluorines. It is indicated that although the F_N descriptor model provides good statistical results, this model cannot distinguish among PFASs with the same number of attached fluorines.

Setting aside the F_N descriptor models, models based on V_M were statistically better than those based on TSA. Therefore, in order to obtain reasonable estimates of experimental PFASs properties, simple QSPR models are suggested based on the V_M of the PFASs. As a result, more reliable properties and predictive models are provided to improve the ability to understand and predict the behavior and fate of PFASs in the environment.

ACCESS | Metrics & More | Article Recommendations

ABSTRACT: This commentary presents a scientific basis for managing as one chemical class the thousands of chemicals known as PFAS (per- and polyfluoroalkyl substances). The class includes perfluoroalkyl acids, perfluoroalkylether acids, and their precursors; fluoropolymers and perfluoropolyethers; and other PFAS. The basis for the class approach is presented in relation to their physicochemical, environmental, and toxicological properties. Specifically, the high persistence, accumulation potential, and/or hazards (known and potential) of PFAS studied to date warrant treating all PFAS as a single class. Examples are provided of how some PFAS are being regulated and how some businesses are avoiding all PFAS in their products and purchasing decisions. We conclude with options for how governments and industry can apply the class-based approach, emphasizing the importance of eliminating non-essential uses of PFAS, and further developing safer alternatives and methods to remove existing PFAS from the environment.

INTRODUCTION

When chemicals have similar molecular structures, environmental properties, and/or biological hazards, managing them as a class can be an effective means of reducing adverse effects on human and ecological health.[1−4] While a class-based approach to chemical management can pose challenges to the traditional paradigm of individual chemical risk assessment, the extreme persistence and potential for harm from thousands of PFAS (per- and polyfluoroalkyl substances)[5,6] demand a more efficient and effective approach. Examples of cases in which substances with common chemical characteristics are currently managed as a class include organophosphate pesticides, organochlorine pesticides, and organohalogen flame retardants.[1,7] Thus, a class-based approach not only is feasible but also has already been implemented by regulatory agencies globally.

Here we provide scientific justification for why a class-based approach is appropriate and necessary for all PFAS, defined as chemicals with at least one aliphatic perfluorocarbon moiety (e.g., -C_nF_{2n}-).[5,6] We discuss the following major subclasses of PFAS in detail: perfluoroalkyl acids and perfluoroalkylether acids (together termed PFAA) and their precursors, fluoropolymers and perfluoropolyethers, and other (primarily less reactive) PFAS (see Figure 1 for examples). PFAA are nonpolymer PFAS with at least one perfluorocarbon moiety (e.g., -CF_2-, >CF-) directly linked to an acid functional group. The most well-known are perfluorooctanesulfonic acid (PFOS) and perfluorooctanoic acid (PFOA). Many other PFAS may transform and yield PFAA in the environment and biota and are thus regarded as precursors to PFAA. Examples are PFAS derived from fluorotelomers and perfluoroalkanesulfonyl fluorides, including so-called side-chain-fluorinated polymers (i.e., polymers with nonfluorinated backbones and fluorinated side chains). Fluoropolymers and perfluoropolyethers include polymers with backbones being per- or polyfluorinated. Other PFAS in the class include primarily nonpolymeric PFAS with limited chemical reactivity, such as linear and cyclic perfluoroalkanes, perfluoroalkylethers, and perfluoroalkyl amines.

PFAS function in many capacities, including as surfactants, friction reducers, and repellents of water, dirt, and oil. As such, they are used in a wide variety of consumer products to confer nonstick (waterproof, greaseproof, and stainproof) and low-friction properties. Examples of products that contain or are coated with PFAS include carpets, glass, paper, clothing and other textiles, plastic articles, cookware, food packaging, electronics, and personal care products. PFAS are also used directly or as technical aids (dispersants and emulsifiers) in many industrial applications, such as in metal coatings, lubricants for machinery, membranes, and firefighting foams. PFAS are used in the synthesis of or as adjuvants in pesticides,

in medical procedures and products, and in many other applications.[8]

The most consistent feature within the class of PFAS is that their perfluorocarbon moieties do not break down, or do so very slowly under natural conditions, which is why PFAS are often termed "forever chemicals".[9] Because PFAS are persistent, they accumulate or concentrate in the environment, including water, air, sediment, soil, and plants.[10] Elevated levels of PFAS and their widespread presence in environmental media and drinking water stem from industrial sites that produce or use PFAS (or have done so in the past), airports, military bases (fire-training and response areas), landfills, wastewater treatment plants, and the spreading of PFAS-contaminated biosolids.[11−13] Some PFAS are highly mobile in either air or water, allowing them to travel long distances from their source.

Environmental and human exposure to PFAS can occur throughout the life cycles of these chemicals and products containing them, including during chemical production, product manufacturing, distribution, use, disposal, and recycling. Many PFAS, particularly PFAA, have been detected globally and are in the bodies of nearly all people living in the United States (US), Europe, and other countries worldwide.[14,15] Major sources of human exposure to PFAS are from contaminated food, water, air, and other media such as consumer products and house dust.[16,17] Limited testing of primarily large public water sources in the US found PFAS in the water supplies serving an estimated 16.5 million people, including 6 million with a combined PFOS and PFOA concentration over the US EPA's lifetime health advisory of 70 ng/L.[11] More recent testing of 25 public water systems in the US identified PFAS in every one, with an average of nearly 10 different PFAS at a combined concentration near 20 ng/L.[18] Such testing is lacking in many other parts of the world, including many European countries. PFAS are also found in a variety of foods.[19,20] The highest levels are found in fish and shellfish, but meat, eggs, and milk may also contain PFAS if animals have consumed contaminated feed or water. Fruits and vegetables have been shown to contain PFAS taken up from the soil and water used to grow them.[21] Food contact materials are another source of exposure,[22,23] as are consumer products and house dust.[24−28]

Exposure to PFAS occurs in complex mixtures of multiple PFAS, yet at present, fewer than 50 individual PFAS (often fewer than 10) are commonly measured in environmental media.[29,30] New analytical methods allow for more comprehensive screening such as measuring total fluorine or extractable/adsorbable organofluorine in the environment,[31−33] products,[22,23,34,35] dust,[27] biota,[36] and humans.[37] These methods reveal evidence that humans and wildlife are exposed to more PFAS than previously estimated. For example, in one study of tap water in five US cities, less than half the total organic fluorine measured in treated drinking water was accounted for by the sum of individually identified PFAS, indicating far more PFAS and other organofluorine com-

pounds were present in the water than were identified with targeted analysis.[38]

The most well-studied of these substances, PFOA and PFOS, have been linked to a variety of health problems. They are termed "long-chain" PFAS, a designation that includes perfluoroalkylcarboxylic acids (PFCA) with seven or more fluorinated carbons, perfluoroalkanesulfonic acids (PFSA) with six or more fluorinated carbons, and their precursors. When some major manufacturers phased out the production of long-chain PFAS, most industries turned to structurally similar replacements, including homologues with fewer fluorinated carbons (short-chain PFAS) or other less well known PFAS (e.g., per- and polyfluoroalkylether-based substances).[39,40] These replacement PFAS were marketed by producers as safer alternatives because of their presumed lower toxicity and lower level of bioaccumulation in human blood.[41] However, several lines of evidence suggest that short-chain PFAS are not safer alternatives. Research has demonstrated that short-chain PFAS can be equally environmentally persistent and are even more mobile in the environment and more difficult to remove from drinking water than long-chain PFAS.[33,42,43] Bioaccumulation of some short-chain PFAS occurs in humans and animals,[44−46] and research in fish suggests they can do so in excess of the long-chain compounds they aimed to replace.[47,48] Short-chain PFAS also can be more effectively taken up by plants.[49−51] Because short-chain PFAS have, to a large extent, replaced the long-chain PFAS in commerce, the levels of short-chain PFAS, such as perfluorobutanoic acid (PFBA), perfluorobutanesulfonic acid (PFBS), and perfluorohexanoic acid (PFHxA), have increased in environmental media.[37,43,52,53] To date, relatively little is known about possible health effects of long-term exposure to short-chain PFAS. However, a growing body of evidence suggests they are associated with similar adverse toxicological effects as long-chain PFAS.[54−57] The ongoing accumulation of persistent chemicals that are known or potentially hazardous increases risks to human and environmental health over an indefinite period of time.

Fluoropolymers consist of molecular segments (monomers) that are linked together, with up to hundreds of thousands of linked monomers in high-molecular weight polymers. While they are commonly regarded as PFAS,[58] fluorochemical producers now argue that fluoropolymers should be separated from other PFAS for hazard assessment or regulatory purposes.[59] However, the production of fluoropolymers and perfluoropolyethers is responsible for extensive environmental PFAS contamination, including releases of both intentionally added PFAA processing aids and unintentional PFAS by-products.[13,43,60−65] It is estimated that the vast majority (~80%) of PFCA in the environment is from fluoropolymer manufacture and use.[60] Below, we discuss reasons why fluoropolymers and perfluoropolyethers should be included in the class approach to managing PFAS.

To date, managing the risk of PFAS has focused primarily on one chemical at a time, or a small group of PFAS. This approach has not been effective at controlling widespread exposure to this large group of chemicals with known and potential hazards. Below, we present scientific justification for managing PFAS as a single chemical class, and we suggest ways in which government and industry can reduce PFAS-related risks. For example, a class-based approach can be implemented to more effectively eliminate non-essential uses of PFAS, develop safer alternatives, and clean up highly contaminated areas. Ultimately, this will reduce and prevent further accumulation of these hazardous chemicals in people and the environment and avoid replacing them with other related and harmful substances.

HEALTH AND ENVIRONMENTAL HAZARDS

With regard to biological activity and the potential for human health impacts, PFAA, particularly PFOA and PFOS, are the most well studied PFAS. Data from toxicokinetic studies of PFAA indicate that they are generally well-absorbed after ingestion.[66] After absorption, they distribute from blood to organs and tissues that receive high blood flow, such as the liver, kidney, lung, heart, skin, testis, brain, bone, and spleen.[46,66−70] Because PFAA can occupy sites on multiple receptors, proteins, and cell interfaces in the body, they can produce physiological effects across a range of tissues.[66] Toxicological (*in vitro* and *in vivo*) and epidemiological (in occupational, highly exposed, and general populations) studies have identified a broad range of adverse health outcomes associated with exposure to PFAA in people and animals. In studies of exposed humans, elevated blood levels of PFAA have been associated with kidney and testicular cancer, elevated cholesterol, liver disease, decreased fertility, thyroid problems, changes in hormone functioning, changes in the immune system, and adverse developmental effects.[54,71,72] Studies of experimental animals provide biological support for associations seen in human epidemiological studies, and mechanistic studies increase confidence in a causal relationship between PFAA and health effects in humans.[72,73] To understand the potential of every PFAS to adversely affect health would require testing across the entire range of different biological end points.

Effects on the immune system are some of the most well studied health effects of PFAA. Multiple lines of evidence support PFAA as immunotoxicants and, more specifically, immunosuppressants at small administered doses in rodents, and measured serum concentrations in humans. Findings of suppressed vaccine response in humans and T cell-dependent antibody response in experimental animals led the US National Toxicology Program (NTP) to classify PFOA and PFOS as presumed immune hazards to humans.[72] In a recent draft toxicological profile, the US Agency for Toxic Substances and Disease Registry (ATSDR) extended this finding to PFHxS and perfluorodecanoic acid (PFDeA), identifying all four compounds as suppressants of antibody response in humans.[54] These reviews provide strong evidence for immunotoxicity, especially when seen across multiple compounds, species, and studies. Notably, suppressed vaccine response in children indicates the period of early life as an exposure window of specific concern.[74,75] As such, developmental toxicity has been used as the basis for managing PFAS in drinking water and food contact materials.[76−80] Although the immune system, particularly during development, appears to be sensitive to these chemicals, few PFAS have been studied for such effects.

To date, a majority of human epidemiological studies have focused on long-chain PFAA. In experimental animal models, however, short-chain PFAA have shown effects similar to those of long-chain PFAA. For example, exposure to GenX has been associated with hepatic and renal effects[81,82] and suppressed immune function in mice.[83] A study of PFBA in rats indicated changes to liver weight, serum cholesterol, and thyroid hormones,[84] and a two-generation study of PFBS in rats demonstrated increased liver weight and pathological changes

Environ. Sci. Technol. Lett. 2020, 7, 532−543

KD2173

in kidneys.[85] Recent reports by NTP found that both PFBS and PFHxA had numerous adverse effects, including decreased thyroid hormones in male and female rats.[55,56] Effects on kidneys[86] and on reproduction and development[87] also have been reported for PFHxA. Notably, effects observed with other PFAA may occur at larger administered doses compared to the long-chain PFAA. However, humans are exposed to multiple PFAS at once, and there is little research to date on the effects of combined exposures. To account for such effects, an additive model for PFAS toxicity is used by the US EPA for two PFAS and in several US states for five to six PFAS. In Europe, an additive model is used by the European Food Safety Authority (EFSA) for four PFAS,[88] by the EU drinking water directive listing 20 PFAS, and by individual European countries, including Sweden and Denmark.

Some manufacturers have proposed that fluoropolymers should not be grouped with other PFAS for regulatory purposes, arguing that they are biologically inert because of their high molecular weight.[59] However, these chemicals can release low-molecular weight PFAS and other hazardous substances to the environment throughout their life cycle. Thus, we argue for the inclusion of fluoropolymers and perfluoropolyethers in the overall class approach for PFAS, specifically for the following reasons.

(1) During production of fluoropolymers and perfluoropolyethers, low-molecular weight PFAS used as raw materials, processing agents, or additives, or generated as intermediates, can be released into different waste streams (air and water) and current emission filters do not completely capture them, nor is there an effective means of disposing of captured PFAS.[13,89−91] For example, it was the production of fluoropolymers and the associated use and release of PFOA that led to the widespread contamination of the US mid-Ohio river valley and its residents.[92] In addition, potent greenhouse gases such as HFC-23 [trifluoromethane (CHF_3)] can be formed during fluoropolymer production, and emissions to the atmosphere have been reported.[93,94]

(2) During use, low-molecular weight PFAS may be released, for example, PFCA in personal care products that contain PTFE.[95]

(3) During disposal, PFAA and other hazardous byproducts may be generated and released, such as when they are incinerated at an insufficiently high temperature for insufficient time.[96−100] For example, when PTFE is heated above 350−400 °C, it decomposes and releases various gases that cause the so-called "Teflon fever" in workers.[101]

Other important considerations are that (1) some perfluoropolyethers (e.g., Krytox 157FS[102]) are mixtures of PFAA with molecular weights of only several thousand grams per mole and thus potentially biologically active; (2) in the EU and many other countries, substances registered as polymers can consist of fewer than 10 monomers, which are likely to be small and bioavailable molecules;[103] (3) fluorine is 19 times heavier than hydrogen, and therefore high-molecular weight PFAS can be relatively small molecules, compared to hydrocarbon molecules of the same weight; and (4) fluoropolymer microplastics contribute to global plastic and microplastics debris,[104,105] thus adding to ongoing environmental plastic and PFAS pollution.

Similar to fluoropolymers, other PFAS such as perfluoroalkanes and perfluoroalkylamines are generally inert,[106] but they can be very potent greenhouse gases, up to 3 orders of magnitude more potent than CO_2.[107−113]

In sum, scientific evidence supports the possibility that adverse effects of PFAS can occur in several bodily systems, with the developing immune system being particularly sensitive. Health effects have been demonstrated for several PFAS, including long- and short-chain PFAA, and chemicals associated with polymers. However, <1% of all PFAS have been tested for their hazardous effects. Proceeding with the approach of testing one chemical at a time will cause substantial delays in the effort to protect health and the environment from this large class of potentially hazardous chemicals.

■ ENVIRONMENTAL EXPOSURE: PERSISTENCE, ACCUMULATION, AND MOBILITY

An overarching property of all PFAS is that they have highly stable perfluorocarbon moieties in their molecular structure. Thus, all PFAS either are extremely persistent in the environment and biota or partially transform into extremely persistent PFAS.[114−117] Studies have estimated that PFAS such as perfluoroalkanes have lifetimes in the thousands of years.[113,118] Thus, PFAS will be present in the environment for centuries or longer, even if environmental releases cease immediately.

The high persistence of PFAS results in long-term accumulation in the environment and living organisms, which increases the risk of harm. A key concern in recent years is that some replacement PFAS, such as PFBA, PFBS, and GenX, have been widely detected in surface water and groundwater.[43,65,119] PFAS can concentrate in plants, including food crops, when grown in contaminated soil or irrigated with contaminated water.[20,120−122] Bioaccumulation occurs through the food chain, with top predators (e.g., whales, bald eagles, and humans) having the highest levels.[123−127] Most concerning is that when PFAS accumulate, they can reach concentrations where hazardous effects are observed in humans and ecosystems, particularly when the effects of combined exposure to multiple PFAS are considered.[128,129]

The high mobility of many PFAS further exacerbates the concern.[130] Many PFAS can travel long distances from their sources. PFAA, particularly short-chain types, are very water-soluble, being distributed readily in groundwater, surface waters, and the oceans.[53,131,132] They can be difficult, costly, and sometimes even impossible to remove from water with conventional and even advanced treatment processes.[13,43,133,134] Many other PFAS may be highly mobile in air, including the volatile perfluoroalkanes, fluorotelomer alcohols (FTOH), and many other (semi)volatile PFAA precursors.[116]

The extreme persistence of the fluorocarbon chain, combined with the propensity for accumulation and mobility of many PFAS, has resulted in PFAS being ubiquitous globally, even in remote regions like the Arctic.[36,53,135,136] The continued use of PFAS will result in increasing concentrations of PFAS, increasing numbers of exposed organisms,[137] and increasing probabilities of harm. Once adverse effects are identified, it will take decades, centuries, or even longer to reverse contamination and reduce the harm to our health and the environment.

■ MANAGING RISK

Risk management consists of various actions to minimize the chance of harm. Chemical risk management can be carried out

Downloaded from pubs.acs.org/estlcu/article-pdf/7/8/532/6699767/9/acs.estlett.0c00255.pdf by guest on 09 November 2026

KD2174

by governments and businesses and includes the cessation or restriction of production and use of the chemicals, and efforts to clean up contamination.

Regulatory Approaches. Many different regulatory frameworks are used for managing the risk of exposure to hazardous chemicals. While traditionally PFAS have been regulated one chemical at a time, subgroups of PFAS have also been regulated, with a focus on PFAA and their precursors.[79,138−142] An advantage of targeting chemical subgroups is that the toxicological end points are often assumed to be similar, which allows for extrapolation from well-studied chemicals to those less studied. However, assessing only small subgroups systematically ignores the majority of PFAS and underestimates the overall risk, particularly when many of the chemicals are unknown. For example, the EU drinking water directive, which addresses a relatively large subgroup, covers only 20 PFAS.[143]

Governments are increasingly using broader management approaches to control PFAS exposure, such as targeting all PFAS within certain use categories. For example, the US states of Maine and Washington banned all PFAS in food contact materials[144,145] and Denmark banned PFAS from paper and paperboard food packaging.[146,147] South Australia and Washington state (and other US states) enacted bans on PFAS in firefighting foam.[148,149] California has proposed to regulate any PFAS used in carpets and rugs.[150] In the case of drinking water, a "PFAS - Total" limit was recently adopted by the European Commission.[143] Regulatory agencies in Europe and the US are working to advance, validate, and standardize currently available methods to measure total PFAS in certain media.

A more comprehensive risk management approach that has been gaining traction is to limit the uses of hazardous chemicals to only those considered "essential", while fostering development of safer alternatives. In 1987, the Montreal Protocol defined essentiality (in the case of ozone-depleting chlorofluorocarbons) as being necessary for health or safety, or critical for the functioning of society, and without technically and economically feasible alternatives or substitutes that are acceptable from the standpoint of environment and health.[151] In the 2015 "Madrid Statement", more than 200 scientists advocated using a similar approach for PFAS, i.e., limiting the production and use of the entire class of PFAS, including polymers, to essential uses.[152] A more recent publication applied the essentiality concept to specific PFAS use categories and described examples of current PFAS-free alternatives, as well as uses where alternatives still need to be developed.[153] In 2019, several European countries committed to phasing out all non-essential uses of PFAS by 2030.[154] Limiting PFAS to essential uses would incentivize further development of alternatives that do not require fluorinated chemicals. Focusing on pollution prevention is critical because remediation of PFAS-impacted media, such as polluted groundwater aquifers, is costly, is energy-intensive, and cannot fully reverse the damage.

Managing PFAS as a class has additional benefits. It reduces the likelihood of replacing well-studied hazardous chemicals with poorly studied but structurally similar PFAS that have the potential to be similarly hazardous (i.e., "regrettable substitution"). It can be simpler and less expensive to implement: for example, for premarket regulation of uses for the entire class, for setting procurement standards, for testing for compliance and communicating test results through the supply chain, and for authorities monitoring the extent of PFAS contamination of humans, products, food, water, and the environment. Simpler, cheaper, class-based methods also typically result in more frequent testing, which improves compliance and detection of emerging risks. Methods to screen for fluorine already exist, for example, extractable organic fluorine methods coupled to combustion ion chromatography (EOF-CIC) and particle-induced γ-ray emission (PIGE).[23,155,156] Hence, focusing on risk management tools that address PFAS as a class has the potential not only to prevent pollution by known PFAS but also to prevent regrettable substitution, to improve the efficiency and effectiveness of chemical management, and to encourage the selection of treatment approaches that effectively reduce total PFAS exposure when remediating PFAS-contaminated sites.

Marketplace Approaches. Compared to governments, retailers and manufacturers can make more rapid changes to reduce their use of chemical classes of concern. For instance, home retailer IKEA committed to a complete phase-out of all PFAS in its textile products and reported achieving this goal as of 2016.[157] Recently, H&M, Danish COOP, and ChemSec's corporate initiative called to end the use of PFAS in products and the supply chain.[158] Numerous factors are encouraging companies to stop using the entire class of PFAS. Increasing demand for products containing fewer harmful chemicals is one driver. For example, demand from retailers for food contact materials, from textile brands for sportswear, or from large purchasers and green builders for carpets has resulted in safer PFAS-free products on the market. Pressure from environmental groups is another driver. One prominent campaign contributed to the decision of many apparel companies to eliminate PFAS in their textile treatments.[159] Companies' values can also play a role, such as when member-owned retailer COOP Denmark announced a phase-out of all PFAS-containing cosmetics "on the basis of a precautionary principle".[160] Similarly, Kaiser Permanente, Levi Strauss & Co., and Crate and Barrel are phasing out all PFAS based on the companies' environmental and health values.[3]

New international, national, state, and local regulations focusing on PFAS in certain products are additional influences,[150] as are threats of future litigation and liability.[161] While some companies may find it challenging to eliminate all PFAS from their products, others view it as important for mitigating business risks, or as a business opportunity. For example, treating PFAS as a class can help companies avoid multiple cycles of reformulations due to regrettable substitutions. Regulatory action addressing the class of PFAS will encourage further preventive actions from companies and help "level the playing field" by reducing the financial disadvantage of industry front-runners developing safer alternatives while incentivizing even further innovation toward safer alternatives.

■ OPTIONS MOVING FORWARD

Thousands of PFAS have already been documented across multiple industries and business sectors, and the list is growing.[5,6] Managing PFAS one by one is neither feasible nor cost-efficient. More comprehensive solutions are needed, given that traditional approaches have failed to control widespread exposures to PFAS and resulted in inadequate public health protection. For Europe alone, the annual health costs linked to exposure to just a few PFAS are estimated at 52−84 billion Euros, and environmental remediation costs at roughly 17 billion Euros.[162] Here we suggest class-based

Environ. Sci. Technol. Lett. 2020, 7, 532−543

KD2175

options to more comprehensively and efficiently reduce PFAS exposure.

Government policy makers have already begun limiting PFAS through bans in certain product categories. However, to more effectively manage PFAS, governments can apply the essential uses framework. Examples of essential and non-essential uses of PFAS have already begun to be described.[153] To make the criteria fully operational for inclusion in legislation, a more precise set of decision criteria is needed to guide the categorization. Such decisions involve both scientific and ethical considerations and thus require input from a broad set of scientists, civil society, industry, and policymakers.

Limiting the entire class of PFAS, including fluorinated polymers, to essential uses is critical, given that currently, remediating PFAS, once released to the environment, is at best extremely costly and, in some cases, impossible.[114,163] Governments can take a class-based approach to cleanup efforts, for example, by prioritizing research and development funding for treatment and disposal/destruction methods that are effective for the entire class of PFAS. Such an approach would ensure that treatment strategies remove all PFAS from all impacted environmental media (water, air, and soil) and that treatment residuals (for example, spent activated carbon and reverse osmosis concentrate) are managed such that the entire PFAS class is destroyed and its degradation products (or minerals) captured, so that unknown fluorinated reaction intermediates and harmful levels of organofluorines and hydrogen fluoride are not reintroduced into the environment. A class approach can also be used in developing cleanup standards, so that responsible industries are held accountable for remediation of all PFAS, not just a few. Additionally, governments can hold responsible parties accountable for exposure and health monitoring in heavily exposed populations, in order to promote effective and lasting solutions.

Regulatory agencies can also adopt class-based strategies to reduce exposure and minimize health risk. For example, they may extrapolate risk from well-understood PFAS when limiting uses of PFAS in commerce or setting protective cleanup levels. They can also assess combined exposures to PFAS (e.g., in drinking water, food, air, consumer products, and waste) as a basis to set regulatory limits and treatment standards. Establishing limits to the class rather than doing so on a chemical-by-chemical basis would result in lower exposure values that better protect vulnerable populations such as pregnant women, children, and workers. In addition, systems that can track historic, current, and future uses of all PFAS, and releases to the environment, could help to guide and prioritize monitoring, for instance, for emerging risk detection and compliance/enforcement testing. The further development, use, and interlaboratory standardization of analytical methods to measure total PFAS would complement this effort, improving the accuracy, speed, and cost of screening for PFAS in the environment, consumer products, and people. Collaboration within and across national and international policy and regulatory bodies to foster class-based strategies would be beneficial. Such concerted efforts could help prevent shifting burdens from one geographical location to another and may evolve into "de facto" industry standards as international actors attempt to minimize costs of complying with multiple different regulations.

Solutions are also available in the marketplace. Chemical manufacturers can move quickly to develop safer non-fluorinated alternatives for PFAS with current essential uses. They can also work with product manufacturers and businesses to rapidly replace all PFAS uses that have technically and economically feasible alternatives that are acceptable from the standpoint of environment and health. Chemical and product manufacturers can be transparent about the use of any PFAS chemistries in the supply chain and monitor and strictly control releases of all PFAS into the environment until their use can be phased out. In addition, PFAS manufacturers can assist in developing better methods to detect, remove, and destroy PFAS, although regulatory incentives or pressures may be needed.

The more we study PFAS, the more we learn about the harm they can do to our health and the environment. However, it is not possible to thoroughly assess every individual PFAS, or combination of PFAS, for their full range of effects in a reasonable time frame. Without effective risk management action around the entire class of PFAS, these chemicals will continue to accumulate and cause harm to human health and ecosystems for generations to come. As demonstrated above, managing PFAS as a class is scientifically sound, will provide business innovation opportunities, and will help protect our health and environment now and in the future.

Box Key Messages

1. Per- and polyfluoroalkyl substances (PFAS) make up a class of extremely persistent chemicals, numbering in the thousands, that accumulate in the environment and living organisms and can be highly mobile, leading to global contamination.
2. The use of PFAS in numerous consumer and industrial applications has led to widespread human and environmental exposure from, for example, drinking water, food, and consumer products.
3. Toxicological and epidemiological studies have identified a broad range of adverse health outcomes associated with exposure to PFAS in people and animals.
4. We suggest a class-based approach to managing the human and environmental risks associated with all PFAS, including polymers.
5. We provide options for how governments and industry can apply the class-based approach, emphasizing the importance of eliminating non-essential uses of PFAS, and further developing safer alternatives and methods to remove all existing PFAS from the environment.

ABSTRACT: The undisclosed and ubiquitous use of perfluoroalkyl and polyfluoroalkyl substances (PFAS) in consumer products has led to a growing issue of environmental pollution, particularly within the solid waste community, where the fate of volatile (neutral) PFAS in landfilled refuse is not well understood. Here, three municipal solid waste landfills in Florida were assessed for neutral PFAS in landfill gas and ionic PFAS in landfill leachate to compare the relative mobility between the two pathways. Landfill gas was directly sampled using a high volume, XAD-2 resin based sampling approach developed for adsorption and analysis of 27 neutral PFAS. Across sites, 13 neutral PFAS were identified from fluorotelomer alcohol (FTOH), fluorotelomer olefin (FTO), secondary FTOH, fluorotelomer acetate (FTOAc), and fluorotelomer methyl acrylate (FTMAc) classes; however, FTOHs dominated concentrations (87−97% total neutral PFAS), with most detections surpassing utilized calibration levels. Even under conservative assumptions, the mass of fluorine leaving in landfill gas (32−76%) was comparable to or greater than the mass leaving in landfill leachate (24−68%). These findings suggest that landfill gas, a less scrutinized byproduct, serves as a major pathway for the mobility of PFAS from landfills.

KEYWORDS: *volatile, emissions, GC, fluorotelomer alcohol*

1. INTRODUCTION

Widespread per- and polyfluoroalkyl substance (PFAS) contamination has been a mounting environmental concern due to their chemical persistence and toxicity to human and biotic health.[1−4] While numerous industries are being confronted with PFAS-related management challenges, the burden of remediation and PFAS removal has often fallen on downstream industries—namely, the solid waste sector.[5−9] Discarded, PFAS-laden consumer products including textiles, wood products, and packaging and commonly landfilled industrial byproducts like MSW incineration ash and wastewater biosolids are known contributors to PFAS loading in landfills.[10−16] Existing research suggests most discarded PFAS mass is retained within landfills[9,17] with liquid-phase byproducts of waste decomposition, leachate and gas condensate, currently considered prevalent pathways for PFAS mobilization.[2,7,9] However, the extent of PFAS release to another major byproduct, landfill gas (LFG), has remained largely unscrutinized.

The bulk of PFAS characterization studies focus on nonvolatile/semivolatile (ionic) perfluoroalkyl acids (PFAAs) measured in liquid and solid matrices, in part because of a high presence and awareness of these species within the PFAS community but largely because analytical capabilities for ionic PFAS measurement are better established.[18−21] Volatile (neutral) PFAS are also utilized in consumer products[13,22−27,27] and have been determined in a few studies on ambient air surrounding landfills and near wastewater treatment plants,[28−32] but a lack of volatile analytical standards and latency in methodological development has hindered the progression of gas phase research in environmental matrices. Whereas PFAS characterization in leachate is established, concentrations ranging from thousands to tens of thousands of nanograms per liter are commonly encountered;[33−38] only two studies characterize volatile PFAS directly in LFG.[39,40] Titaley et al. identified fluorotelomer alcohol (FTOH), fluorotelomer acrylate (FTAc) and fluorotelomer olefin (FTO) homologues in LFG with combined concentrations ranging from 4,600 to 14,000 ng m^{-3} across three landfills. Goukeh et al., only assessing FTOHs, identified higher combined concentrations than Titaley et al., finding ∼18,000 ng m^{-3} (sum of 6:2 and 8:2

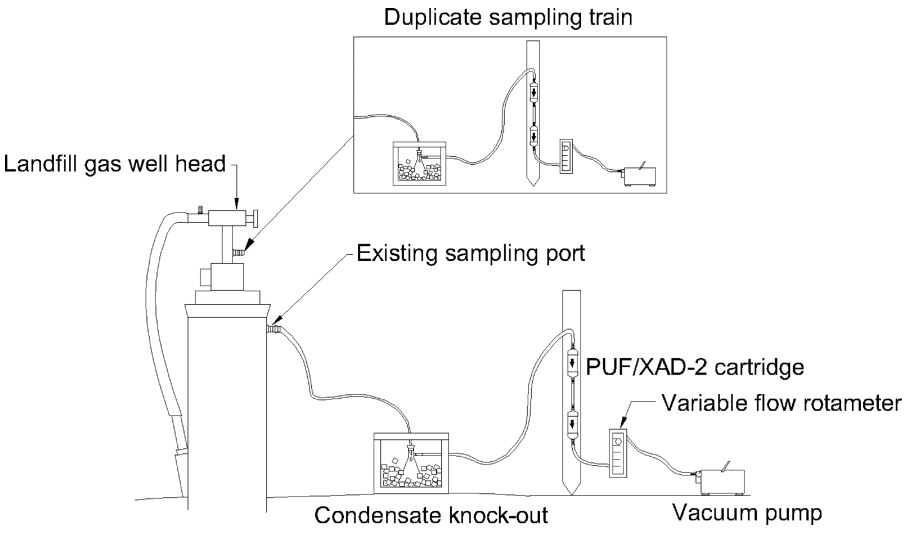

Figure 1. Developed system for sampling neutral PFAS directly from landfill gas well heads.

FTOH) in the one LFG sample examined. These studies suggest PFAS variability in LFG, which motivates further investigation, deploying higher sampling volumes[39] and larger analyte lists[40] to understand the potential presence of other neutral PFAS and distribution among landfills of different regions, compositions, and sizes.

With the ongoing development of PFAS regulation,[19] understanding the partitioning behavior of PFAS in major repositories like MSW landfills grows increasingly critical to minimize environmental and human risk. Unlike leachate, LFG is not always captured by collection systems, and management varies broadly across landfills, ranging from no treatment (i.e., passive venting) to some treatment (i.e., flaring, LFG to energy projects), but current treatment, if any, is not intended for PFAS.[41,42] Emerging research suggests the toxicity of volatile species (specifically 6:2 FTOH) to be significantly higher than their ionic counterparts via the inhalation pathway (a main route of exposure for volatile compounds).[43−47] Further, degradation of neutral species to ionic PFAAs once emitted to the atmosphere is well established.[48−58] The potential for long-range atmospheric transport of PFAS from landfills underscores the importance of considering neutral species and their fate during management to prevent further environmental contamination of highly scrutinized PFAAs such as perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS). As the only studies on LFG primarily identified FTOHs in LFG, the magnitude and significance of other neutral species remains unclear.

Here, LFG was sampled directly from gas well heads at three MSW landfill locations in Florida using a higher volume sampling protocol. XAD-2 resin sandwiched between polyurethane foam (PUF) was utilized for PFAS capture, then samples were analyzed for 27 volatile/semivolatile (neutral) PFAS via targeted gas chromatography high resolution mass spectrometry (GC-HRMS). To contextualize release in the gas phase, leachate was also collected at each landfill and analyzed for ionic PFAS (n = 93) using ultrahigh pressure liquid chromatography tandem mass spectrometry (UHPLC-MS/MS). The observed LFG and leachate concentrations were normalized on a mass of fluorine basis to compare the potential mobility in gas versus leachate matrices. This study provides foundational data critical for understanding the role of landfills in anthropogenic PFAS release and for informing LFG management.

2. METHODS AND MATERIALS

For brevity, materials and methods associated with ionic PFAS analysis in landfill leachate are provided in section 1 of the Supporting Information (Tables S-1 through S-4).

2.1. Standards and Reagents. Targeted neutral PFAS (≥97% purity, n = 27) were purchased from Wellington Laboratories Inc. (Guelph, ON, Canada), SynQuest Laboratories (Alachua, FL), and Chiron (Stiklestadveien, Trondheim, Norway). Nine classes of neutral PFAS (perfluoroalkane sulfonamides (FASAs), perfluoroalkane sulfonamidoethanols (FASEs), fluorotelomer acetates (FTOAcs), fluorotelomer methyl acrylates (FTMAcs), fluorotelomer iodides (FTIs), fluorotelomer secondary alcohols (sFTOHs), FTOHs, FTAcs, and FTOs) were measured using eight isotopically labeled internal standards (IS) from FASA, FASE, FTOH, and FTMAc classes for quantitation (Table S-5).

2.2. Sample Preparation and Collection. Polyvinyl chloride (PVC) cartridges filled with 4−5 g of Amberlite XAD-2 resin retained between two polyurethane foam (PUF) discs were utilized for PFAS capture.[29,59,60] Before use, XAD-2 sorbent was made PFAS-free through sequential Soxhlet extractions.[61] All cartridge components, sampling vessels, and tubing were sonicated in a mixture of Liquinox and PFAS-free water, rinsed, and then sonicated in methanol and methanol rinsed before use. Once dried and assembled, cartridges were stored in individually sealed polyethylene bags at 4 °C until sampling.

As neutral compounds were the focus of this investigation, aerosolized/particulate-bound PFAS were not specifically targeted for capture; however, a condensate collection system was included to prevent moisture interference. The developed sampling system (Figure 1) consisted of a condensate knockout (borosilicate, barbed Erlenmeyer flask contained in a cold box), two PUF/XAD-2 cartridges (installed in-series), a rotameter for flow control, a portable vacuum pump, and PFAS-free Tygon tubing. Before each sampling event, gas well head connection to the larger landfill gas collection system was disabled to create a neutral to positive pressure, workable for flow through the sampling system, then gas composition/

Table 1. Average Concentrations (n = 2) of 13 Neutral PFAS (ng m^{-3}) from Three Municipal Solid Waste Landfills in Florida (Site Characteristics Are Provided in Table S-9)[a]

	concentration (ng m^{-3})					
analyte	landfill 1	E	landfill 2	E	landfill 3	E
4:2 FTOH	220		ND		57	
6:2 FTOH	*>9,900*	**170,000**	*>6,000*	**22,000**	*>6,500*	**62,000**
8:2 FTOH	*>6,800*	**200,000**	*>6,000*	**140,000**	*>6,500*	**740,000**
10:2 FTOH	*>5,100*	**14,000**	*>3,000*	**23,000**	*>5,000*	**120,000**
12:2 FTOH	860		1,400		5,000	
5:2 sFTOH	*>2,900*	**8,800**	*>1,700*	**9,000**	*>1,900*	**5,900**
7:2 sFTOH	320		*>1,300*	**13,000**	*>1,400*	**11,000**
8:2 FTO	2,500		1,300		550	
10:2 FTO	650		840		540	
12:2 FTO	97		580		160	
8:2 FTOAc	610		90		490	
10:2 FTOAc	99		19		140	
6:2 FTMAc	3,800		56		150	

[a]Concentrations of 6:2, 8:2, and 12:2 FTOH and 5:2 and 7:2 sFTOH consistently exceeded the upper limit of developed calibration ranges; therefore, both a minimum concentration (assuming the highest calibration concentration) and a maximum extrapolated concentration are provided. Italicized values denote a minimum concentration. Column "E" presents average maximum concentrations. "ND" denotes non-detect measurements. FTAcs, FASAs, FASEs, FTIs, and 8:2 FTMAc were not detected in any samples. Analyte acronyms and details are provided in Table S-5.

temperature was recorded using an Optimax Biogas analyzer (MRU Instruments, Humble, TX). Duplicate sampling trains were connected to existing gas well sampling ports. Approximately 1,200 L was sampled through each train at a flow rate of 5 L min^{-1}. After sampling, PUF/XAD-2 cartridges were sealed and individually stored at ≤4 °C for transport/storage. Quality control (QC) procedures are provided in the SI, section 2.

2.3. Extraction and Analysis. Spent XAD-2 from each cartridge was weighed and transferred to a 50 mL polypropylene centrifuge tube and vortexed, and approximately 2 g aliquoted for extraction. Samples were spiked with a mixture of mass labeled IS (Table S-5), rotated end-over-end for 18 h in 4 mL of 75/25% (v/v) ethyl acetate and methanol, and centrifuged for 10 min at 4,000 rpm. Supernatants were transferred to 15 mL centrifuge tubes, and the extraction process was repeated, combining supernatants from the two-fold extraction. Extracts were concentrated to 3 mL via gentle nitrogen evaporation, aliquoted, and stored no more than 30 days at −20 °C until analysis. QC details are provided in the SI, section 2 (Table S-6 and Figure S-1).

Targeted analysis of 27 neutral PFAS by positive chemical ionization (PCI) with selected ion monitoring (SIM) was conducted using a Thermo Scientific TRACE 1310 gas chromatograph coupled to a Thermo Scientific Orbitrap Exploris GC 240 mass spectrometer (GC-HRMS; see SI, section 2 for details regarding GC separations and instrumentation). A 12-point external calibration curve (from 1 to 2,000 pg μL^{-1}) was developed for quantitation, prepared through serial gravimetrically derived dilutions of primary stock solutions. A mixture of mass labeled IS at concentrations of 150 pg μL^{-1} was added to each calibration level. When a labeled standard was not available for a compound, a labeled standard with a similar retention time or structure was utilized for quantitation (Table S-5).

3. RESULTS AND DISCUSSION

Unexpectedly, several neutral PFAS concentrations in LFG exceeded the implemented calibration levels. Because of considerable exceedance for some compounds, dilution would reduce IS below instrument detection; therefore, in instances where sample concentrations exceeded calibration limits, two concentrations are presented (Equation S-1): a minimum value which assumes the highest calibration concentration and a maximum extrapolated concentration. Fluorine mass release calculations utilize minimum values, preventing overextrapolation while providing a conservative estimate for leachate comparison. Even under these assumptions, substantial concentrations of neutral PFAS, higher than those previously observed, were identified. Future assessments should deploy shorter sampling durations to refine findings.

3.1. Neutral PFAS in Landfill Gas. Except for 4:2 FTOH in one landfill, 13 PFAS were detected in duplicate samples across the three sites (site characteristics are provided in Table S-9). Observed concentrations are displayed in Table 1. At minimum, combined concentrations of neutral PFAS in LFG ranged from 22,000 to 33,000 ng m^{-3}. Considering extrapolated values, total concentrations ranged from 210,000 to 940,000 ng m^{-3}, an order of magnitude higher than those previously reported in LFG.[39]

3.1.1. FTOHs and sFTOHs in Landfill Gas. Like previous studies on LFG and air surrounding landfills, FTOHs dominated neutral PFAS concentrations;[28,31,32,39,40] however, extrapolated concentrations in this study surpassed previous reports in LFG, in some cases by 2 orders of magnitude, and were more comparable (although much lower) to concentrations recently identified in soil vapor near a PFAS manufacturing facility.[55] While there are uncertainties given the degree of extrapolation, the magnitude of FTOHs found in this study compared to existing research suggests fundamental differences potentially related to sampling methodology (e.g., much larger sampling volumes) and/or sampled landfill characteristics (e.g., waste type, age, air intrusion), although these data were not available for comparison. Across the three sites, 6:2, 8:2, and 10:2 FTOH, combined, made up 87 to 97% of total concentrations, but 8:2 FTOH alone constituted 50 to 79%. The shortest and longest analyzed homologues, 4:2 and

KD2185

Downloaded from pubs.acs.org/estlcu/article-pdf/11/7/730/3156488/ez4c00364.pdf by JOHN JAY COLG OF CRIMINAL JUSTICE user on 12 November 2026

12:2 FTOH, were significantly lower in concentration (Table S-10). This is supported by previous FTOH distributions determined from source fluoro-telomer polymers[62] and observations in LFG, urban air, and air surrounding wastewater treatment/landfill sites.[28−31,39,40,63] Concentrations of 12:2 FTOH were of similar magnitude to those in Titaley et al., but 4:2 FTOH has not been detected in LFG, suggesting MSW landfills to be a previously unidentified potential source of atmospheric 4:2 FTOH.[39]

Secondary FTOHs have not been targeted in gas-phase landfill research but have been identified in condensate associated with LFG collection systems.[37] As intermediary byproducts of 6:2 and 8:2 FTOH biodegradation to PFAAs, 5:2 and 7:2 sFTOH, were unsurprisingly elevated, they were at least an order of magnitude lower than respective parent FTOH homologues.[64−66] All detections of 5:2 sFTOH and two out of three detections of 7:2 sFTOH were above calibration, combined sums attributed to 2 to 10% of total concentrations.

3.1.2. Other Neutral PFAS in Landfill Gas. Other neutral PFAS fell within acceptable calibration ranges and together accounted for 0.22 to 1.9% of total concentrations. FTO homologues have been encountered in other LFG and ambient air studies, but in past assessments 8:2 and 10:2 FTO were below limits of quantitation and 12:2 FTO concentrations were consistently an order of magnitude higher than those reported here.[39,59] To the authors' knowledge, 8:2 and 10:2 FTOAc and 6:2 FTMAc have not been determined in LFG. FTOAcs are not commonly assessed analytes but are associated with fluoropolymer textile treatments and have been identified in one indoor air study from Japan.[67,68] Similarly, 6:2 FTMAc has only been analyzed in a few studies on cosmetics and wastewaters but at lower concentrations.[69−71]

3.2. Comparative Fluorine Mass Release between Landfill Byproducts. Normalizing PFAS concentrations on a fluorine basis allows comparisons to be drawn between different matrices and PFAS types (e.g., gas−liquid, neutral−ionic, precursor−terminal). This methodology is widely used to assess the "mass balance" of PFAS within systems, given that the long-term environmental fate of measurable PFAS is transient, whereas the mass of fluorine is conserved.[17,72,73]

Here, the same approach is utilized to compare the PFAS mobility in leachate versus LFG pathways. Neutral (Table 1, minimum values) and ionic (Table S-4) PFAS concentrations in LFG and leachate from this study were individually normalized to a mass of fluorine (Equation S-2) using compound specific fluorine mass fractions (Table S-8). Summed fluorine masses in leachate and LFG were then scaled according to site-specific annual generation volumes reported for each landfill (Table S-9).[41] A caveat of this comparison is the absence of measurements for neutral species in leachate and ionic species in LFG; however, the literature suggests FTOHs (the dominant neutral class identified) predominantly exist in the gaseous phase, while PFAAs exist in liquid or particulate phases.[28,74] Subsequent research should assess neutral and ionic compounds in both matrices to validate findings and further elucidate the PFAS behavior in landfills.

Even utilizing minimum concentrations observed in LFG, equal magnitudes of fluorine release are observed between LFG and leachate at each site (Figure 2)—contrasting from existing estimates of PFAS mass flow from landfills.[9] Existing

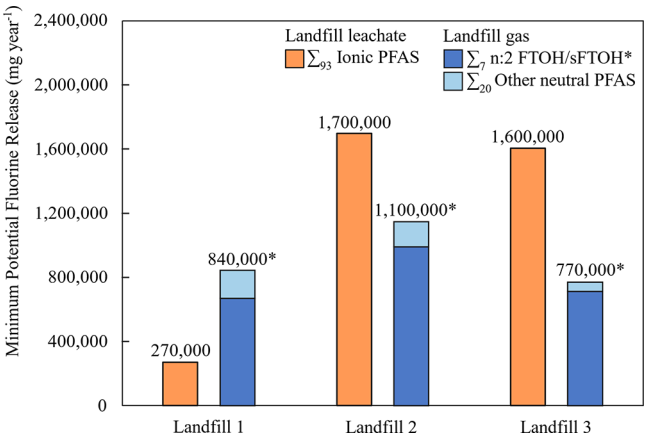

Figure 2. Annual fluorine mass release in landfill leachate versus landfill gas (LFG) from three municipal solid waste landfills in Florida. Fluorine masses in leachate are derived from ionic PFAS ($\sum_{93}$ PFAS) concentrations measured in leachate from each site (Table S-4) multiplied by the annual leachate generation volume and scaled using each detected compound's fluorine mass fraction (Tables S-8, S-9). The same methodology was applied for neutral PFAS ($\sum_{27}$ PFAS) in LFG by using the average of minimum concentrations (Table 1). Asterisked (*) values denote input FTOH/sFTOH concentrations which were above calibration levels developed for this study and therefore assumed to be at the highest calibration concentration. Consequently, these findings should be viewed as minimum values which conservatively estimate the magnitude of PFAS mobility in leachate versus LFG.

estimates, based on limited data, suggest that most PFAS mass mobilized from landfills releases through leachate (~62%).[9] However, our data from Landfill 1, showing over 76% fluorine release in LFG, along with substantial masses released by LFG in Landfills 2 and 3 (at minimum 40% and 32%, respectively), indicate that LFG may serve as an equal, likely greater, conduit of PFAS mobility from landfills than leachate, concurring with previous reactor studies on FTOH volatilization and neutral/ionic PFAS assessments of select waste materials.[17,75,76]

At least 79 to 92% of the fluorine mass in LFGs were derived from FTOH/sFTOH classes, with minimal contribution from FTOs, FTOAcs, and FTMAcs. In this conservative assessment, fluorine from LFG surpassed leachate in only Landfill 1. Although actual fluorine emission from LFG is higher than reported here, the elevated ratio of gas-to-leachate generation at Landfill 1 likely caused this difference (Table S-9). Landfill 2, the largest site, demonstrated the highest combined fluorine release from leachate and LFG, followed by Landfill 3, and then Landfill 1, corresponding to descending waste mass in place at each location.

4. IMPLICATIONS

This study provides fundamental data about neutral PFAS in LFG from MSW landfills. Unexpectedly, FTOH/sFTOH detections in LFG from this study exceeded implemented calibration levels; subsequent research should deploy shorter sampling durations. Regardless, even under more conservative assumptions these findings suggest that LFG, largely unscrutinized for PFAS, contains similar or greater magnitudes of PFAS compared to leachate, mostly attributed to midlength FTOH homologues. As landfills can be viewed as unabating PFAS repositories, the significance of LFG management in mitigating the long-term, long-range atmospheric transport of

neutral PFAS, and subsequently derived PFAAs, cannot be understated. Unlike landfill leachate, LFG collection systems (when in place) are not fully efficient, collecting an estimated ~50−70% of generated biogases.[77] Though this is a considerable collection efficiency of biogas and presumably neutral PFAS, management of captured LFG fractions varies globally, from no treatment to degrees of carbon filtration and thermal treatment (i.e., flaring, advanced renewable natural gas technologies). Because the feasibility of PFAS destruction through thermal treatment remains unclear, research is needed to determine the treatment/removal efficiency of existing LFG management technologies. Considering the range of LFG capture efficiency, the retention and emission of neutral PFAS via fugitive emissions (i.e., migration through the waste layer) should also be examined, along with the role of landfill waste type, age, and temperature in neutral PFAS variability.

LOGAN CITY COUNCIL

Technical Report

Loganholme Wastewater Treatment Plant:

Biosolids Gasification Demonstration Plant

(PBE-075)

March 2021

KD2191

Contents

EXECUTIVE SUMMARY **6**
1. INTRODUCTION **9**
1.1 Objectives 10
1.2 Components of the demonstration plant 10
2. SOURCE OF BIOSOLIDS **12**
2.1 Source 1 biosolids 12
2.2 Source 2 biosolids 13
2.3 Loganholme biosolids 13
2.4 Approvals process for movement of biosolids 14
2.5 COVID-19 15
3. RELIABILITY **16**
4. AIR EMISSIONS **20**
4.1 Background 20
4.2 Regulation requirements 20
4.3 Status of air pollution control equipment used for the demonstration plant 22
4.4 Stack emission results 22
4.5 Timeline 23
4.6 Summary of continuous stack monitoring results. 23
4.7 Full air emission results 35
5. BIOSOLIDS AND BIOCHAR CHARACTERISATION **42**
5.1 Biosolids analysis 42
5.2 Biochar analysis 45
6. EMERGING CONTAMINATES OF CONCERN **49**
6.1 Perfluoroalkyl substances 49
6.2 Loganholme and Beenleigh WWTP PFAS concentrations 53
6.3 Biochar and PFAS 54
6.4 Mass valance for PFAS 54
6.5 Microplastics 57
7. HEAT BALANCE **61**
7.1 Background 61
8. OPERATING COSTS **63**
8.1 Urea 63
8.2 Magnesium hydroxide 63
8.3 Diesel 64
8.4 Boiler shield 64

9. CONCLUSION 65

WESP	Wet Electrostatic Precipitator
w/w	Weight per weight

Executive Summary

Logan City Council, via the Logan Water Partnership, conducted the *Loganholme Wastewater Treatment Plant (WWTP) Gasification Demonstration Plant* that illustrates how to treat biosolids with gasification to produce a more environmentally friendly product, called biochar, and renewable energy while reducing the operation and maintenance costs of treating biosolids.

Gasification or carbonisation of biosolids produces biochar that is classified as a Grade A product. Gasification of biosolids destroys persistent organic pollutants (POPs), micro-plastics, and nano-plastics, while retaining phosphorus in a plant-available form. The final biochar product is sterile, does not generate odours, is not subject to a restricted storage time before application, and is easier to handle than the current biosolids form. Biochar also reduces the volume of biosolids (dewatered sludge cake) by more than 90%, requiring fewer truck movements and significantly reducing disposal volumes and costs.

Logan Water developed an industry-first demonstration facility at Loganholme Wastewater Treatment Plant (WWTP) to confirm that the production of biochar from biosolids is viable technology and that associated waste streams can meet the environmental license requirements. The overall project is split into two stages:

1. Stage 1: Demonstration plant designed to showcase both the technology process of gasification on dewatered sludge and its reliability for incorporation into a WWTP to assist obtaining all relevant approvals for the full-scale gasification facility.
2. Stage 2: Full-scale gasification facility will process sludge dewatering, drying and gasification at the Loganholme WWTP, including centrifuges, paddle dryers and gasifiers.

To approve the construction of Stage 2, the demonstration plant had five key objectives to validate or measure:

1. Reliability: to demonstrate reliable operation of the facility (see Section 3: Reliability)
2. Air emissions: to measure the air emissions from the facility and confirm compliance with Queensland regulations (see Section 4: Air emissions)
3. Persistent organic pollutants (POPs): to measure the quality of the biochar product and confirm the destruction of POPs (see Section 5: Biosolids and biochar characterisation and Section 6: Emerging contaminates of concern)
4. Heat balance: to confirm the heat balance for an integrated drying facility (see Section 7: Heat balance)
5. Operating costs: to assess operating costs of the facility (see Section 8: Operating costs).

Biosolids were sourced from two WWTP in Victoria (Source 1 and Source 2) for the demonstration plant as the gasification system requires a biomass that is 90% dry. In the full-scale facility, biosolids will be dewatered through centrifuges and then dried through belt dryers before being treated in the gasifier. In the demonstration plant, the sourced biosolids were from WWTPs that have waste activated sludge (WAS) that has been dried to 90% weight per weight (w/w) and then transported to the Loganholme WWTP.

In total, 12 runs of the demonstration plant were completed between 22 January and 11 August 2020. This consisted of small 4–6 hour runs ramping up to runs that were over 100 hours. The gasification plant had over 450 hours of run time on two sources of biosolids, demonstrating its reliability.

Reliability

Reliability is a major requirement for incorporating a permanent biosolids gasification facility at Loganholme WWTP. Loganholme WWTP is Logan City Council's (LCC) largest WWTP. In the future, Beenleigh WWTP could be diverted to Loganholme WWTP, which would mean that the WWTP will treat over 97% of LCC's wastewater network. The reliability of the demonstration plant was tested over two 100-hour trial runs, successfully processing biochar, and producing heat energy throughout these periods. The trial runs complied with the air emission limits set by the Logan City Council Environmental Authority (EA) (EPPR00867913). However, the trial runs were not completed at full operational threshold, as detailed in Section 3; throughput was reduced to ensure compliance with the requirements of the EA.

Air emissions

The requirements of air emission regulations in relation to the demonstration plant relate to emissions from the 7.1m stack. The stack allowed the discharge air/gas to mix and disperse quickly into the atmosphere, as well as allowing sampling and measuring of the quality. Most of the footprint of the demonstration plant is used to purify the off gas/biogas produced and for heat recovery. The demonstration plant was required to adhere to strict conditions as part of the EA Condition LGN-A2.

Two types of air emissions were monitored:

1. Basic air emissions: monitored on a continuous basis by the continuous emission monitoring systems (CEMS) unit for every run, including parameters for oxygen (O_2), nitrous oxide (NOx), carbon monoxide (CO), and oxidised Sulphur's (SOx).
2. Full air emissions: monitored by specialist samplers and equipment at times to measure all parameters required by the EA, including particulates, heavy metals and emerging contaminates of concern, such as per- and poly-fluoroalkyl substances (PFAS).

In summary, the air emissions passed most of the limits when an external NATA-accredited laboratory analysed the results. The only exceedance of the limits was the particulates for the second 100-hour test when the throughput was increased.

The CEMS unit concluded that the demonstration plant was unreliable, with condensate causing blockages; therefore, an additional monitoring unit was used throughout the trial period. The data from this second CEMS unit shows that the air emissions can be controlled when dosing magnesium hydroxide (MgOH2) to control SOx in the air stream and urea to control NOx. The levels of CO and particulates that occurred with increased throughput required modifications to the throughput; however, these modifications introduced complications with particulates. Solutions have been identified and outlined in Section 6 to ensure this issue will be engineered out in the full-scale facility design.

Persistent organic pollutants

Persistent organic pollutants (POPs) were a major driver for this demonstration plant, with the inclusion of PFAS into the Queensland Department of Environment and Science's (DES) *End of Waste Code for Biosolids* (DES, 2020). In the *End of Waste Code for Biosolids*, target limits have been set for soil application. The measurement of other POPs, such as microplastics, are under consideration and it is anticipated they will also be incorporated in some form into the *End of Waste Code for Biosolids* (DES, 2020).

Both sources of dried biosolids came from Victoria and contained PFAS limits that would have triggered the limits set for soil application. On average, Source 1 dried biosolids had a concentration of 0.173 mg/kg of PFOS and PFHxS. Source 2 dried biosolids had a concentration of 0.367mg/kg of PFOS and PFHxS, on average. The biochar produced from the demonstration plant had a concentration of <0.005 mg/kg of PFOS and PFHxS on average or were non-detectable. This means that the dried biosolids had PFAS that would not meet soil trigger values and, once processed through the gasifier, the biochar did not contain any PFAS. This shows that through the gasification process, the PFAS compounds are made volatile and are then treated through the oxidation process.

Microplastics are an emerging contaminant of concern and were analysed as part of the demonstration plant. Source 1 dried biosolids contained 8.8 particles/gram, on average. Once processed through the gasifier, the

biochar contained 3.3 particles/gram, or a 63% reduction of this contaminant. Source 2 dried biosolids contains 8.8 particle/gram on average. Once processed through the gasifier, the biochar contained 5.06 particles/gram, or a 43% reduction of this contaminant. This source material was small and dense because it was pelletised; however, in the full-scale facility design, the belt dryers will produce a more uniform crumb rather than a pellet. Therefore, it is expected that the destruction of microplastics will be greater when processed through the belt dryer than what was achieved with the Source 1 and Source 2 dried biosolids.

Heat balance

One of the main requirements of the demonstration plant trials was to confirm that sufficient heat could be produced for the permanent plant belt dryers. The heat recovery achieved was approximately 700kW at 85% of design rate, on the Source 2 dried biosolids. Scaling to 100% of the design rate (565 kg/hr) and 80% efficiency, the heat recovery is forecast to be greater than 1.1 MW, measured against a design requirement of 1 MW.

Operating costs

The main operational consumables and costs of the gasification facility include power, potable water, and chemical dosing. During the demonstration plant trials, the following consumables were monitored and optimised, where possible:

1. Chemical dosing for SOx control was initially via hydrated lime. Hydrated lime did not perform well and was replaced with Mg(OH)2 The dosing locations and rates were optimised throughout the trials, with the optimal dosing rate was determined to be 0.4% of the weight of dried biosolids processed, or about 2.6 litres per tonne.
2. Chemical dosing for NOx control was via urea. The dosing locations and rates were optimised throughout the trials and the optimal dosing rate was determined to be around 20 litres per tonne.
3. Potable water and power usage were both as expected.

The demonstration plant confirmed that gasification of biosolids is a reliable process that can be incorporated into a WWTP. Each of the objectives set for the demonstration plant in terms of reliability, air emissions, persistent organic pollutants, heat balance and operating costs were achieved.

Therefore, it is recommended to proceed with the full-scale facility at Loganholme WWTP.

1. Introduction

Biosolids treatment and disposal is a significant component of wastewater treatment plant operation and operating costs. In Australia, most biosolids are mechanically dewatered and disposed to land (land application) under programs aimed at 'beneficial re-use'. Biosolids are a source of organic material, nitrogen, and phosphorus; however, land application often requires dewatered biosolids to be transported long distances from metropolitan areas to farming areas. Transport is costly and impacts on communities via truck movements, fuel usage, fumes and odours, noise, and high greenhouse gas emissions.

In Queensland, land application of biosolids is regulated by the Department of Environment and Science (DES). The *End of Waste Code for Biosolids* (DES, 2020) require operators to meet stabilisation quality criteria and limits on land application uses and rates.

An emerging threat to existing practices of land application of biosolids is organic micro-pollutants and persistent organic pollutants (POPs). POPs are toxic chemicals that are not biodegradable and can accumulate up the food chain and within soils and within sludge produced by WWTP processes. Examples of POPs include polybrominated diphenyl esters (PBDEs), hexabromocyclododecane (HBCD), and perfluorooctanesulfonic acid (PFOS).

Another emerging issue for the land application of biosolids is microplastic and nanoplastic pollutants. These pollutants are shed during machine washing of certain fabrics such as those used to produce active wear. Plastic microfibres from the fabric enter the wastewater network. Where sewage is treated by activated sludge processes, the microfibres become enmeshed in the biosolids. These microfibres are not destroyed by anaerobic or aerobic digestion biosolid treatment processes. Consequently, there are concerns about the potential for these pollutants to enter the terrestrial food chain when biosolids are applied to land used for agricultural production.

While POPs and microplastic and nanoplastic pollutants are present in Australian biosolids, they are not listed as contaminants in Australian biosolids guidelines. In Europe, 50% of biosolids do not meet POPs limits set for land application. Switzerland and Germany have banned land application of biosolids, with incineration a more common practice of disposal (European Commission, 2008) (German Federal Environment Ministry, 2016). Many Australian biosolids would not meet the limits established in Europe. The Australian water industry is also not prepared for this threat to the land application of biosolids.

Logan City Council, via the Logan Water Partnership, has been investigating how to better treat biosolids to produce biochar a more environmentally friendly product, while reducing the operation and maintenance costs of treating biosolids. This work recommended treatment via gasification, with other upstream processes to obtain a biochar product and produce a renewable energy.

Thermally treating biosolids produces biochar, a Grade A pathogen product that meets the criteria set in the *End of Waste Code for Biosolids* (DES, 2020). Thermal treatment of biosolids destroys POPs, micro-plastics, and nano-plastics, while retaining phosphorus in a plant-available form. The final biochar product is sterile, does not generate odours, is not subject to a restricted storage time before application, and is easier to handle than the current biosolids form. Biochar also reduces the volume of biosolids (dewatered sludge cake) by more than 90%, requiring fewer truck movements and significantly reducing disposal volumes and costs.

Logan Water's industry-first demonstration plant confirmed that the production of biochar from biosolids is a viable technology and associated waste streams can meet the environmental regulations. Funding was made available for the Loganholme Wastewater Treatment Plant: Demonstration Biosolids Gasification Facility (demonstration plant) and the Loganholme WWTP Gasification Facility (full-scale).

1.1 Objectives

Five key objectives were set for the demonstration plant:

1. Reliability: to demonstrate reliable equipment operation
2. Air emissions: to measure the air emissions from the facility and confirm compliance with Queensland regulations
3. Persistent organic pollutants (POP): to measure the quality of the biochar product and confirm the destruction of POP
4. Heat balance: to confirm the heat balance for an integrated drying facility
5. Operating costs: to assess operating costs of the facility.

1.2 Components of the demonstration plant

Because the demonstration plant is a first of its kind in Australia, it was critical to demonstrate proof of concept using a sole supply of biosolids not a blend and therefore be able to move forward with the full-scale Loganholme WWTP Gasification facility.

The demonstration plant consists of eight key components that were part of Pyrocal's scope: dried biosolids feed system, hearth, biochar system, thermal oxidisers, heat recovery system, scrubber, air steam release and control room. Figure 1-1 illustrates these key components of the demonstration plant.

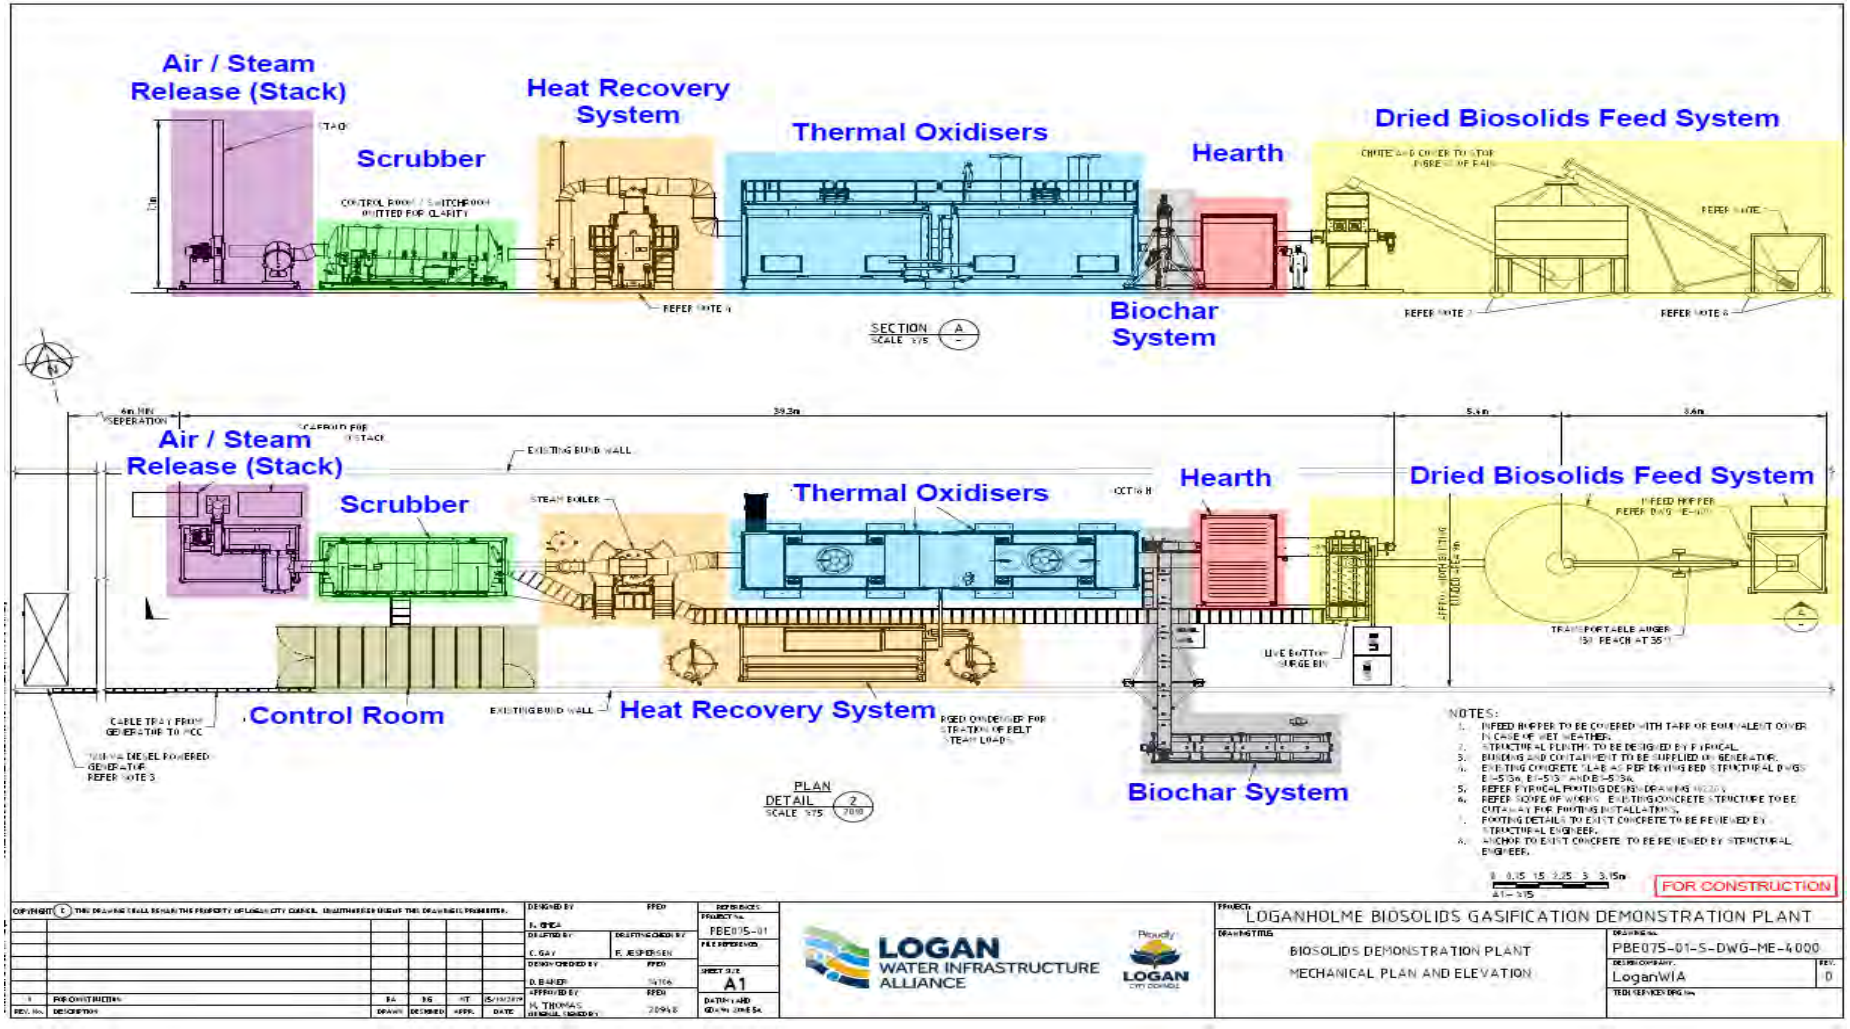

Figure 1-1: Key components of the Loganholme Wastewater Treatment Plant: Biosolids Gasification Demonstration Plant

2. Source of Biosolids

Biosolids were sourced from Victoria for the demonstration plant as the gasification hearth requires a biomass that is 90% dry. In the full-scale facility, biosolids will be dewatered through centrifuges and then dried through the belt dryers before being treated in the gasifier. In the demonstration plant, the sourced biosolids were from WWTPs that have waste-activated sludge (WAS) that has been dried to 90% w/w and then were transported to the Loganholme WWTP.

Two types of biosolids were processed in the demonstration plant. To de-identify the sources of these biosolids, throughout this chapter they are referred to as Source 1 and Source 2. This chapter details the biosolids from each source and outlines the approval process to move biosolids from Victoria to Queensland. The biochar produced that is available for beneficial reuse is also quantified.

Certain parameters of biosolids were required for the demonstration plant, as outlined in the Dryer Technology Review (LoganWIA, 2020; DT0007). These parameters include particle size, dust ratio, moisture content and volatile solids:

- The ideal particle size range for the carbonisation process gasifier unit is 3–10 mm
- Both regular and irregular particle shapes are acceptable
- Larger particles are also acceptable
- Concentration of fines/dust must comply with the specification for the carbonisation equipment that less than 2.5%, by mass, of dried particles must have an aerodynamic equivalent diameter below 3 mm.

2.1 Source 1 biosolids

The Source 1 facility uses a thermal sludge dryer to process waste. The sludge goes through a process of centrifuge, like the planned Loganholme WWTP full-scale design, through to a feed screw directly into the thermal dryer, which has a gas fired burner (up to 600 °C) that tumbles the product. The end-product is 90% dry biosolids. The biosolid are cooled in a water-cooled auger to 40 °C.

However, the biosolids from Source 1 are processed through a third-party and the batch of ~60T received was several months old and had degraded with a lower calorific value of volatile solid (VS) around 73% and moisture content of 85% dry. The particle size was less than 5mm, and this meant that the hearth had to be retrofitted to receive smaller particles, which in turn affected the airflow. Figure 2-1 shows the Source 1 biosolids.

Figure 2-1: Source 1 biosolids

Although the batch that was received did not fit the specific design parameters for particle size set for the gasification unit, these biosolids were still able to be processed and provide assurance that the hearth can be adapted to fit the performance of the dryer units. This created confidence that although technical specifications for the dryer have been set, slight variations to particle size and distribution can be adapted so that the gasification unit can process slightly irregular material.

2.2 Source 2 biosolids

Source 2 biosolids uses a drum dryer to produce a biosolid pellet that is >88% dry. The sludge is dewatered through belt presses and then is brushed on a series of heated revolving turntables. The heat treatment kills all micro-organisms, resulting in a small, pelletised product that is safe to handle. As shown in Figure 2-2, the biosolids were pellet sizes of around 8–10 mm, with a VS 81% and greater than 90% dry.

Figure 2-2: Source 2 biosolids—pelletised

The Source 2 biosolids granules were approximately ten times the size of the Source 1 biosolids. The size of the dry crumb produced by the belt dryers in the full-scale facility is expected to be between the size of the biosolids from Source 1 and Source 2, and similar to the Source 2 biosolids in terms of volatile solids and approximately 10% moisture. Table 2-1 shows the average calorific value of the biosolids from Source 2.

Table 2-1: Average calorific value of biosolids from Source 2

Calorific value	Unit	Source 2
Net	MJ/kg dry matte (DM)	19.26
Gross	MJ/kg (calc)	2.23

2.3 Loganholme biosolids

In the full-scale facility design, strict criteria have been set for the dryers, outlined in the Dryer Technology Review (LoganWIA, 2020; DT0007) report. However, the Eliquo Stultz low-temperature dryer is the preferred supplier because it can produce the biosolid to 88% w/w solids at a particle size between 3–10mm. Also, a low- temperature dryer allows hot water to be used rather than thermal oil, providing improved efficiency in the heat–energy balance and reduced long-term operational costs. Because the process in the Loganholme gasification facility will be continuous (8000 hours per year), there will not be issues with the source material degrading during storage as it will be immediately transferred between the belt dryers and gasification unit.

As noted, the gasifier works optimally with biosolids ranging from 3–10mm due to the design of the rotating plates within the hearth and the ability to gain as much energy as possible from the sludge (greater than 70% volatile solids). The design has been optimised from paddle dryers to belt dryers due to the high dust fraction produced by paddle dryers.

The calorific value or net energy value of biosolids from Loganholme and Beenleigh WWTPs are shown in Table 2-2. This compares favourably with the calorific value of the biosolids from Source 2.

Table 2-2: Average calorific value of biosolids from Loganholme and Beenleigh WWTPs

Calorific value	Unit	Loganholme WWTP	Beenleigh WWTP
Net	MJ/kg dry matter (DM)	18.80	18.4
Gross	MJ/kg (calc)	2.25	2.20

2.4 Approvals process for movement of biosolids

Transporting biosolids from Victoria has a lengthy approvals process, which was heightened with the COVID-19 pandemic. Figure 2-3 provides an overview of the process.

Loganholme WWTP

Environmental approvals issued by Department of Environment and Science (DES) (Queensland Environmental Protection Agency).

Loganholme WWTP has an Environmental Approval (EA EPP00867913).

The environmental authority includes ERA633 to conduct wastewater activity.

The license includes the prescribed ERA61-Waste incineration and thermal treatment.

Under ERA61, Loganholme WWTP can accept regulated waste, such as biosolids.

Consignment Authority

Department of Science—Waste Track team issue consignment authorities for prescribed waste such as biosolids.

Movement of biosolids interstate requires a consignment authority.

The Waste Track team check that:

- the waste transporter holds the appropriate license to transport regulated waste
- the waste generator material is not going to cause environmental harm—for example they will check the biosolids' characteristics are within the PFAS NEMP 2.0
- the waste receiver (in this case Loganholme WWTP) is allowed to receive the waste.

Waste track then approves the consignment authority and LCC is issued with a consignment authorisation number.

Statutory Approval

Statutory Approval Document for the transport of waste from Victoria is issued by the Victorian EPA

LCC applies to the Victorian EPA for approval for the movement of prescribed industrial waste from Victoria (F1007), providing the Queensland DES Consignment Authority number

Victoria EPA provide an R26 Assessment Report—the assessment is based on the authority being satisfied that the proposed transport of the prescribed waste is for the purposes of reuse or recycling in accordance with the principal waste hierarchy

Victoria EPA then provide an approval for the movement of non-liquid prescribed industrial waste, issued to LCC.

Figure 2-3: Approvals process for transporting biosolids interstate

Until both approvals from Queensland DES and Victorian EPA were granted, the biosolids could not be moved between states. Because the biosolids moved through NSW, the NSW EPA was informed.

> *As NSW is only a transit state, NSW should be advised of the movement of trackable waste by the receiving jurisdiction when the consignment authorisation is generated. The NSW EPA waste tracking system (online waste tracking (OWT) system) is not used to track the waste. A waste transport certificate is used to track each load and would capture that the waste has passed through NSW as a transit state.*

2.5 COVID-19

During the Phase 2 of the demonstration plant, when biosolids from Source 2 were tested, COVID-19 impacted the project, especially the freight component. Transporting biosolids from Victoria to Queensland became increasingly difficult from July, with several restrictions put in place. To transport freight from Victoria, the following documentation had to be obtained:

1. **NSW Border Pass:** NSW temporarily imposed border restrictions with Victoria. Only persons authorised under the Public Health Order could enter NSW if they had been in Victoria in the previous 14 days
2. **Queensland Border Pass:** Entry to Queensland was temporarily restricted under the Border Restrictions Direction. Personnel were only permitted to enter Queensland in accordance with the Border Restrictions Direction (No. 8), which required additional documentation and a completed Queensland Border Declaration Pass
3. **Letter of Exemption:** Letters of exemption were sent to the company transporting the biosolids stating that the transport of the material was an ‘essential activity’ as per the Queensland Border Directive No.8.

A journey plan was developed for each run of biosolids from Victoria and protocols were put in place at Loganholme WWTP to ensure minimum contact with drivers and written records of close contacts were maintained.

During this time, four runs of biosolids (160 t) were received at the Loganholme WWTP without issues or delays.

3. Reliability

The demonstration plant ran continuously for a series of shorter tests, including 6-hour, 24-hour and 48-hour tests, as well as two 100-hour tests. Stable reliability of the demonstration plant and the associated equipment was expected; however, some reliability issues were encountered.

During commissioning, a number of issues were experienced, and some modifications were required to optimise the operation to match the dried biosolids that were being used for testing, including modifications to cater for the different properties of the biosolids received from the two sources.

Table 3-1 outlines the reliability lessons learned, the implications for the permanent biosolids gasification facility and the modifications undertaken in the preparation phase and during the demonstration plant trials.

Table 3-1: Plant performance and operations and lessons learnt

Component/performance parameter	Findings	Implications for the permanent biosolids gasification facility
Bulk feed handling	Bulk handling via a modified grain silo was abandoned early in the trials due to blockages. A steeper-angled transfer hopper was found to be more suitable. Dust release during the transfer of biosolids to the feed metering system was a concern to consider for the permanent plant.	Control of fugitive dust release in the bulk feed handling systems will need to be minimised and managed. Minimising product handling and storage is a constraint of the design, to reduce the generation of fines in the feed. Handling and road transport of biosolids over 3000 km for the demonstration plant trial increased the dust fraction in the already partly degraded material.
Particle size	Source 1: particle size <5 mm Source 2: particle size 8–10 mm	The gasification unit can process particle sizes that vary against the optimum range of 3–7 mm. It does require a change to the hearth and can affect the heat exchange, but the process is robust enough to accommodate changes in particle size and, therefore, reduces the risk for the belt dryers to meet this requirement 100% of the time.
Oxidisers	The demonstration plant has two oxidisers to increase the retention time as part of destruction of POPs such as PFAS. To determine if the two oxidisers were necessary, air emissions were measured between the oxidisers, which proved that the second oxidiser was not necessary.	The second oxidiser was contributing more to heat loss than heat gain. As such, it provided additional residence time for the flue gases, but otherwise was not obviously performing a useful function.
Feed metering	The drop-out hatch burn-back prevention system proved to be unreliable (false trips) and was bypassed before the trials commenced. The feed metering system required minor modification to deal with the fine free-flowing biosolids that were initially used for the trials. Some logic changes were also required to alter the way the live bottom screws fed the metering screw, to avoid	Pyrocal has developed a new live bottom feed bin that uses a slow-moving agitator and metering flap, rather than multiple floor-mounted screws. This system also has a burn-back prevention arrangement that does not use a drop-out hatch. The system also includes online mass flow measurement.

	over filling. Once these changes were put in place, the feed system achieved a typical reliability of 98%. On rare occasions, the live bottom screws experienced over-torque protection events, causing temporary disruption to the feed and the need for operator intervention.	The revised system is being evaluated by Pyrocal, so that an optimised system is available for the permanent plant that incorporates all the lessons learned from this demonstration plant.
Hearth	Slagging, which is the partial or complete melting of ash species in contact with equipment surfaces, is of concern in the gasification, combustion, or incineration of fossil fuels, biomass, and wastes. Slags can cause fuel agglomeration, damaging ash deposits (e.g. clinker) or corrosion of equipment, which shortens the achievable run time between maintenance shutdowns. Pyrocal's rotary hearth and oxidiser are operated at temperatures well below the ash softening point for most feedstocks, typically 500–800 °C for the hearth and 750–900 °C for the oxidiser, relative to typical ash softening points of 1000–1400 °C. Where a feedstock has an exceptionally low ash softening point, the positive rotary action of the rake system in the hearth tends limit any the build-up. Flux agents, such as lime, are also used by Pyrocal to raise the ash softening point of problematic feeds, such as cotton gin trash. In the case of biosolids, lime dosing into the feed is used to control hot corrosion caused by the presence of Sulphur in the feed. Lime dosing also assists to raise the ash softening point, although the softening point is reported to be 980–1100 °C for sewage-derived biomass.	Fouling of duct work is a common concern for updraft gasifiers, as they are known to generate high concentrations of soot and tars (condensates with a condensation point as high as 400 °C). Pyrocal's systems use a close coupling between the hearth and the oxidiser, which ensures that the off-gas released from the hearth is maintained at temperatures exceeding 600 °C until they enter the oxidiser, where the tars are mixed with air and burned off at temperatures in the range of 750–900 °C and 2–4 seconds residence time. This leaves a hot flue gas that contains a moderate concentration of non-sticky carbon/ash dust to pass through to the downstream heat recovery system. This dust is periodically blown off heat exchange surfaces in a soot- blowing process. Soot and tar build-up in the hearth became apparent during the two longest test runs. This restricted the primary air manifolds, which significantly reduced the capacity of the equipment. The soot and tar build-up readily burned off during a pause in feed or shutdown. Inspections revealed that the hearth and associated equipment remained in good order throughout the tests. The dry crumb from the permanent plant is intended to have a median particle size greater than 6 mm, so that the feed is compatible with the standard hearth decks. For soot and tar build-up, the primary control measure will be to ensure that a hearth-operating temperature exceeding 600 °C is maintained. The permanent system will also include logic and a hearth primary air pressure sensor to detect fouling of the primary air manifolds, to enable a scheduled burn-off sequence to be triggered. The net result is expected to be 30 minutes of lost production every 50–80 hours.
Char Thermal combustion of char (4-day rule)	The char handling and quench system performed reliably for the duration of the tests, except for two incidents where the base of the char transfer conveyor flooded with quench fluid, causing char to float and back up. No quench failures or spontaneous combustion events were experienced during the trials.	Pyrocal's transfer conveyor design will be amended to ensure quench water flooding cannot occur in the permanent plant.
Radiant heat exchanger	The radiant heat exchanger in the shell of the thermal oxidiser removed excessive heat when the Source 1 biosolids were trialed. This exchanger performed according to design on the Source 2 biosolids feed and recovered approximately 360kW of heat at 85% of design rate. The design intent for this first	No changes are required for the permanent plant, as the desired 400 kW of recovery at the nominal design rate has been demonstrated.

	stage heat recovery is 400 kW at a nominal design rate (565 kg/hr).	
Heat recovery steam boiler	The boiler performance was hindered by a relatively low inlet temperature (i.e. ~600 °C rather than the intended 800 °C and well below typical values of 1200 °C during conventional operation with a fossil fuel burner). In addition, fouling of the heat transfer surfaces was evident by the progressive increase in exhaust temperature from 205–300 °C during extended operation. This performance was typically restored via soot blowing operations, which could only be performed on shutdown or start-up. Hence, the typical heat recovery efficiency of this unit was 51–66% compared to an intended value of greater than 80%. Despite this, the heat recovery achieved by the boiler was approximately 700kW at 85% of design rate, on the Source 2 biosolids. Scaling to 100% of the design rate (565 kg/hr) and at 80% efficiency, the heat recovery is forecast to be greater than 1.1 MW, compared to a design requirement of 1 MW. Attempts to operate the system above 85% of the design feed rate led to the heat rejection system starting to reach capacity, which created condensate flow surging, resulting in signal noise in the heat recovery measurement.	The heat recovery steam generator will be replaced with a heat recovery water heating unit to better suit the requirements of the permanent plant. The proposed unit has in-built soot blowing arrangements (online compressed air type). The proposed heat exchanger is also designed to achieve a heat recovery exceeding 80% at the expected flue gas inlet temperatures (600–800 °C). Pyrocal recommends the addition of a downstream condensing heat exchanger (200 kW rating) to ensure that the overall heat recovery is achieved with a suitable design margin.
Scrubber	The absorption scrubber was upgraded with a venturi stage after the initial emissions tests, when it became apparent that the dust loads could not be catered for. This improved the emissions performance, at the expense of limiting the ID fan flow capacity by 15%, due to increased pressure differential. This directly impacted on the achievable feed rate of biosolids. As a result of very high dust loads, it was necessary to drain liquid from the scrubber, back into the treatment plant, on a continuous basis.	Pyrocal estimates that the PM10 and PM2.5 dust loading from the biosolids were four to ten-fold greater than that typical of plant derived biomass. Therefore, the permanent plant design has been amended to allow for a high pressure drop venturi and a downstream PM2.5 capture device (refer to the filter section in this table) and upgraded capacity ID fan.
Filter	The barrier type filter installed on the demonstration plant proved to be unsuitable as it fouled too rapidly in service.	Pyrocal recommends implementing a wet electrostatic precipitator (WESP) on the permanent unit, to cater for the high PM2.5 loads that the biosolids release into the flue gas. The benefit of this approach is improved reliability, lower operating costs and complexity compared to a barrier filter, as well as reduced ID fan pressure differential relative to barrier filters.

Continuous Emissions Monitoring Systems (CEMS)	The online CEMS was installed as part of Pyrocal's scope. The unit that was installed by Aquagas was a MAMOS CEMS designed for online measurement of O, CO_2, SO_2, NO, NO_2. NOx and O_2 as well as stack gas temperature and velocity. However, this unit had several issues including blockages due to the high moisture content. The internal fix was to install a gravity head drain instead of the peristatic drain pump. This allowed a continuous monitoring, although this solution would not be suitable for the full-scale facility.	The appropriate CEMS monitoring system for this type of analysis would be an extractive system or Fourier Transform Infrared (FTIR). FTIRs can operate in a high moisture environment because every component of the system is heated above dew point, including the analyser itself; therefore, a condenser is not required. This recommendation is included in the scope of the full-scale facility.
Processing rate	The maximum processing rate achieved during the trials was 600 kg/hr. The absorption scrubber was upgraded with a venturi stage when it became apparent that the dust loads could not be catered for. This improved the emissions performance at the expense of increased pressure differential and reduced fan flow capacity. This addition of the venturi directly impacted on the achievable feed rate of biosolids.	Modifications to the thermal oxidiser and upgrading of the ID fan pressure and low capacity are planned to ensure that a capacity of 650 kg/hr is achievable.
Particulates	Venturi was added after running 2 of the full air emissions to mitigate particulates. When the threshold was increased, the venturi and fans could not cope and increased the particulates in the air stream. Another run was planned for September with the addition of a cyclone and modified oxidiser. This is so that the threshold can be optimised at the same time to obtain reliable results on dosing and chemical rates while still being within the limits set for air emissions and particulates.	In the full-scale facility, the issues surrounding the particulates has been engineered out with the inclusion of an ESP into Pyrocal's scope. An ESP is a filtration device that removes fine particles, like dust and smoke, from a flowing gas using the force of an induced electrostatic charge, minimally impeding the flow of gases through the unit.
Carbon monoxide (CO) Carbon monoxide exceedances related to particulates	The performance with respect to carbon monoxide slip vs excess O_2 and visual inspection of the swirl pattern suggested that turbulent mixing was less than desired. Therefore, a swirl vane was installed at the oxidiser inlet and a directional nozzle implemented for the secondary air inlet. This reduced the carbon monoxide slip; however, it was evident that further reduction in short circuiting was necessary as higher feed rates were required.	It is proposed to include a deflector baffle before the oxidiser outlet to reduce the ability for flue gas to short circuit from the inlet to outlet. Improved turbulence in the oxidiser is expected to reduce the residual oxygen concentration required to achieve the desired destruction in the thermal oxidiser. This will, in turn, reduce the necessary ID fan flow demand. Both solutions worked in the October trial and will be replicated on the full-scale facility.

4. Air Emissions

4.1 Background

The air emissions from the gasification plant will be substantially less than a typical incineration plant because the carbonisation process is not destroying 100% of the mass, but rather removing the volatile fraction and treating that fraction, while carbonising the non-volatile fraction. The volatile fraction represents 40–60% of the total dry mass. Consequently, imposing best practice emission limits for incinerators on the plant for the demonstration plant was sufficient to protect environmental values while actual release data is gathered.

The gas residence time and temperature in the thermal oxidiser is 2 seconds at 800–850 °C. This residence time and temperature has been demonstrated in previous tests on a range of biomasses, sufficient to exceed 99% destruction of the organic matter presented to the oxidiser. The percentage destruction or alteration of halogenated species is not known and measuring this percentage was an objective of the demonstration plant.

After the thermal oxidiser, the next air emission control unit is a venturi through to a wet scrubber. The scrubber is a spray absorber with extended residence time for particulate-seeded condensation capture of the PM10 fraction. This allows rapid quenching of the gas to avoid the dioxin reformation temperature range. The gas/liquid contact allows acid gases and other species to be physically or chemically captured (Bouzaza, Laplanche, & Marsteau, 2003). Fine mist that carries over in the exit gas is captured in a wire mesh mist eliminator and recirculated to the scrubber sump.

The accumulated solids from the scrubber are discharged to the biochar from the carbonisation stage, to perform the quench duty. This results in no liquid emissions from the system.

In the first phases of the trial, lime was added to the biosolids feed and to the scrubber as many of the potential air pollutants can be are sequestered as calcium salts. This includes acid gas species such as HCl, HF, H2SO4, metals such as Hg, As, Cd, Pb, Zn, Cu and Cr and many of the halogenated species (Busca & Pistarino, 2003) (Dias, Alvim-Ferraz, Almeida , Rivera-Utrilla, & Sanchez-Polo, 2007) (Kailiva & Smith, 1983).

A change to Mg (OH)2 was made (5/05/2020) for the SOx control because although the lime dosing can hold the SOx concentration at around 30–150 mg/Nm^3 (not oxygen corrected). The lime contributes to fouling in the wet scrubber, so it is prudent not to dose any more than necessary to protect the steel in the hot zones. Therefore, it was determined to use Mg (OH)2 dosing at the wet scrubber for mitigating SOx in the air emissions. The results are shown in Section 4.6.

In the original design, a moisture-tolerant, 5-micron-pleated filter element (barrier filter) followed the scrubber and captured the residual PM5 matter before the flue gases were drawn into an induced draft fan and discharged to the atmosphere. Experience proves that the action of the scrubber to remove the bulk of the particulate matter allows the barrier filter to be used without incurring impractical service intervals.

However, the Source 2 biosolids were extremely dusty materials and demonstrated that although the filters worked, they would have to be cleaned more often than expected compared to other types of materials processed through the gasification facility. Therefore, the filter element was removed, and a venturi device added at the entrance of the scrubber (12/05/2020). This configuration was used for all tests after this date, including the 100-hour reliability runs.

4.2 Regulation requirements

The regulation requirements mostly relate to the environmental harm perceived from the air emissions via the stack. Therefore, when designing the full-scale facility, 75% of the facility will be focused on purifying the biogas produced, with the dual purpose of measuring the heat recovery. The demonstration plant was run under strict conditions imposed as part of the Environmental Authority (EA) (EPPR00867913) Condition LGN-A2: Contaminants must only be released from the Biosolids Gasification Demonstration Plant to air via point release sources in accordance with Table 4—Point Source Air Release Limits and associated monitoring requirements.

Table 4-1 is the point source air release limits set for the demonstration plant.

Table 4-1: Point source air release limits for the demonstration plant

Contaminant	NSW EPA Protection of the environment policies (POEO) Regulation (see Note 2)	European Commission (2000/76/EC) (see Note 3)	Target limits for the demonstration plant
Total solid particulate	50 mg/Nm^3 (dry)	30 mg/Nm^3 (dry)	30 mg/Nm^3 (dry) at 11% O_2
Carbon monoxide (CO)	125 mg/Nm^3 (dry)	-	125 mg/Nm^3 (dry) 11% O_2
Oxides of nitrogen as NO_2	350 mg/Nm^3 (dry)	400 mg/Nm^3 (dry)	400 mg/Nm^3 (dry) at 11% O_2
Sulphur dioxide (SO_2)	-	200 mg/Nm^3 (dry)	200 mg/Nm^3 (dry) at 11% O_2
Hydrogen chloride (HCl)	-	60 mg/Nm^3 (dry)	60 mg/Nm^3 (dry) at 11 % O_2
Total fluoride (as HF)	50 mg/Nm^3 (dry)	4 mg/Nm^3 (dry)	4 mg/Nm^3 (dry) at 11 % O_2
Total volatile organic compounds	20 mg/Nm^3 (dry)	20 mg/Nm^3 (dry)	20 mg/Nm^3 (dry) at 11% O_2
Cadmium and its compounds	0.2 mg/Nm^3 (dry)	0.05 mg/Nm^3 (dry)	0.05 mg/Nm^3 (dry) at 11% O_2
Mercury and its compounds	0.2 mg/Nm^3 (dry)	0.05 mg/Nm^3 (dry)	0.05 mg/Nm^3 (dry) at 11% O_2
Total heavy metals (see Note 1)	1 mg/Nm^3 (dry)	0.5 mg/Nm^3 (dry)	0.5 mg/Nm^3 (dry) at 11% O_2
Dioxins and furans (I-TEQ for PCDDs and PCDFs, including half LOD)	0.1 ng/Sm^3 (dry) at 11% O_2	0.1 ng/Sm^3 (dry)	0.1 ng I-TEQ/Nm3 (dry) at 11 % O_2
Polycyclic aromatic hydrocarbons (PAH)	-	-	-
PFAS extended suite containing 28 compounds (see Note 4)	-	-	-

Table notes:

Note 1: Total heavy metals limit is for the total of antimony, arsenic, cadmium, lead, mercury, beryllium, chromium, cobalt, manganese, nickel, selenium, and vanadium and their compounds.

Note 2: The concentrations limits for solid waste incineration refer to 7% O_2, except dioxins that refers to 11% O_2.

Note 3: All concentrations limits (100% compliance) refer to 11% O_2 reference level and average over the sample period of 30 minutes.

Note 4: The samples should be analysed to quantify the PFAS, by applying the total oxidisable precursor analysis (TOPA), to analyse the PFAS extended suite of 28 compounds. To determine PFAS concentrations, at least the PFAS extended suite containing 28 compounds should be analysed from the following sources:

- sewage sludge used in the demonstration plant
- stack emissions during the selected demonstration plant where emissions are expected to be maximum.

4.3 Status of air pollution control equipment used for the demonstration plant

The online CEMS was installed as part of Pyrocal's scope. The unit installed by Aquagas was a MAMOS CEMS designed for online measurement of O, CO2, SO2, NO, NO2. NOx and O2 as well as stack gas temperature and velocity. However, this unit had several issues including blockages due to the high moisture content and a gravity-head drain in place of the peristatic drain pump. This allowed continuous monitoring, although labour intensive and would not be suitable for the full-scale facility.

The appropriate CEMS monitoring system for this type of analysis would be an extractive system or FTIR as both systems can withstand a high-moisture environment because every component of the system is heated above dew point, including the analyser; therefore, a condenser is not required. This approach is included in the scope of the full-scale facility.

4.4 Stack emission results

Two types of air emissions analysis were undertaken for the demonstration plant:

1. Basic air emissions: This analysis is performed by the CEMS unit for every run and including parameters: O2, NOx, CO, and SOx. All data is stored, but a summary is in Section 4.6.
2. Full air emissions: This analysis includes all parameters including particulates, heavy metals and emerging contaminates of concern, such as PFAS. Three runs were performed, and a summary is in Section 4.6 and full reports supplied by Assured Environmental are included in Appendix D.

Stack monitoring was conducted by Assured Environmental, an external third party. This approach ensured that all air emission stack monitoring was conducted by an experienced provider holding current National Association of Testing Authorities (NATA) accreditation. Due to the CEMS unit having issues, for example blockages, some of the results for the continuous monitoring were also undertaken by Assured Environmental. This approach ensured that the demonstration plant was meeting all required parameters, not causing environmental harm, and meeting all conditions stipulated in the license to operate issued by DES.

4.5 Timeline

Table 4-2 lists of all the runs that were performed, and the analysis undertaken.

Table 4-2: Timeline of runs of the demonstration plant

		Date	Comment
4–6-hour run			
Run 1	SOx, NOx, and heat balance	22/01/2020	CEMS unit
Run 2	SOx, NOx, and heat balance	04/03/2020	CEMS unit
Run 3	SOx, NOx, and heat balance	17/03/2020	CEMS unit
6-hour run			
Run 4	SOx, NOx, and heat balance	23/03/2020	CEMS unit
Run 5	SOx, NOx, and heat balance	02/04/2020	CEMS unit
Run 6	SOx, NOx, and heat balance	11/06/2020	CEMS unit
Run 7	SOx, NOx, and heat balance	11/08/2020	CEMS unit
24-hour run			
Run 8	SOx, NOx, and heat balance	10/08/2020	Assured Environmental
Run 9	Full air emissions, SOx, and NOx	02/04/2020	Assured Environmental—full air emissions data
48-hour run			
Run 10	SOx, NOx, and heat balance	21/07/2020	CEMS unit
100-hour run			
Run 11	Full air emissions, SOx, NOx, and heat balance	22/7/2020	Assured Environmental—full air emissions data
Run 12	SOx, NOx, and heat balance	27/07/2020	CEMS Unit supplied by Assured Environmental

4.6 Summary of continuous stack monitoring results.

Figure 4-1 to Figure 4-13 provide an overview of each of the runs performed. The data shown is the chemical parameters for the basic air emissions: NOx, SOx, and CO. Each run highlights the set limit in red.

This section presents the data from the online CEMS unit. As discussed, this unit had issues and was found not to be fit-for-purpose and therefore will be replaced for the full-scale facility; however, it does give an overall perspective of the range of each analyte: NOx, Sox and CO.

Figure 4-1 was one of the first runs completed using the Source 1 biosolids after the hearth had been fitted for the difference in the material size. However, this run was also completed when the throughput was not at full capacity; rather, it was gradually increased starting at 320kg/hour. This run illustrates that the gasification unit can meet the criteria set in the license limits.

With regards to start-up and shutdowns, there will be a spike in air emissions until the system is stable (~1 hour) and this should be factored for license limits. However, the full-scale facility is being designed to run with fewer shutdowns limiting the start-up and shutdowns and to integrate with the heat energy balance, keeping the continuous loop. Therefore, this spike would not be a daily occurrence, but rather once every few couple of weeks.

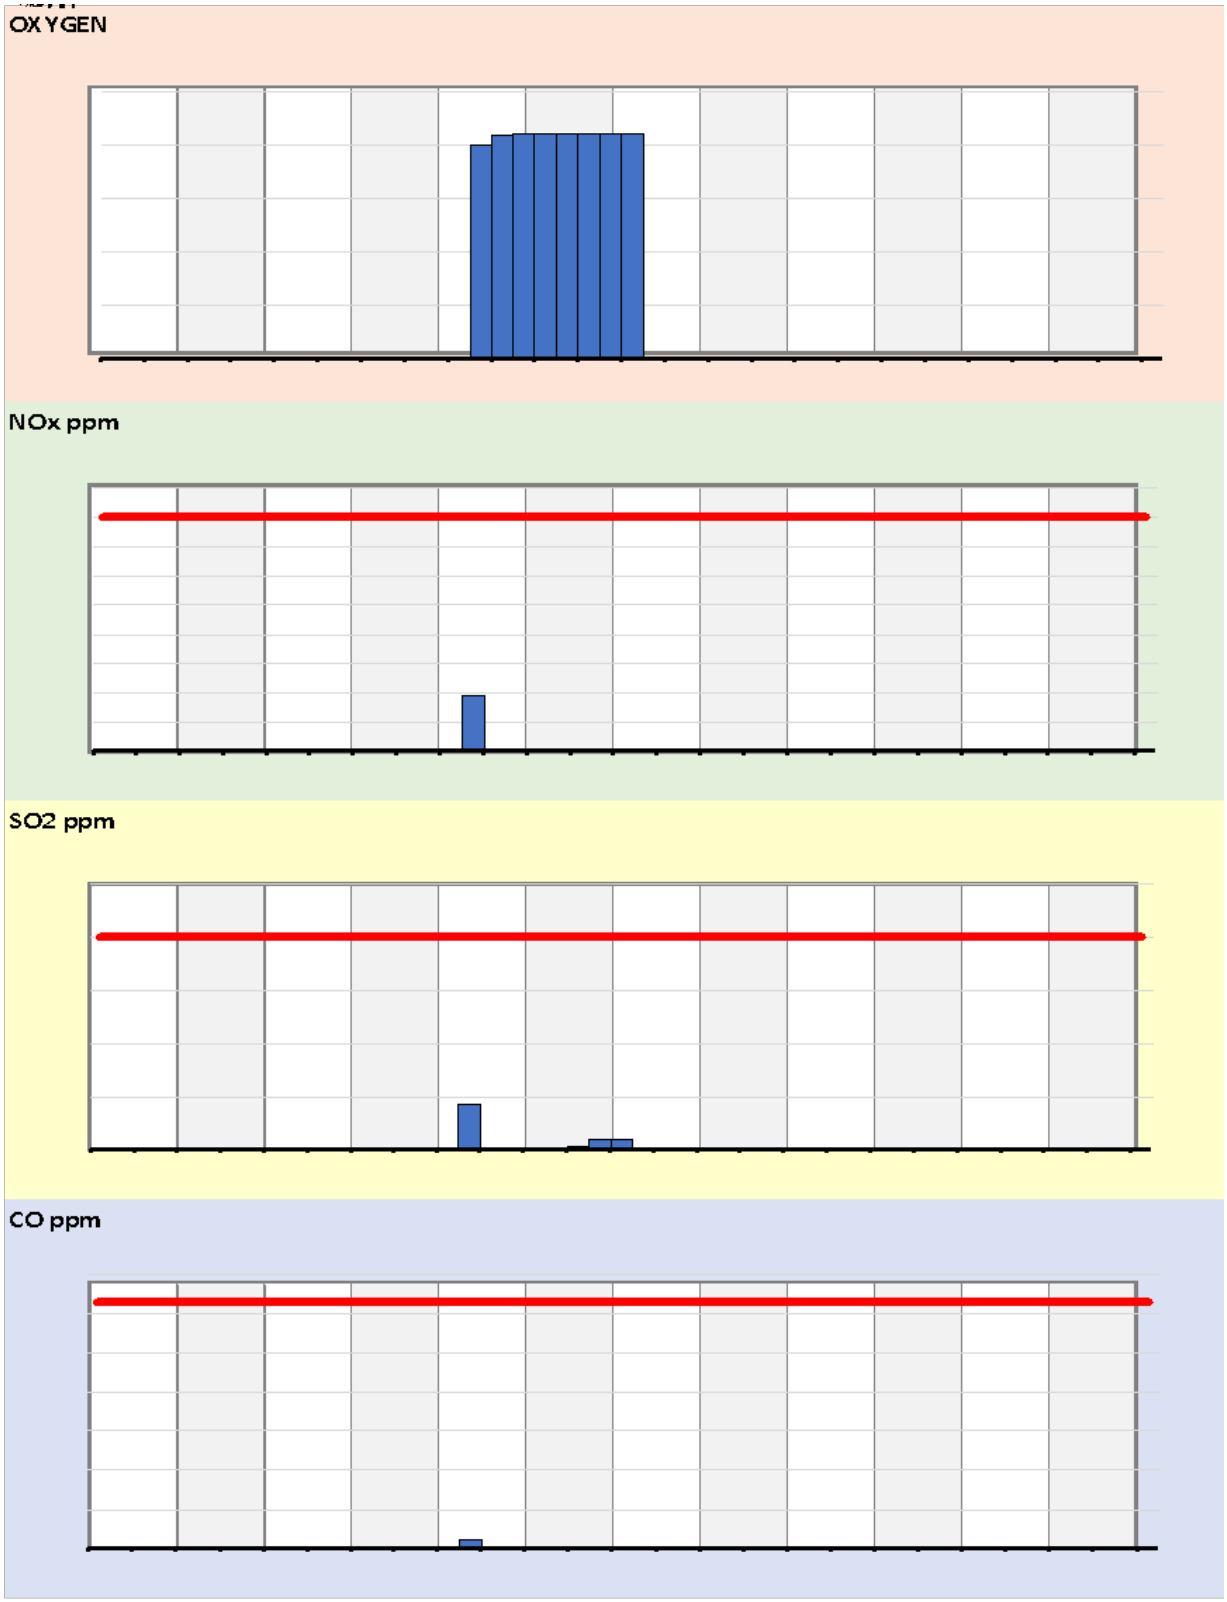

Figure 4-1: Run 1: 4–6 hour run (22/01/2020)

Run 2 (Figure 4-2) was completed using Source 1 biosolids and again illustrates that the license limits can be achieved on biosolids through a gasification system. There was an apparent spike in SOx concentration levels for this run; however, this was the result of a blockage in the CEMS unit.

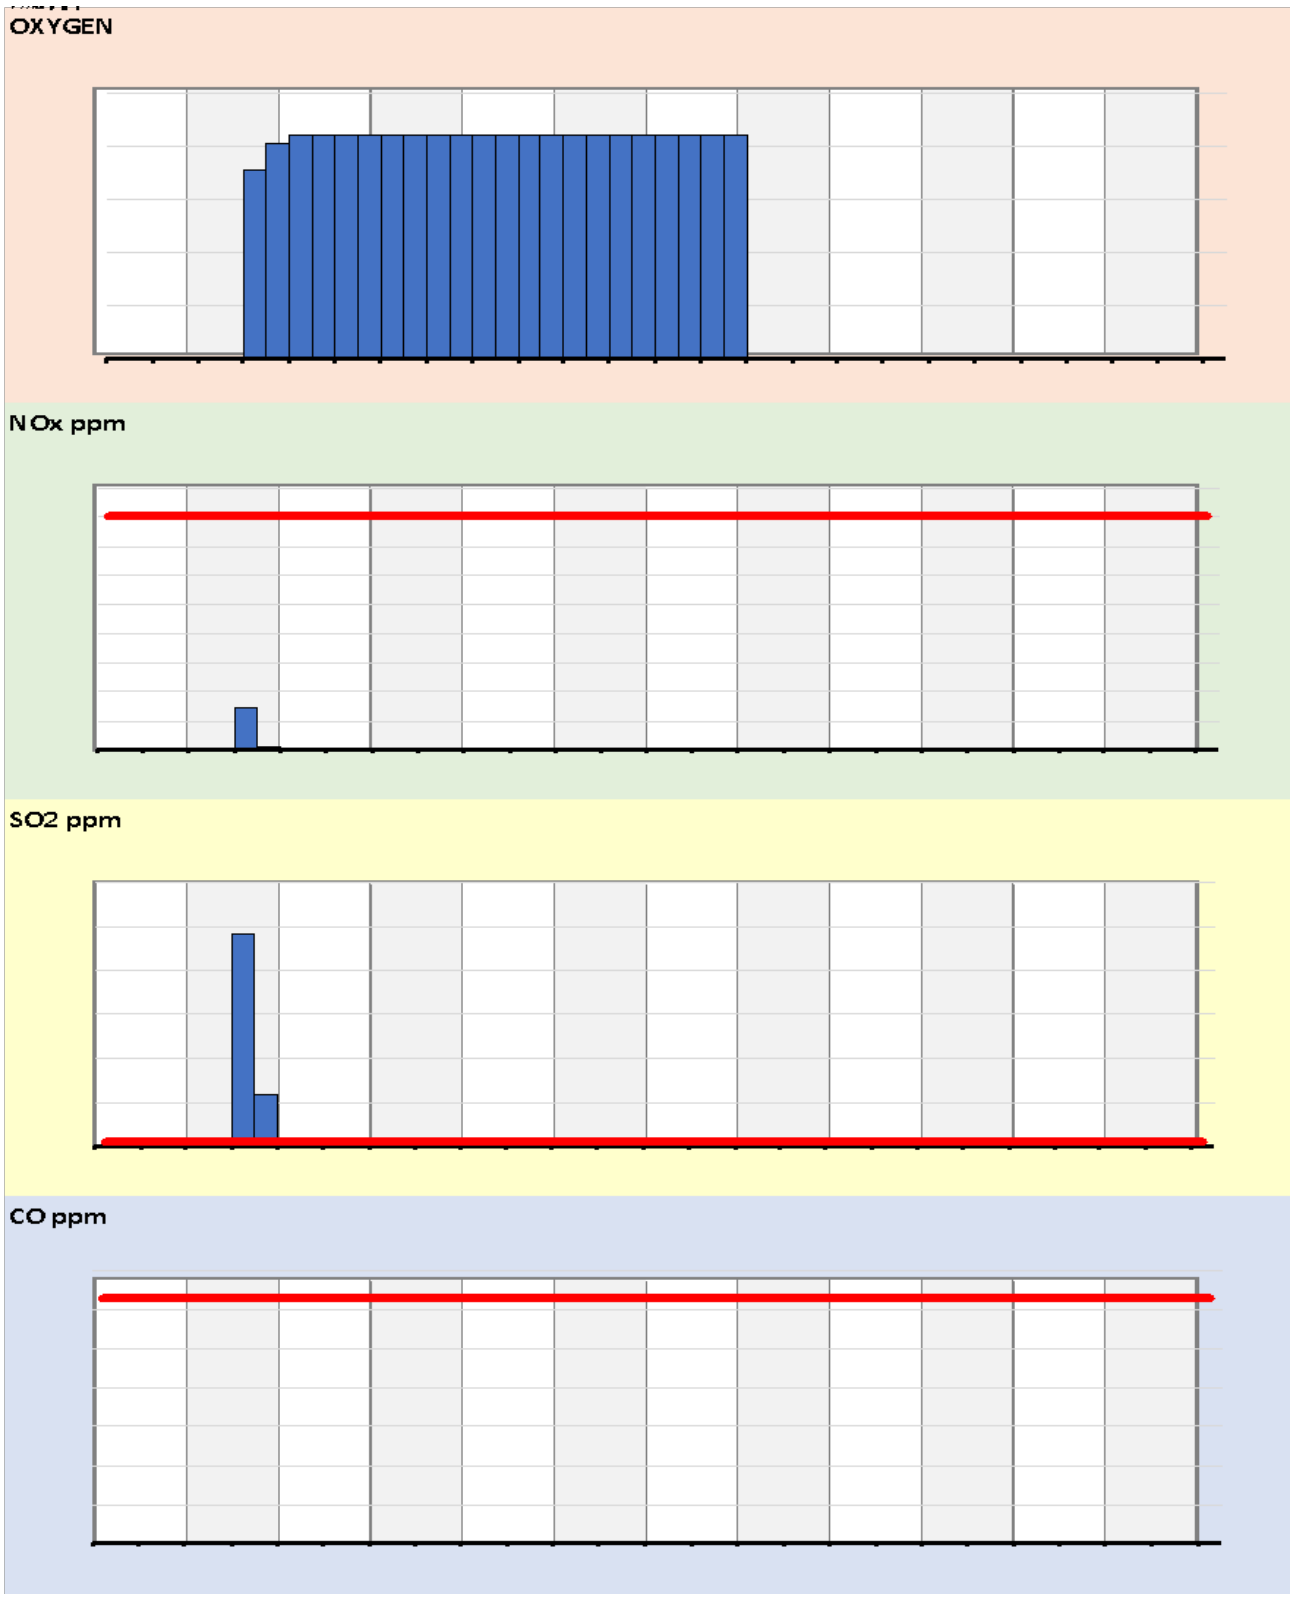

Figure 4-2: Run 2: 4–6 hour run (04/03/2020)

Run 3 (Figure 4-3) was completed using Source 1 biosolids and illustrates that the license limits can be achieved on biosolids through a gasification system. There was a spike in SOx, firstly on start-up, which is to be expected, and then an hour later, which was brought under control. This result is discussed in the lessons learnt in Table 3-1 and is one of the reasons for the change from lime dosing to MgOH because the lime dosing system consistently had blockages and was not the best agent for mitigating SOx.

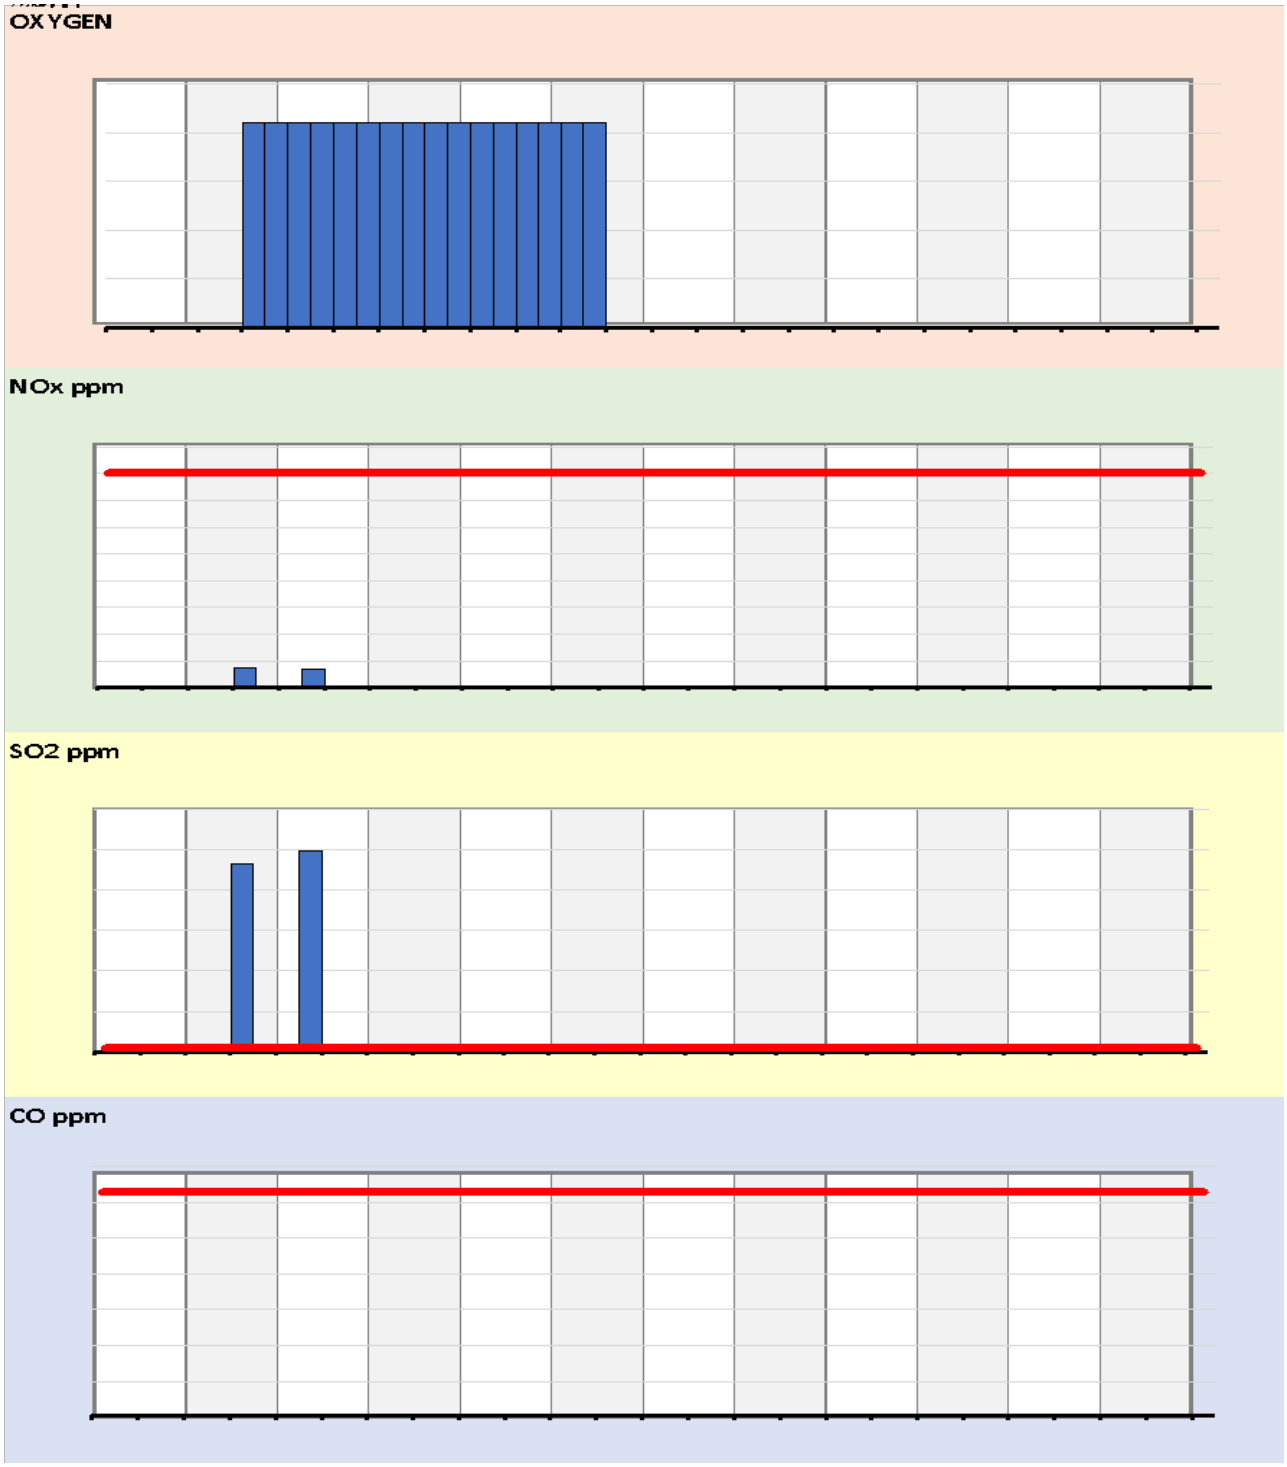

Figure 4-3: Run 3: 4–6 hour run (17/03/2020)

The following data is from the four 6-hour runs and provides an overview of the early lessons learnt on the reliability of the demonstration plant.

Figure 4-4 demonstrates a typical run that occurred on the Source 1 biosolids with spikes in SOx but relatively low NOx and CO. The NOx levels were mostly due to the nature of the biosolids and because they had been stored for such a long period. Ammonia (NH_3) is oxidised, which promotes the simultaneous oxidation of NO to NO_2 (Leppaelahti, Simell, & Kurkela, 1991). If not controlled, this would result in an undesirable visible brownish colour of the plume from the stack. Another nitrogen species that can be present is di-nitrous oxide (N2O), which is a greenhouse gas. This run gave the indication that, for SOx mitigation, the chemical agent did need to be changed to MgOH.

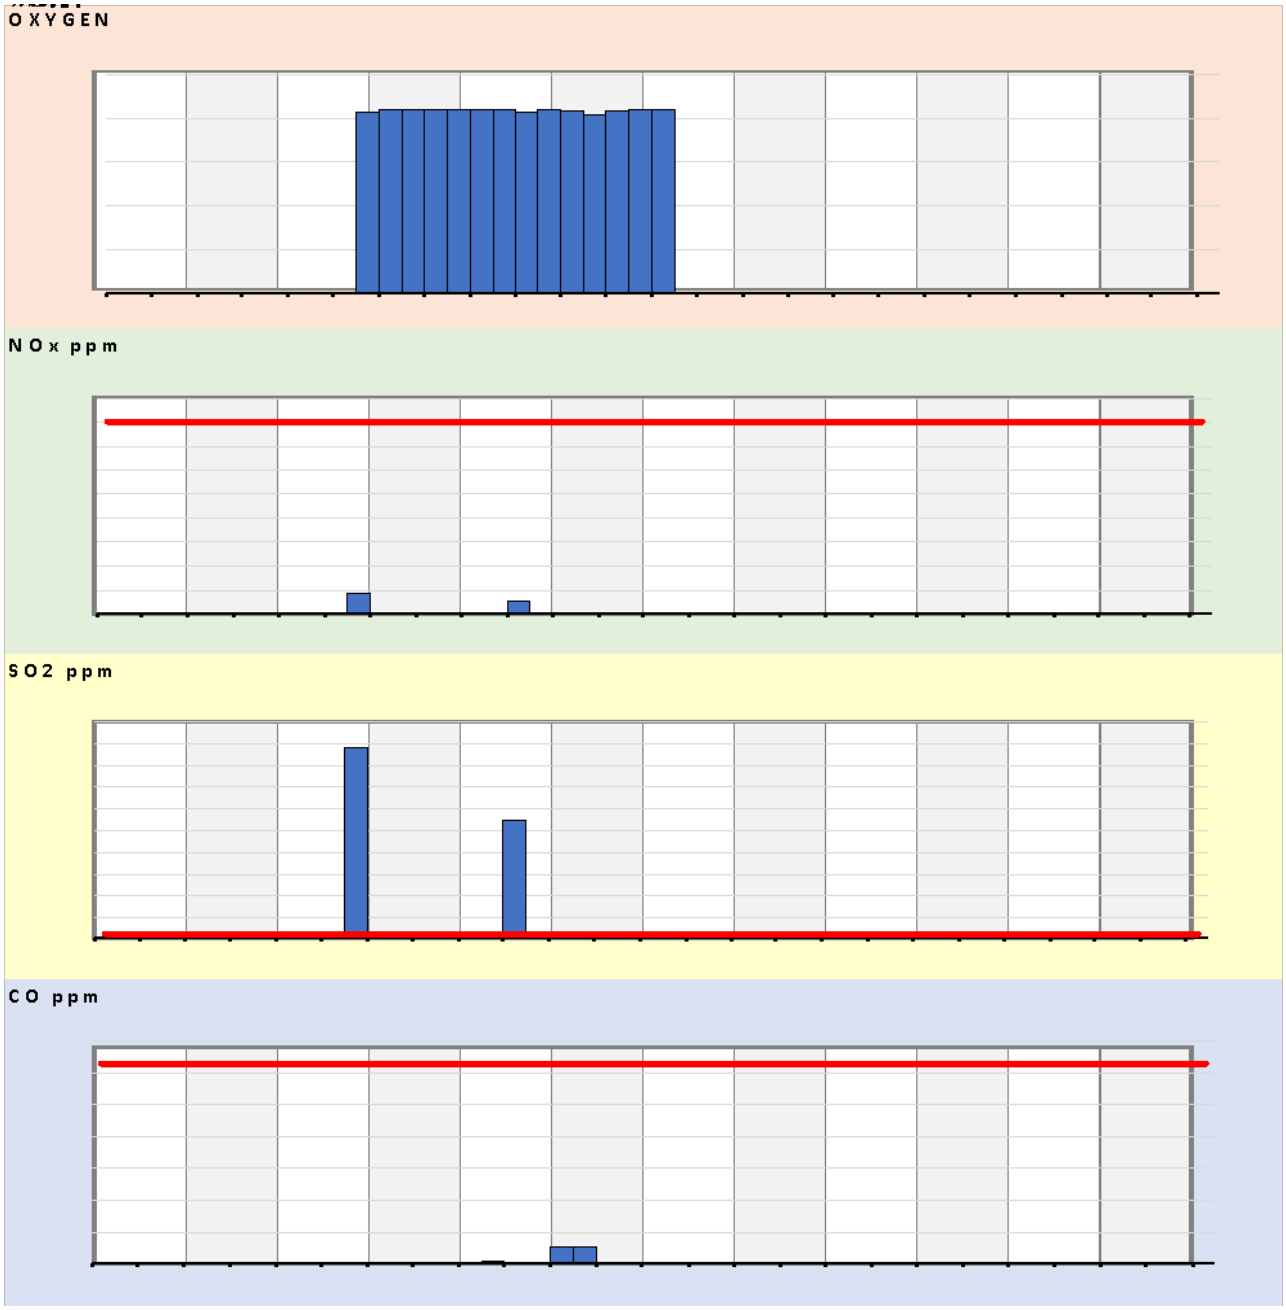

Figure 4-4: Run 4: 6-hour run (23/03/2020)

Run 5 (Figure 4-5) was completed using the Source 1 biosolids and the data reinforces the findings found in the previous runs.

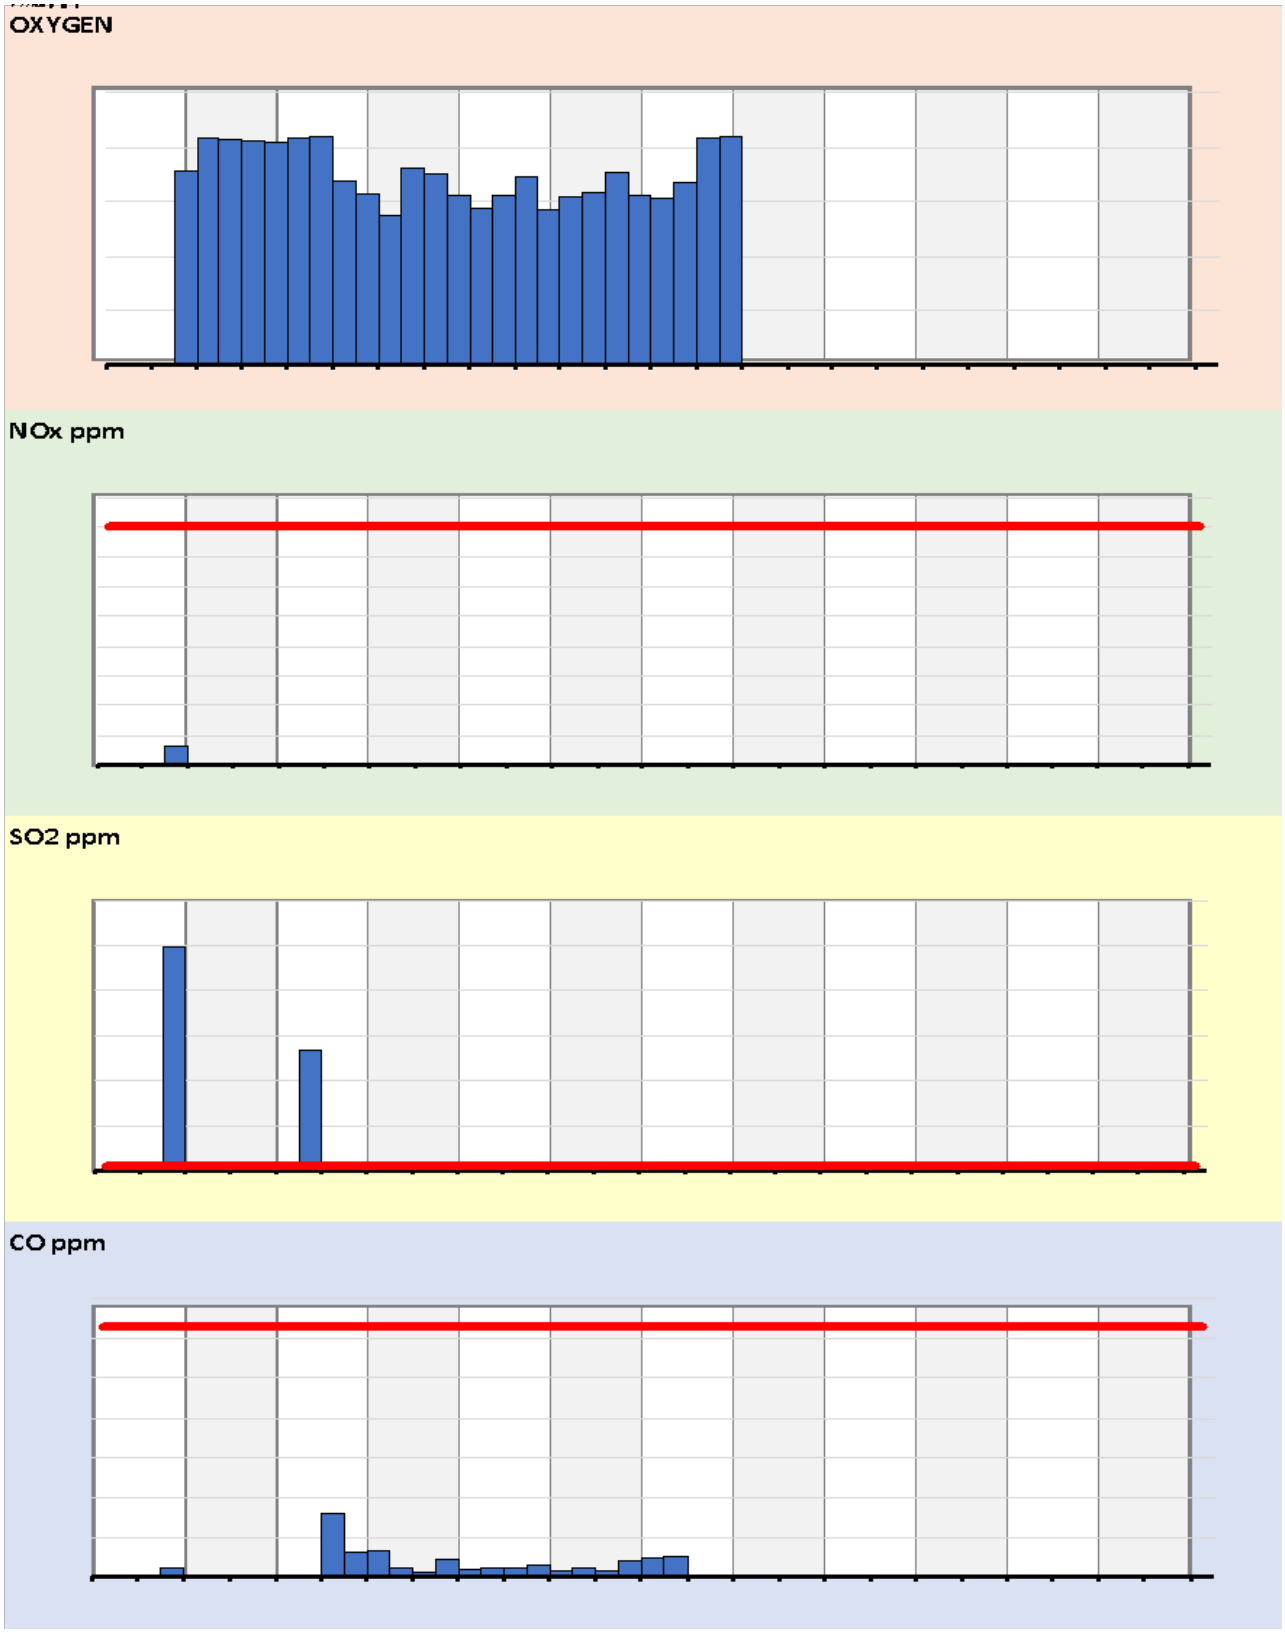

Figure 4-5: Run 5: 6-hour run (02/04/2020)

Run 6 (Figure 4-6) was a longer run on Source 2 biosolids, but demonstrates that on start-up there could be exceedances in the air emissions until the unit has stabilised, which will need to be considered in the scope of the full-scale facility. It also illustrates that the facility can meet the license requirements over a longer period. However, this run was still undertaken at a lower throughput due to the particle sizing of the biosolids.

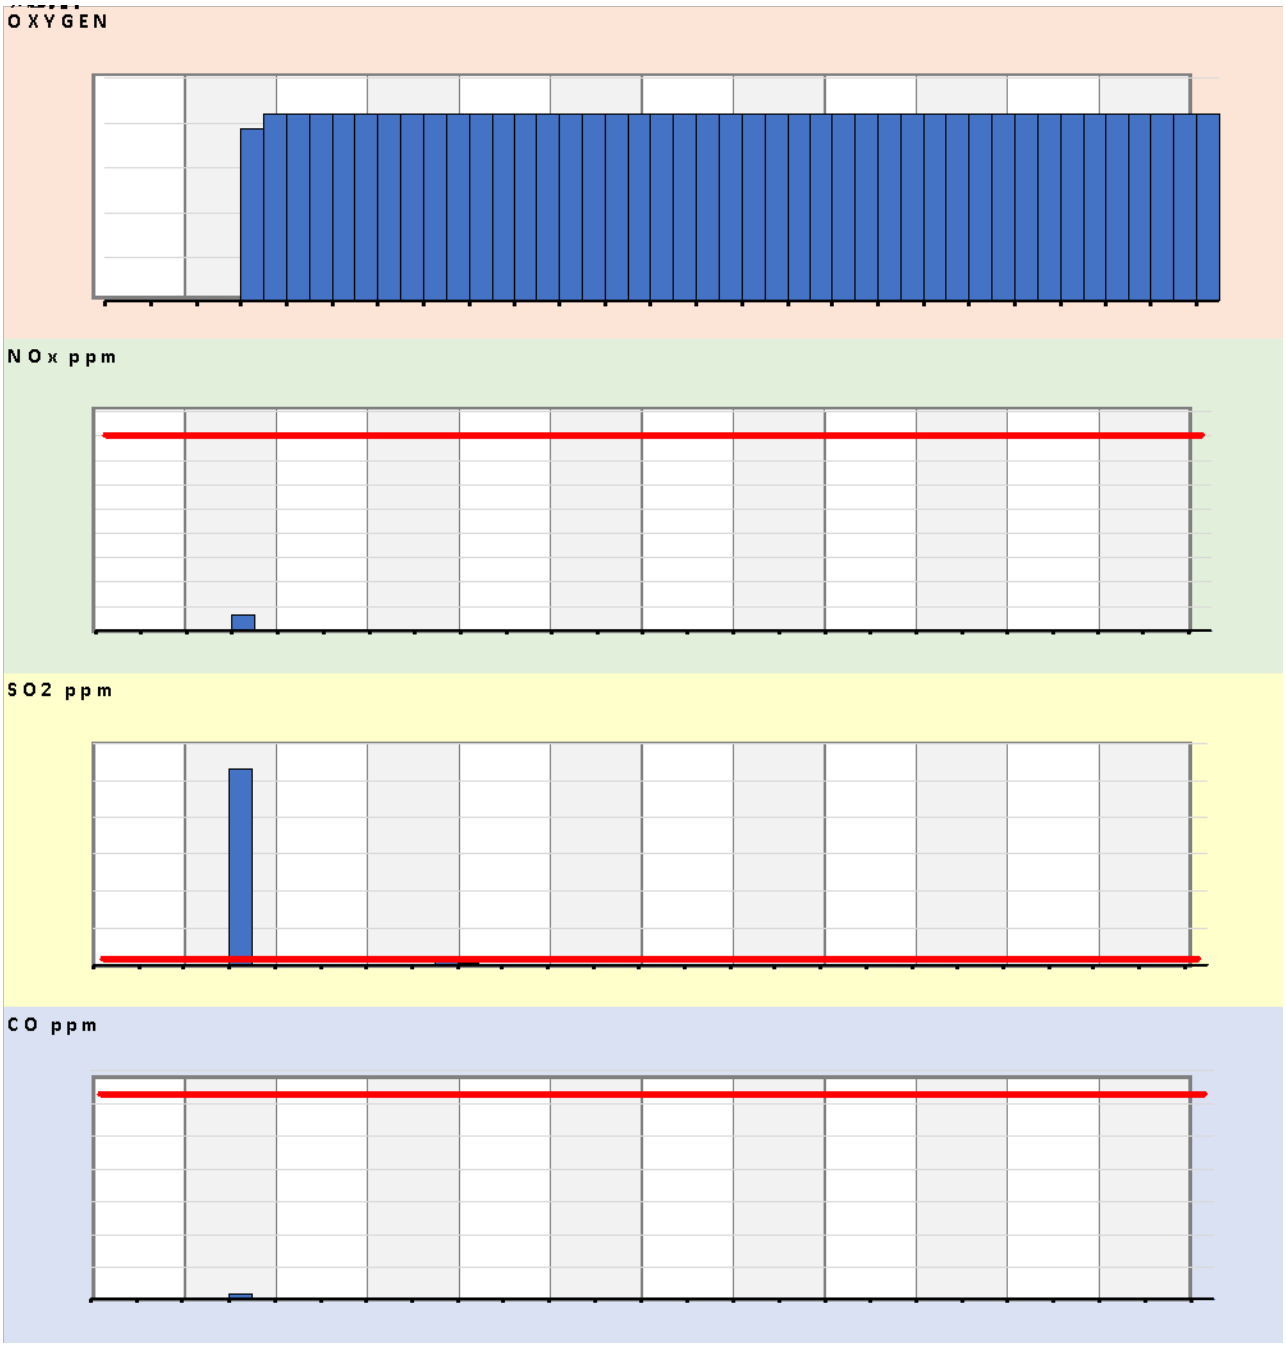

Figure 4-6: Run 6: 6-hour run (11/06/2020)

Run 7 (Figure 4-7) was completed using the Source 2 biosolids. It shows the presence of NOx, due to the source material being fresher because it had not been stored or stockpiled for the same length of time as the Source 1 material. Therefore, data was available for NOx mitigation and chemical dosage rates that appear to be like the rates estimated for the Loganholme WWTP. In Run 7, the SOx chemical mitigation agent was changed from lime to MgOH. Figure 4-7 shows that using MgOH resulted in no spikes, even during the start-up and shutdown periods.

The oxidisers were changed so that they could maintain increased temperature and retention times due to source material having a higher calorific value (more heat being produced) and the addition of insulating cladding previously installed to mitigate the low calorific value of the Source 1 biosolids material.

The issues with CO become apparent on this run and due to the difference in the biosolids, an increase in dust, and an increase in the temperature of the oxidisers that caused 'ashing out'. These issues became apparent in the full-scale air emission and particulates analysis, discussed in Section 4.7.

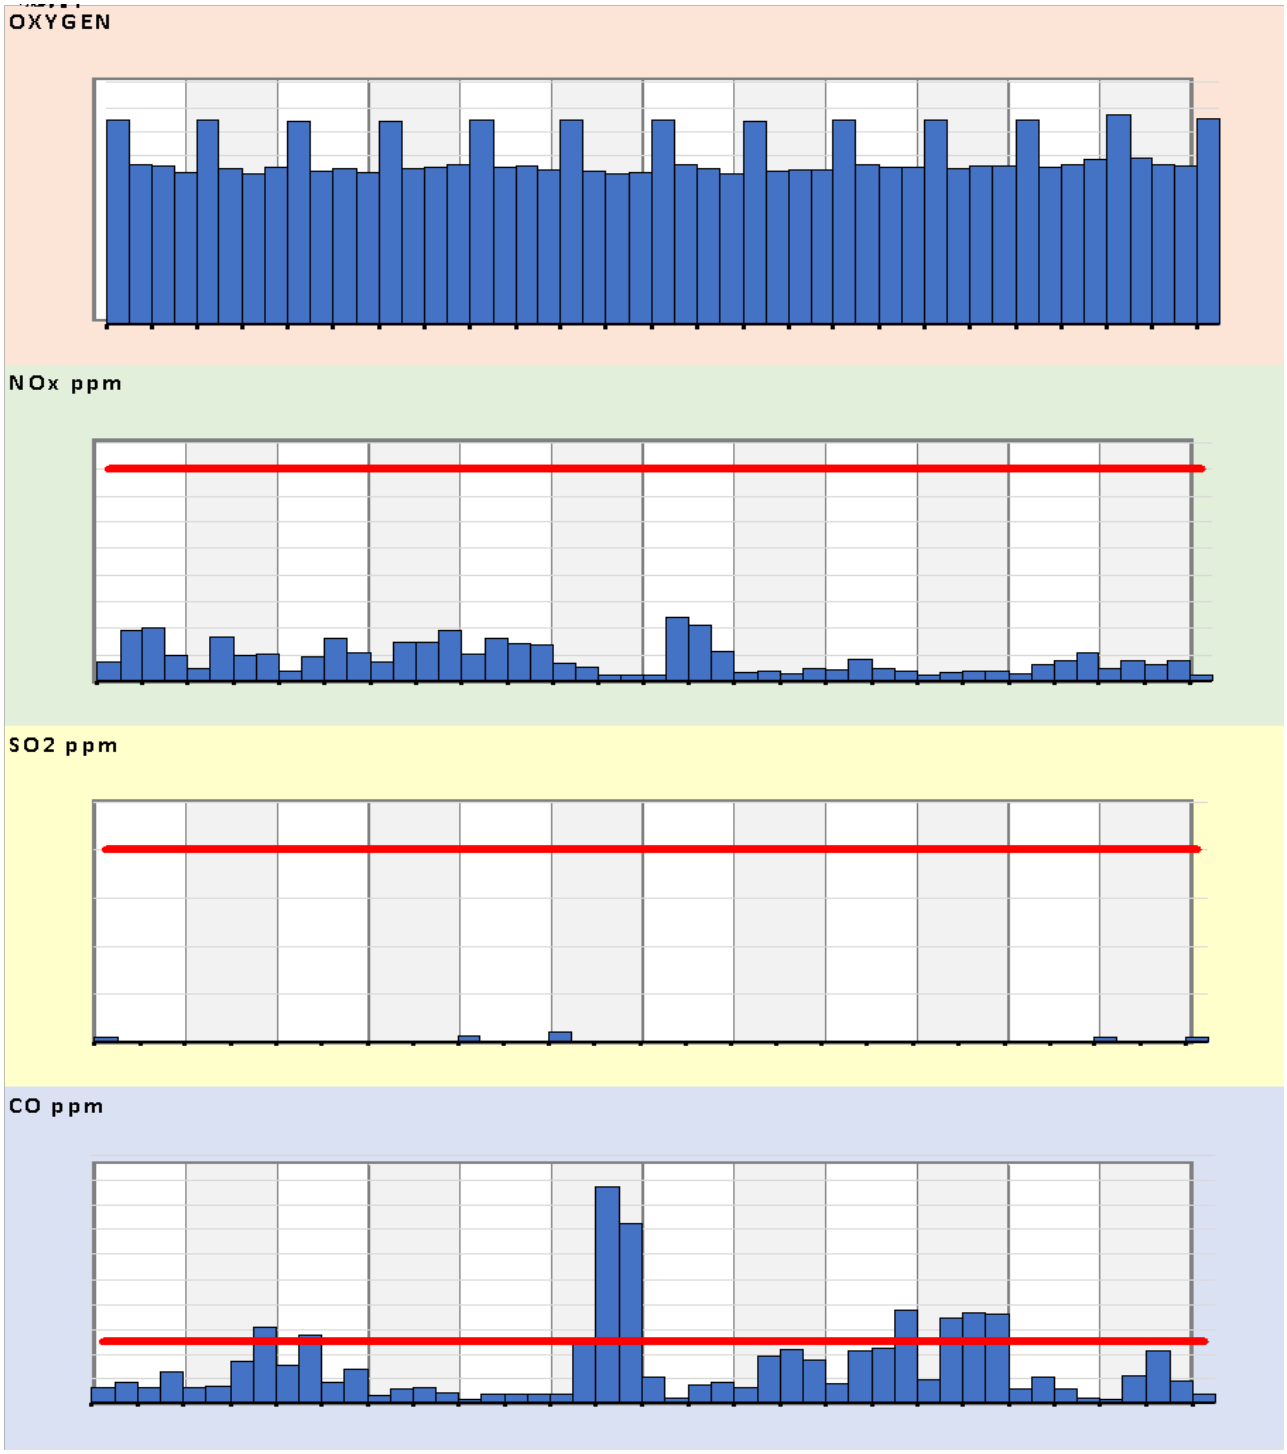

Figure 4-7: Run 7: 6-hour run (11/08//2020)

Figure 4-8, Figure 4-9, and Figure 4-10 show the data for the 24-hour run completed supplied by Assured Environmental. Because the CEMS unit was supplying incorrect data, it was considered prudent to obtain results for the 24-hour run by accredited samplers using their online unit to allow for the CEMS unit to be fixed and calibrated.

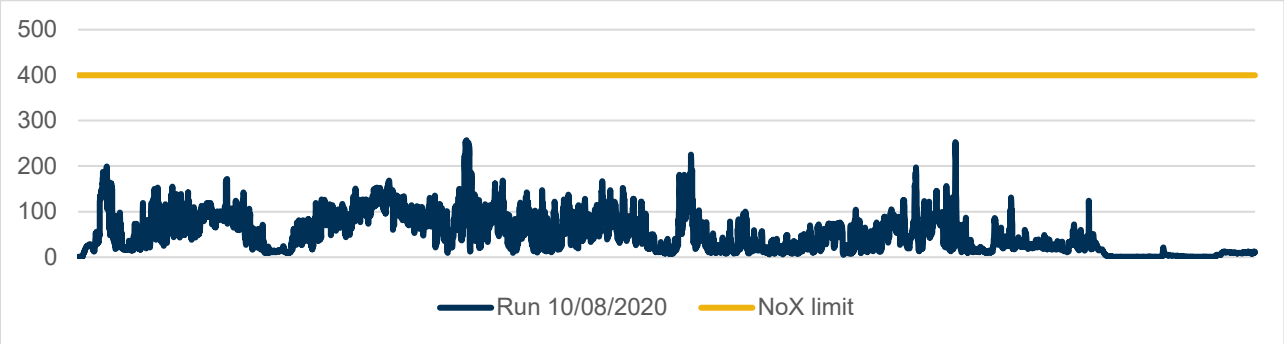

Figure 4-8: Run 8: 24-hour run NOx results (10/08/2020)

Figure 4-8 shows the NOx results over the first 24-hour run were within the license limits for the entire run.

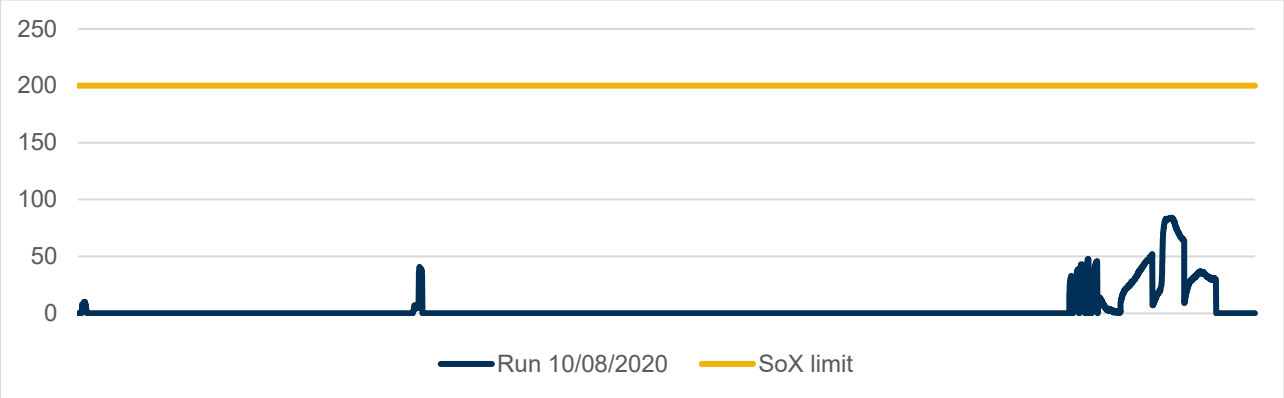

Figure 4-9: Run 8: 24-hour run SOx results (10/08/2020)

Figure 4-9 shows the SOx results over the first 24-hour run were within the license limits for the entire run.

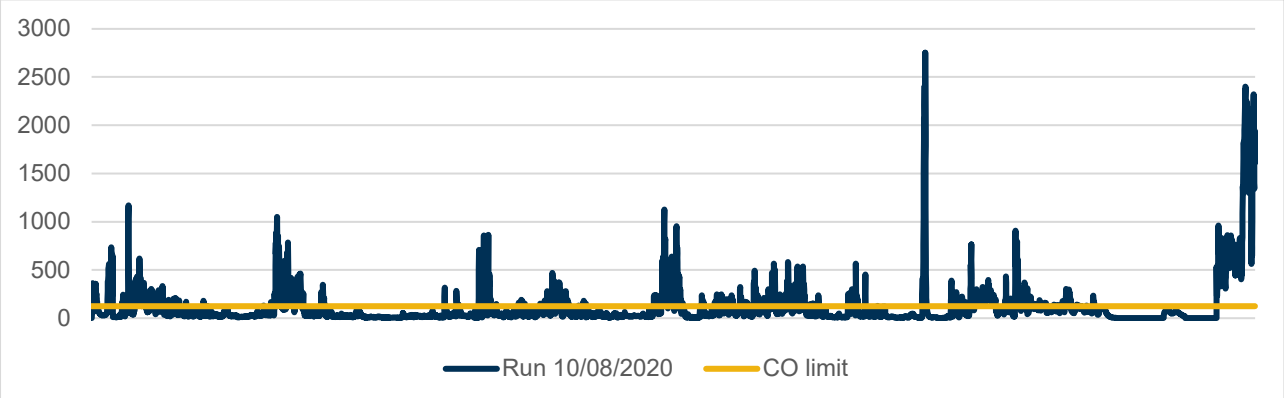

Figure 4-10: Run 8: 24-hour run CO results (10/08/2020)

Figure 4-10 shows that the issues with the current unit is the mitigation of CO. Modifications were made to the oxidisers for the next runs. These high CO results may have been carried over from the particulates with the change from Source 1 to Source 2.

CO, hydrocarbons (HC) and particulate matter are associated with incomplete combustion, which occurs in gasification processes compared to incineration. However, this issue can be engineered out by increasing the temperature in the oxidisers to start the process that will control the CO, and then the addition of an ESP to control the particulates. This strategy is supported by data obtained from the demonstration plant about particulates such as ionic characterisation (cation or anions) and sizing. This data has been used to implement the correct strategy for removing the particulates in the design. Installing an ESP in the demonstration plant was not cost or time efficient, but Assured Environment was able to sample and determine the particulates sizing.

Figure 4-11 shows that during Run 9, NOx and SOx had no exceedances. Although the CO limit appears to exceed a significant amount, these intervals were read every minute and the rolling average was 115 mg/m^3 within the limit of the 125 mg/m^3.

Figure 4-11: Run 9: 24-hour run (11/08/2020)

Run 11 (Figure 4-12) illustrates that NOx and SOx were controlled. The two exceedances for SOx were during start-up, which attributed to a CEMS blockage from previous runs. Although the CO limit was exceeded during a short period due to the maximum throughput being tested, which increased the particulates going through the oxidisers, the CO was again increased. This issue is being engineered out and will not be an issue with the full-scale facility.

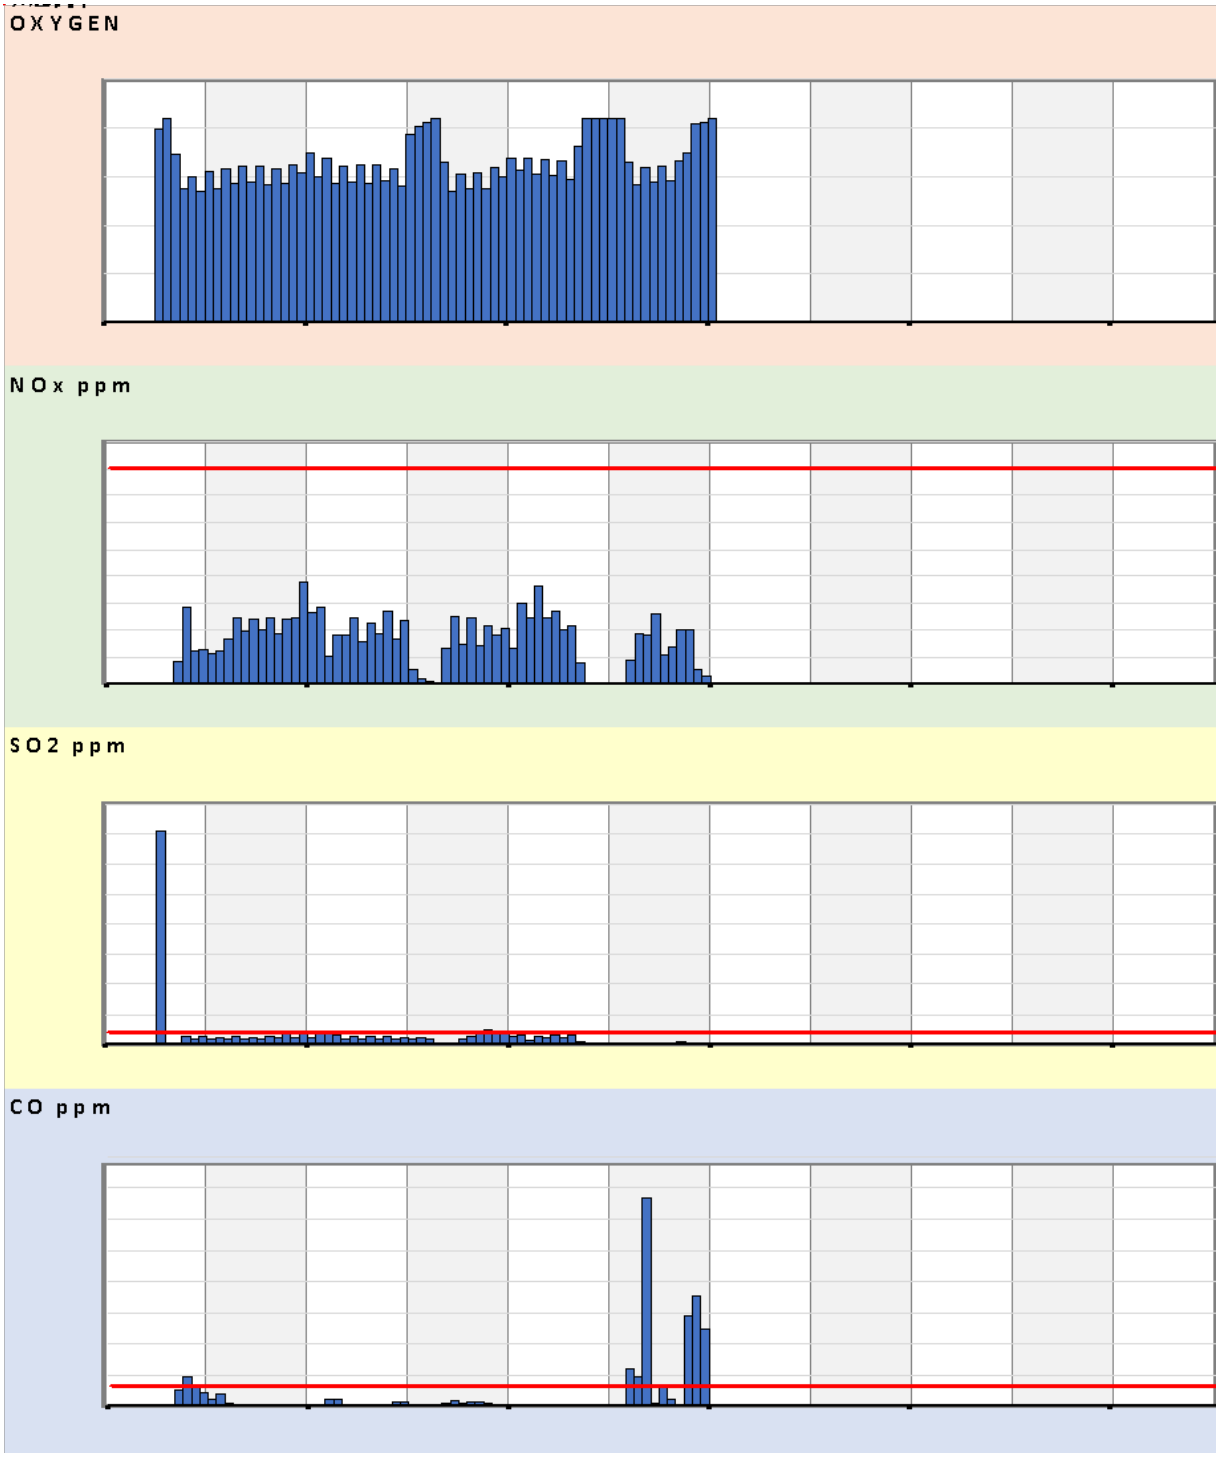

Figure 4-12: Run 11: 48-hour run (21/07/2020)

Run 12 (Figure 4-13) shows the NOx concentrations where within the limits; however, there were a few exceedances. These exceedances where due to dosing issues (blockages) and issues within the actual CEMS unit. This would not be an issue with the full-scale facility as there would also be limits and alerts set in place to assure this did not occur. The demonstration plant is much more manual then what is to be expected with the full-scale facility design. However, what the above results show is that urea can successful be used to mitigate NOx in a gasification facility.

SOx results demonstrate that MgOH is the best agent for mitigation in the air stream. There were two short exceedances, but this was again to do with manual error and would not be an issue with the full-scale facility.

There were issues with keeping within the limit of the CO. This demonstrates that there will be a requirement to engineer improved particulates capture in the full-scale facility, but it also could be due to the pelletizing of the dried biosolids through the respective dryers, which would not be an issue in the full-scale facility using belt dryers. The drum dryer handling techniques do produce a lot of dust and a high dried pellet density meaning that it is hard to get full combustion. Both factors do contribute to the CO and particulates; therefore, it is believed that by using the belt dryers this will reduce the risk.

The following is the data from the 100-hour run on the 27/07/2020.

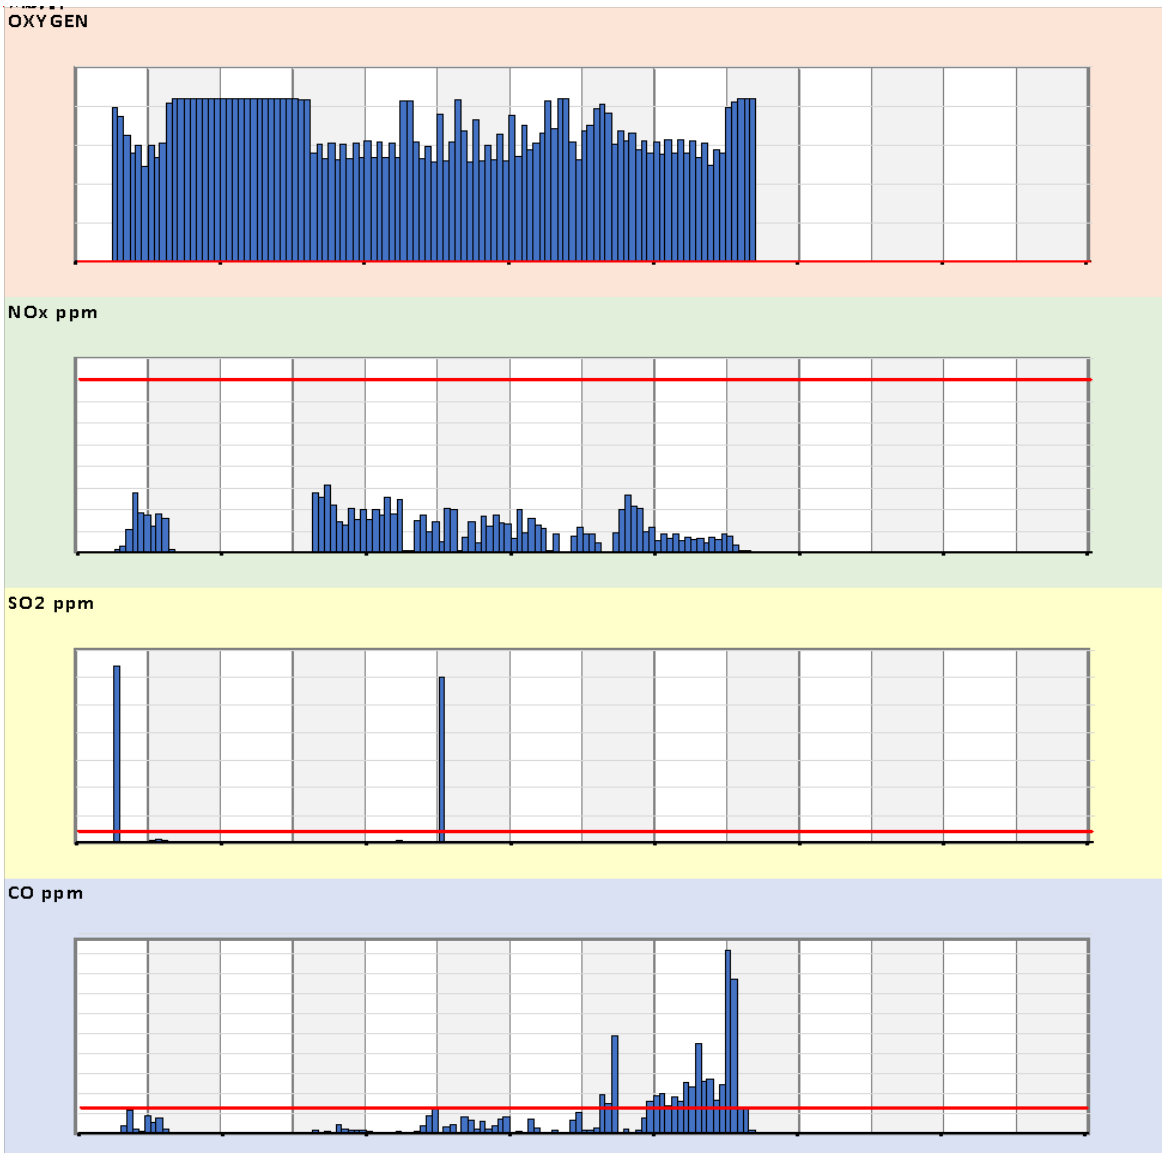

Figure 4-13: Run 12: 100-hour run (27/07/2020)

4.7 Full air emission results

This section provides a summary of the full air emissions results for three runs: 31/03/2020, 02/04/2020 and 22/07/2020.

As shown in Table 4-1 for the run on the 31 March 2020 there were no exceedances to the target limits set by the conditions of the EA.

Table 4-1: Air emission results—24-hour run (31/03/2020)

Parameter	< >	Result	Permit	Unit	Reference
Sample date		31/03/2020	-		-
Average source temperature		66	-	°C	-
Flue gas water vapour content		23	-	vol-%	-
Carbon dioxide concentration		7.0	-	vol-%	Sewage Treatment Plant (STP)
Oxygen concentration		12.2	-	vol-%	STP
Flue gas molecular weight—dry		1.3	-	kg/Nm^3	STP
Flue gas velocity		22.8	15 (min)	m/sec	-
Flue gas volume flow		66.8	-	Nm^3/min	STP
Particulate matter		17	-	mg/Nm^3	STP
- at 11% O_2		23	30	mg/Nm^3	
- emission rate		1.1	-	g/min	
Carbon monoxide		55	-	mg/Nm^3	STP
- at 11% O_2		69	125	mg/Nm^3	
- emission rate		3.5	-	g/min	
Oxides of nitrogen (as NO_2)		12	-	mg/Nm^3	STP
- at 11% O_2		16	400	mg/Nm^3	
- emission rate		0.7	-	g/min	
Sulfur dioxide (SO_2)		130	-	mg/Nm^3	STP
- at 11% O_2		160	200	mg/Nm^3	
- emission rate		8.3	-	g/min	
Hydrogen chloride		4.2	-	mg/Nm^3	STP

As shown in Table 4-2, the particulate matter failed the set limits when the oxygen correction factor was calculated. To mitigate this failure, the easiest and most cost-effective solution was the addition of the venturi as a way of mitigating dust particles. As a precaution, there was a break in runs and extra analysis was added to the schedule to investigate the exceedance and provide a corrective action.

Table 4-2 provides results of the particulate analysis after the addition of the venturi.

Table 4-2: Particulate analysis after the addition of a venturi—24-hour run (02/04/2020)

- at 11% O_2	0.75	-	mg/Nm^3	
- emission rate	0.021	-	g/min	

As shown in Table 4-4, the final full air emissions results show that the Loganholme demonstration plant could meet all the conditions set out in the EA. The 100-hour was the ideal run and showed that with the optimisation scheduled in the full-scale facility would be below the targets set in the EA. Table 4-4 also shows that the known issues, such as CO and particulates, can be optimised for the full-scale facility. Although the current EA can be met with current design, the addition of more analysis and determining the particulate sizing and characterisation has been prudent and efficient for making sure that tithe full-scale designs out these known risks.

Design modifications were made to the full-scale facility as part of the value engineering process. Extra analyses were conducted on 03/09/2020 to test these changes. The results show that the carbon monoxide and particulate concentrations were negatively affected by the changes to the oxidisers. The process can be engineered out in the full-scale facility with the addition of an ESP.

5. Biosolids and Biochar Characterisation

5.1 Biosolids analysis

This section is an in-depth analysis of the biosolids sourced from Victoria, as well as those from Loganholme and Beenleigh WWTPs. For reference, an independent review was undertaken on the Loganholme WWTP and the potential market for biochar using the analytical data from this report, titled *Char characteristics, potential value, and reuse options (Bridle, 2020)* (refer to Appendix A).

Drying concentrates the energy in sludge by removing water and increasing the gross calorific value, transforming the sludge into a combustible material. Several factors such as humidity, air velocity, sludge origin and the physical transformation of the material affect the drying operation, but temperature is the most influential parameter. Temperature affects the drying time, rheological properties, thermal stability, and the physicochemical characteristics of the biosolids, such as calorific value and nutrient content.

Thermal drying removes the moisture from sludge obtained from the Loganholme EETP (14% w/w solids), drying it through the belt filter press, which will change the content to >99% w/w solids. The belt dryers significantly reduce the moisture to below 10% w/w, reducing the cost for handling and transport. Drying biosolids at ≥80 °C also stabilises the material and destroys pathogens.

The potential for energy recovery from biosolids is a function of their composition, which is a mixture of organic (volatile) matter, inorganic matter (inert material) and associated water. The composition of biosolids may vary, and the energy recovery method and corresponding energy products must be compatible with the characteristics of the biosolids. Therefore, the volatile solids are important when considering the heat energy recovery.

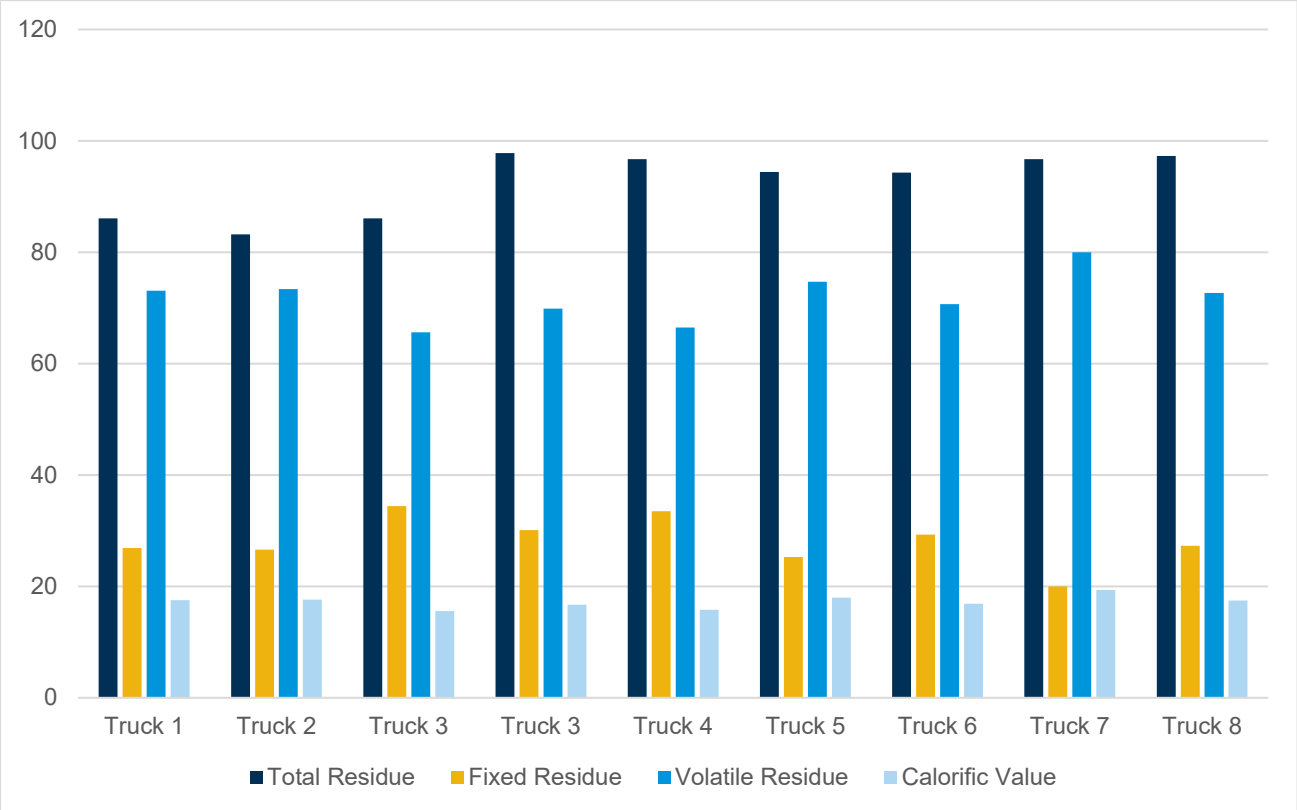

Figure 5-1: Biosolids chemical parameters: total residue (%), fixed residue (%), volatile residue (%) and calculated calorific value

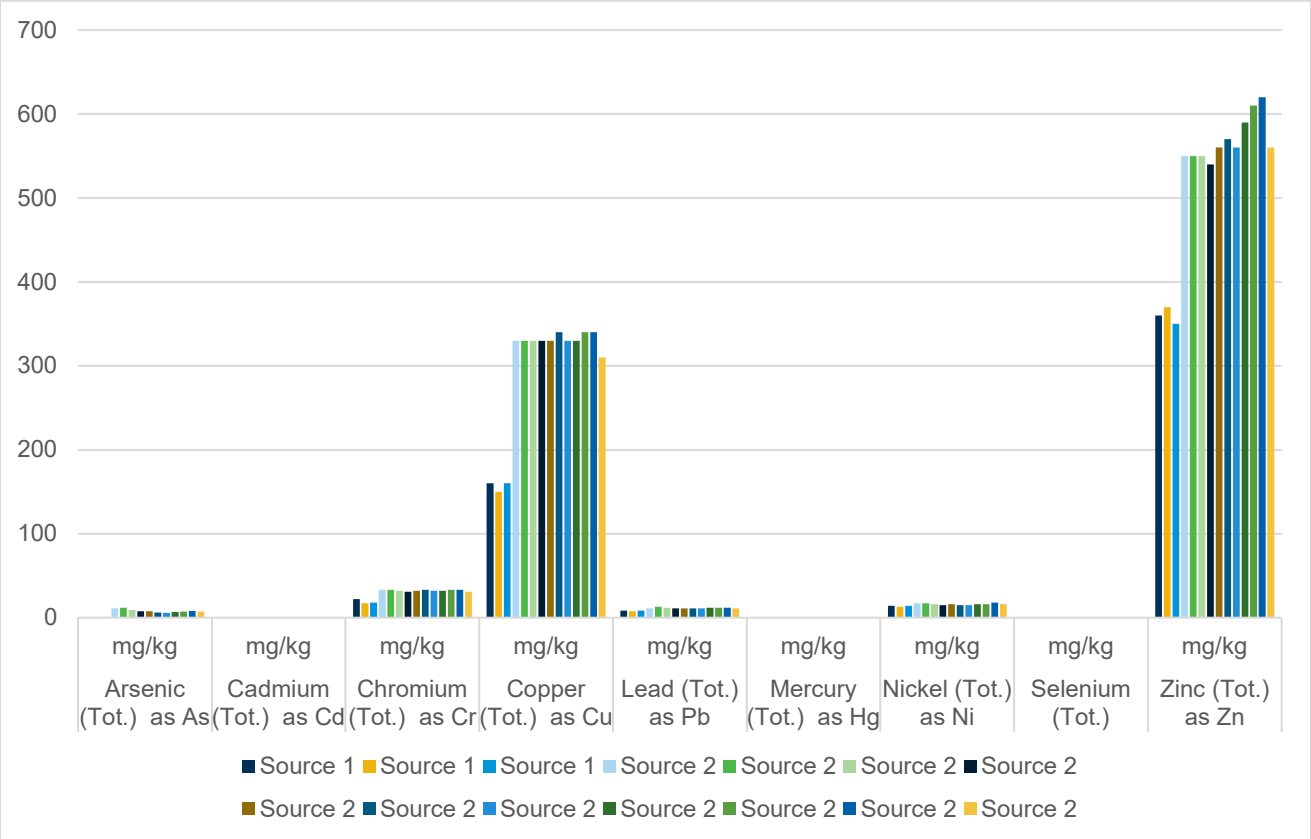
Figure 5-1 shows that the Source 2 biosolids had a higher percentage of total solids and a higher overall percentage of volatile residue, which in turn correlates to a higher calorific value. The Source 1 biosolids had

an average calorific value of 19.26 MJ/kg. Source 2 biosolids had lower calorific values, which is to be expected due to the biosolids degrading while being stockpiled at a third-party storage for many months. This would not be an issue for the Loganholme biosolids gasification facility because it will process all biosolids as they are dried, and no storage will be involved. This is explained in detail in Section 7 Heat balance.

Biosolids are mainly a mix of water and organic matter and may contain:

- Macronutrients, such as nitrogen, phosphorus, potassium, and sulfur
- Micronutrients, such as copper, zinc, calcium, magnesium, iron, boron, molybdenum, and manganese.

Biosolids may also contain traces of synthetic organic compounds and metals, including arsenic, cadmium, chromium, lead, mercury, nickel, and selenium. These trace compounds can limit the uses for biosolids, with all potential uses regulated in Queensland by the *End of Waste Code for Biosolids* (DES,2020).



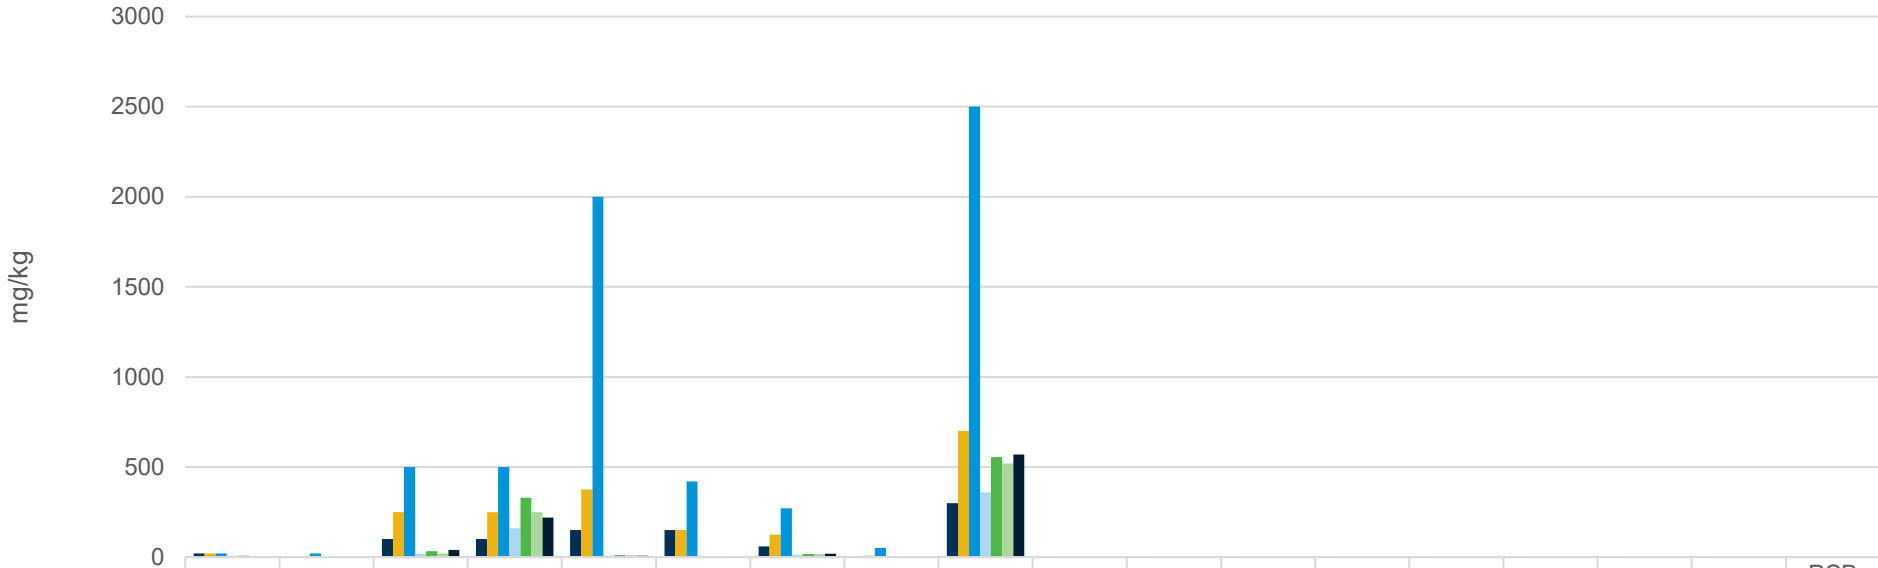


Figure 5-2: Comparison of trace metals in biosolids sources

Figure 5-2 shows the trace metals in the two sources of biosolids. Biosolids from any WWTP will usually have micronutrients such as copper and zinc. These trace metals are of high value in Australia for farmers; this benefit is undervalued in LCC's Biosolids Management Strategy.

The main difference between the two sources of biosolids for detectable heavy metal is that Source 2 has a higher concentration than Source 1, including arsenic, chromium, copper, lead, nickel, mercury, and zinc.

The heavy metal content of biosolids should be taken into consideration, but Source 2 is in a significantly more industrial catchment, which would explain the higher metal concentrations.

Figure 5-2 shows the average of the trace metals in each biosolids source, compared to the average trace metals found in the Loganholme WWTP biosolids.

	Arsenic (Tot.) as As	Cadmium (Tot.) as Cd	Chromium (Tot.) as Cr	Copper (Tot.) as Cu	Lead (Tot.) as Pb	Mercury (Tot.) as Hg	Nickel (Tot.) as Ni	Selenium (Tot.)	Zinc (Tot.) as Zn	DDT/DDD/DDE (sum)	Aldrin	Dieldrin	Chlordane (sum)	Heptachlor (sum)	HCB	Lindane	BHC (sum)	PCB total (sum of Aroclors)

Beenleigh	0	0	40	220	8.2	0.2	19	0	570	0	0	0	0	0	0	0	0	0

Figure 5-3: Comparison of heavy metals in biosolids

Figure 5-3 compares the biosolids from interstate sources to samples from Loganholme and Beenleigh WWTPs and the grades in the *End of Waste Code for Biosolids* (DES,2020). Figure 5-3 illustrates that all the sources of biosolids comfortably fall within in the category of Grade B Biosolids.

The contaminate grading for all sources of biosolids is Grade B (the rules for Zn and Cu from the *NSW Biosolids Guideline* is still in place in the *End of Waste Code for Biosolids* (DES,2020). Loganholme WWTP has several unusually high heavy metal results for As, Cr, Ni and Zn due trade-waste contamination.

The organic contaminates such as aldrin, dieldrin, chlordane, heptachlor, HCB, Lindane, BHC, DDT, DDE, DDD, PCB where analysed for the biosolids sourced from Victoria, but the limits were all below the detectable level. One organic contaminant found in biosolids from Beenleigh WWTP is dieldrin. Dieldrin was popular in the 1950s through to the 1970s as a pesticide, but it was banned in Australia in the late 1990s. Therefore, its presence at Beenleigh WWTP, although in low concentrations, should be monitored by the LCC Trade Waste Team.

5.2 Biochar analysis

Biochar is a kind of charcoal created when biomass or organic material is combusted at temperatures of 300–600 °C with limited oxygen. The biochar produced from 100% biosolids source is currently an unverified medium, which means a significant amount of analysis is required to prove the beneficial reuse of this product. However, overall, biochar contains high levels of carbon and nutrients, and a significant cation-exchange capacity. Most of the carbon in the biochar is sequestered (Lehmann, Gaunt, & Rondon, 2006) meaning that it is highly recalcitrant, with carbon turnover on a timescale of millennium, reducing greenhouse gas emissions from soils or from waste management practices. Biochar has significant demonstrated benefits for improving soil properties. The benefits of adding biochar to soil depends on the material used to produce the biochar (feedstock) and the temperatures achieved during gasification (carbonisation).

One study conducted by Bridle (Bridle, Cote, Constable, & Fraser, 1987) determined that biochar produced from biosolids contains low amounts of plant-available N, despite containing a low C:N ratio value of 7 and an elevated amount of total N (6.4%). This study reported that 45% of the initial N was not present in the final biochar, whereas losses of P during pyrolysis were negligible. Lower amounts of N were present, compared to the original biosolids, corroborated by other studies (Dokht, Naeini, Dordipour, De Jong, & Hezarjanbi, 2017). Biochar from biosolids contributes to soil retention of N in the long-term, acting as a slow release fertiliser. Ammonium and nitrate leaching are reduced following biochar amendment.

As part of the demonstration plant, the biochar produced from the two sources has been analysed. Figure 5-4 illustrates the biosolids and biochar analyses from Source 1.

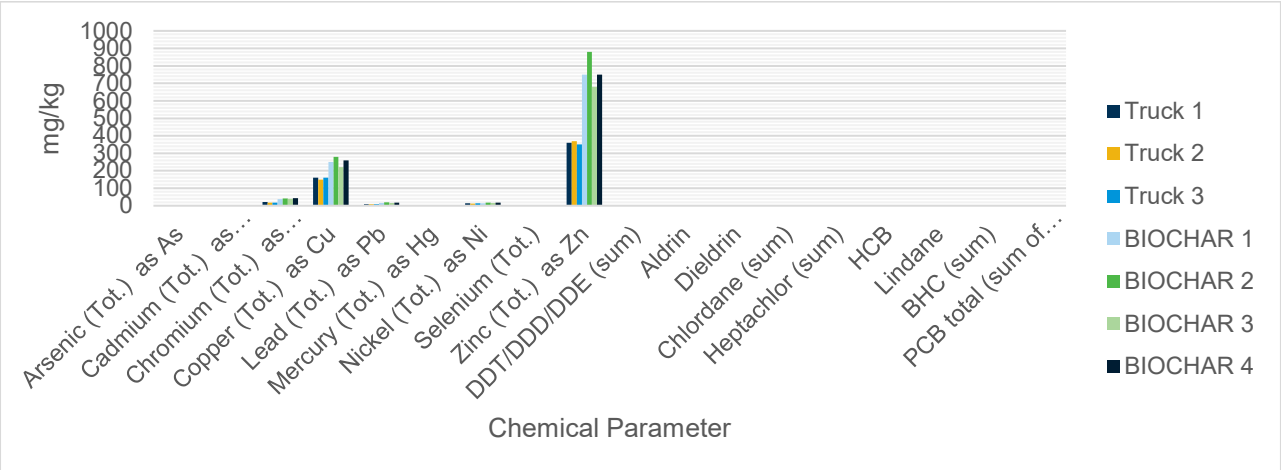

Figure 5-4: Source 1 biosolids and biochar characterization

Figure 5-4 shows that, as expected, once the biosolids are processed through the gasification unit, the concentrations of trace metals increase. Table 5-1 shows the difference in the material after it was treated through the gasification facility and how the biochar compares to the contaminant grading under the *End of Waste Code for Biosolids (*DES, 2020).

Table 5-1: Source 1 analysis of biosolids and biochar processed through the demonstration plant

	Biosolids	Biochar	Difference	Limit set in the EoW Code for Biosolids (Queensland)		
				GRADE A	GRADE B	GRADE C
Arsenic (Tot.) as	<5.0	<5.0		20	20	20
Cadmium (Tot.) as Cd	<0.50	<0.50		3	5	20
Chromium (Tot.) as Cr	19	40	53	100	250	500
Copper (Tot.) as Cu	157	253	38	100	250	500
Lead (Tot.) as Pb	8.2	17	53	150	375	2000
Mercury (Tot.) as Hg	0.1	<0.1		150	150	420
Nickel (Tot.) as Ni	14	16	15	60	125	270
Selenium (Tot.)	<5.0	<5.0		5	8	50
Zinc (Tot.) as Zn	360	765	53	300	700	2500
DDT/DDD/DDE (sum)	<0.02	<0.02		0.5	0.5	1
Aldrin	<0.02	<0.02		0.02	0.2	0.5
Dieldrin	<0.02	<0.02		0.02	0.2	0.5
Chlordane (sum)	<0.02	<0.02		0.02	0.2	0.5
Heptachlor (sum)	<0.02	<0.02		0.02	0.2	0.5
HCB	<0.02	<0.02		0.02	0.2	0.5
Lindane	<0.02	<0.02		0.02	0.2	0.5
BHC (sum)	<0.02	<0.02		0.02	0.2	0.5
PCB total (sum of Aroclors)	<0.1	<0.1		<0.1	0.3	1

Table 5-1 also shows the differences in trace metal concentration. As expected, the metals present in the biosolids, such as Cr, Pb and Zn, increased by ~50%. The other contaminant to note is mercury, which was present in the biosolids, but not in the biochar. Metals such as mercury, cadmium and arsenic have low boiling points; when they are processed through the hearth, they become volatile and become part of the biogas.

Under the *End of Waste Code for Biosolids* (DES,2020), the biochar produced from the Source 1 biosolids would be classified as a Grade C rather than a Grade B contaminate, because of the Zn and Cu levels. The biochar would be classified as Restricted Use 2, as the pathogen reduction is by thermal treatment and the contaminate limits would be graded Grade C. This would mean that the biochar could be used for:

- Agriculture
- Forestry
- Soil and site rehabilitation.

These applications fit the current view that biochar would make a useful soil ameliorant (Hossain, Strezov, Chan, & Nelson, 2010) especially as the increased levels of Zn and Cu, which are typically low in Australian soils, would be sought after by farmers, making the biochar more valuable as a product.

Figure 5-5 shows the biosolids and biochar analysis for Source 2.

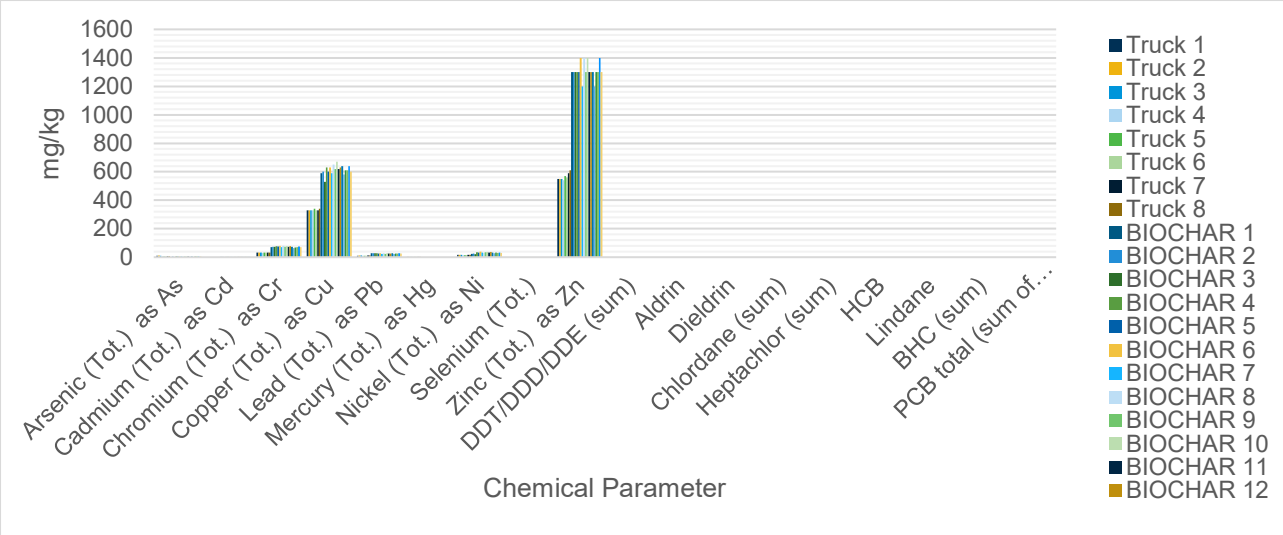

Figure 5-5: Source 2 biosolids and biochar characterisation

Like the biosolids from Source 1, when the biosolids from Source 2 were processed through gasification, the trace metals present were more concentrated in the biochar.

Table 5-2 shows the differences in the Source 2 after it was treated through the gasification facility and how the biochar compares to the contaminant grading under the *End of Waste Code for Biosolids* (DES,2020).

Table 5-2: Source 2 analysis of biosolids and biochar processed through the demonstration plant

	Biosolids	Biochar	Difference	Limit set in the EoW code for Biosolids (QLD)		
				GRADE A	GRADE B	GRADE C
Arsenic (Tot.) as	8.21	4.4		20	20	20
Cadmium (Tot.) as Cd	<1.0	1.4		3	5	20
Chromium (Tot.) as Cr	32.	73	56	100	250	500
Copper (Tot.) as Cu	333	613	46	100	250	500
Lead (Tot.) as Pb	12	26	56	150	375	2000
Mercury (Tot.) as Hg	0.39	<0.1		150	150	420
Nickel (Tot.) as Ni	16	31.	50	60	125	270
Selenium (Tot.)	<5.0	<5.0		5	8	50
Zinc (Tot.) as Zn	565	1312	57	300	700	2500
DDT/DDD/DDE (sum)	<0.02	<0.02		0.5	0.5	1
Aldrin	<0.02	<0.02		0.02	0.2	0.5
Dieldrin	<0.02	<0.02		0.02	0.2	0.5
Chlordane (sum)	<0.02	<0.02		0.02	0.2	0.5
Heptachlor (sum)	<0.02	<0.02		0.02	0.2	0.5
HCB	<0.02	<0.02		0.02	0.2	0.5
Lindane	<0.02	<0.02		0.02	0.2	0.5
BHC (sum)	<0.02	<0.02		0.02	0.2	0.5
PCB total (sum of Aroclors)	<0.1	<0.1		<0.1	0.3	1

Table 5-2 shows that after the biosolids are treated through gasification process, the trace metals present are more concentrated with an ~50% increase in the biochar, except for As and Hg (Yanjun, Guanyi, Wenchao, Mi, & Long, 2016). This result is expected because metals such as and Hg will decrease due to their boiling point because, after being processed through the gasification unit, they become volatile and part of the biogas stream. Therefore, it is recommended that when monitoring it would be prudent to characterise the biosolids before they are processed by the gasifier annually.

Under the *End of Waste Code for Biosolids* (DES,2020), the biochar produced from the Source 2 biosolids would be classified a Grade C rather than Grade B contaminate because of the Zn and Cu levels. The levels increase the value of the product as a soil ameliorant for farmers in the agricultural sector. The bioavailability of Cu and Zn are not usually valued; however, farmers use CU and zinc sulfate as well as a range of other trace metals to aid plant growth. Based on the main micronutrients present in biosolids, that is copper and zinc, the value of biosolids can be derived from the market price for CU and zinc sulfate, given they are the most used metals applied to land.

Comparing the Loganholme WWTP biosolids to those from Source 1 and Source 2, although useful, cannot be a direct comparison because the Source 1 and Source 2 biosolids have already been through a dewatering and drying process; therefore, the biosolids characterisation would be different, although there should not be a change in the metal concentration as mg/kg dry. This illustrates that because of the Zn and Cu values, the same results are expected from the Loganholme biosolids; therefore, they would also be classified as a Grade C contaminant, requiring thermal treatment to be classified as a Restricted Use 2.

Therefore, in a worst-case scenario, biochar from the Loganholme WWTP would be classified as Restricted Use 2 under the *End of Waste Code for Biosolids* (DES,2020) (no change to current classification), which means it can be used for:

- Agriculture
- Forestry
- Soil and site rehabilitation.

Provided that the biosolids meet the contaminant and pathogen reduction requirements specified in the *End of Waste Code for Biosolids* (DES, 2020), the biosolids are not considered to be waste, but rather a resource that can be reused in agriculture. However, to open other areas of marketability for biochar (Martin & Craggs, 2010) would be a key driver to develop an End of Waste Code for Biochar.

6. Emerging Contaminates of Concern

This section is an overview of how the demonstration plant addresses its objective of the quality of the biochar product and confirming destruction of Persistent Organic Pollutants (POPs) and contaminates of concern.

6.1 Perfluoroalkyl substances

PFAS is a POP found in biosolids (Latimer, 2016). PFAS are manufactured chemicals that have been used in everyday household items. PFAS make products non-stick; water repellent; and fire, weather, and stain resistant and are used in a range of consumer products, such as carpets, clothes, and paper, and have also been used in firefighting foams, pesticides, and stain repellents.

The chemical structure of PFAS, including variations in chemical structure between different types of PFAS, is an important consideration for understanding the behaviour of PFAS in the environment. The high solubility of PFAS in water means that PFAS may readily leach from soil to surface water and groundwater, where they can move long distances to enter creeks, rivers and lakes and become part of the food chain, being transferred from organism to organism (Rutludge, Cole, & Prasad) (USEPA, 2017).

In Queensland, PFAS monitoring has been included in the *End of Waste Code for Biosolids* (DES, 2020). This is the only regulatory standard for biosolids in Australia to date and the methodology for monitoring for PFAS is still being developed. As of January 2020, the application of biosolids to agricultural land is subject to the following PFAS-specific trigger values (Table 6-1), which apply after the application of biosolids to land.

Table 6-1: Trigger values for PFAS in soil after the application to land

Sum of PFOS and PFHxS	PFOA	Land use
0.01 mg/kg	0.1 mg/kg	Residential with garden/accessible soil (HIL A)
2 mg/kg	20 mg/kg	Residential with minimal opportunities for soil access (HIL B)
1 mg/kg	10 mg/kg	Public open space (HIL C)
20 mg/kg	50 mg/kg	Industrial/ commercial (HIL D)

Table 6-1 shows the trigger limits are in addition to other maximum allowable soil contaminant concentrations specified in the code. Sampling of the biosolids for PFOS, PFHxS and PFOA must be undertaken for every 120 tonnes of biosolids applied, in addition to post-application sampling to assess against the trigger values (Taylor & Yamada, 2003). TOPA analysis should be used to determine the PFAS concentrations in the soil prior to application of biosolids.

As PFAS analysis is a rapidly evolving field, there are recent advances in analytical systems and techniques. Therefore, PFAS were monitored by three different methods in the demonstration plant: TOP ASSAY, USEPA Method, and TOP Assay EWi (HPLC/MS). Table 6-2 is an extract from the PFAS NEMP 2.0 (Department of Agriculture, Water, and the Environment, 2020), which explains the different analytical methods and the limitations of these methods.

Table 6-2: PFAS standard methods of analysis

Method	Use	Sample matrices	Limitations	Analytes
USEPA Method EPA-821-R-11-007 Draft Procedure for Analysis of Perfluorinated Carboxylic Acids and Sulfonic Acids in Sewage Sludge and Biosolids by HPLC/MS/MS December 2011	To analyse for specific analytes in sewage sludge and biosolids	Sewage sludge and biosolids	**Only analyses for specific PFAS** Further details in the reference	PFBA, PFPA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnDA, PFDoDA, PFTriDA, PFTeDA, PFBS, PFHxS, PFHpS, PFOS, PFOSA, NMeFOSA, NEtFOSA, NMeFOSE, NEtFOSE

Method	Use	Sample matrices	Limitations	Analytes
Total Oxidisable Precursor Assay (TOP Assay)	**Can be used in conjunction with a USEPA method to estimate the total PFAS, and sometimes the approximate end point PFAS.** Can help inform risk assessment	Water samples and extracts including soil, biota, firefighting foam products and wastes	**Cannot be used to target exact PFAS precursors, as it is a semi-quantitiveP69FP69F1PP method. Allows for some inferences as to precursor chain length**	Total PFAS chains (C4-C14)
Total Organic Fluorine Assay (TOF Assay) as combustion ion chromatography (the most common method available)	Can be used in conjunction with a USEPA method to understand the total presence of organic fluorine in a sample and compare this to the organic fluorine equivalent detected by the USEPA method	Water samples and extracts including soil, biota, firefighting foam products and wastes	**Cannot be used to target exact PFAS precursor compounds**	Total organic fluoride corrected to remove inorganic forms

All of the biosolids data analysed in the following section used the accredited method TOP assay, originally published by Houtz and Sedlak (Hossain, Strezov, Chan, & Nelson, 2010), which is widely used as an estimate of the total perfluoro alkyl acids (PFAA) content of a sample, particularly in wastewater and biosolid matrices.

The laboratory contracted to undertake the PFAS analysis is developing an experimental method, which is still TOP assay, but uses a different set of analysis parameters that provide for a more robust oxidation of the pre-cursor substances that yield a higher extraction value. This method is still under development and peer review; however, the current parameters for extraction of samples via this method are consistent. It is believed that:

> '…the Houtz and Sedlak (Houtz, Sutton, Park, & Sedlak, 2016) method significantly underestimated the levels of PFAS compared with the modified method, which showed a 10-fold increase in the measured PFAS after digestion'. (Hutchinson, Rieck, & Wu, 2020).

Each biosolid or biochar sample was analysed via the complementary methods to gain a wholistic understanding of the biosolids and biochar characteristics. However, only data from the accredited method was used in statistical analysis.

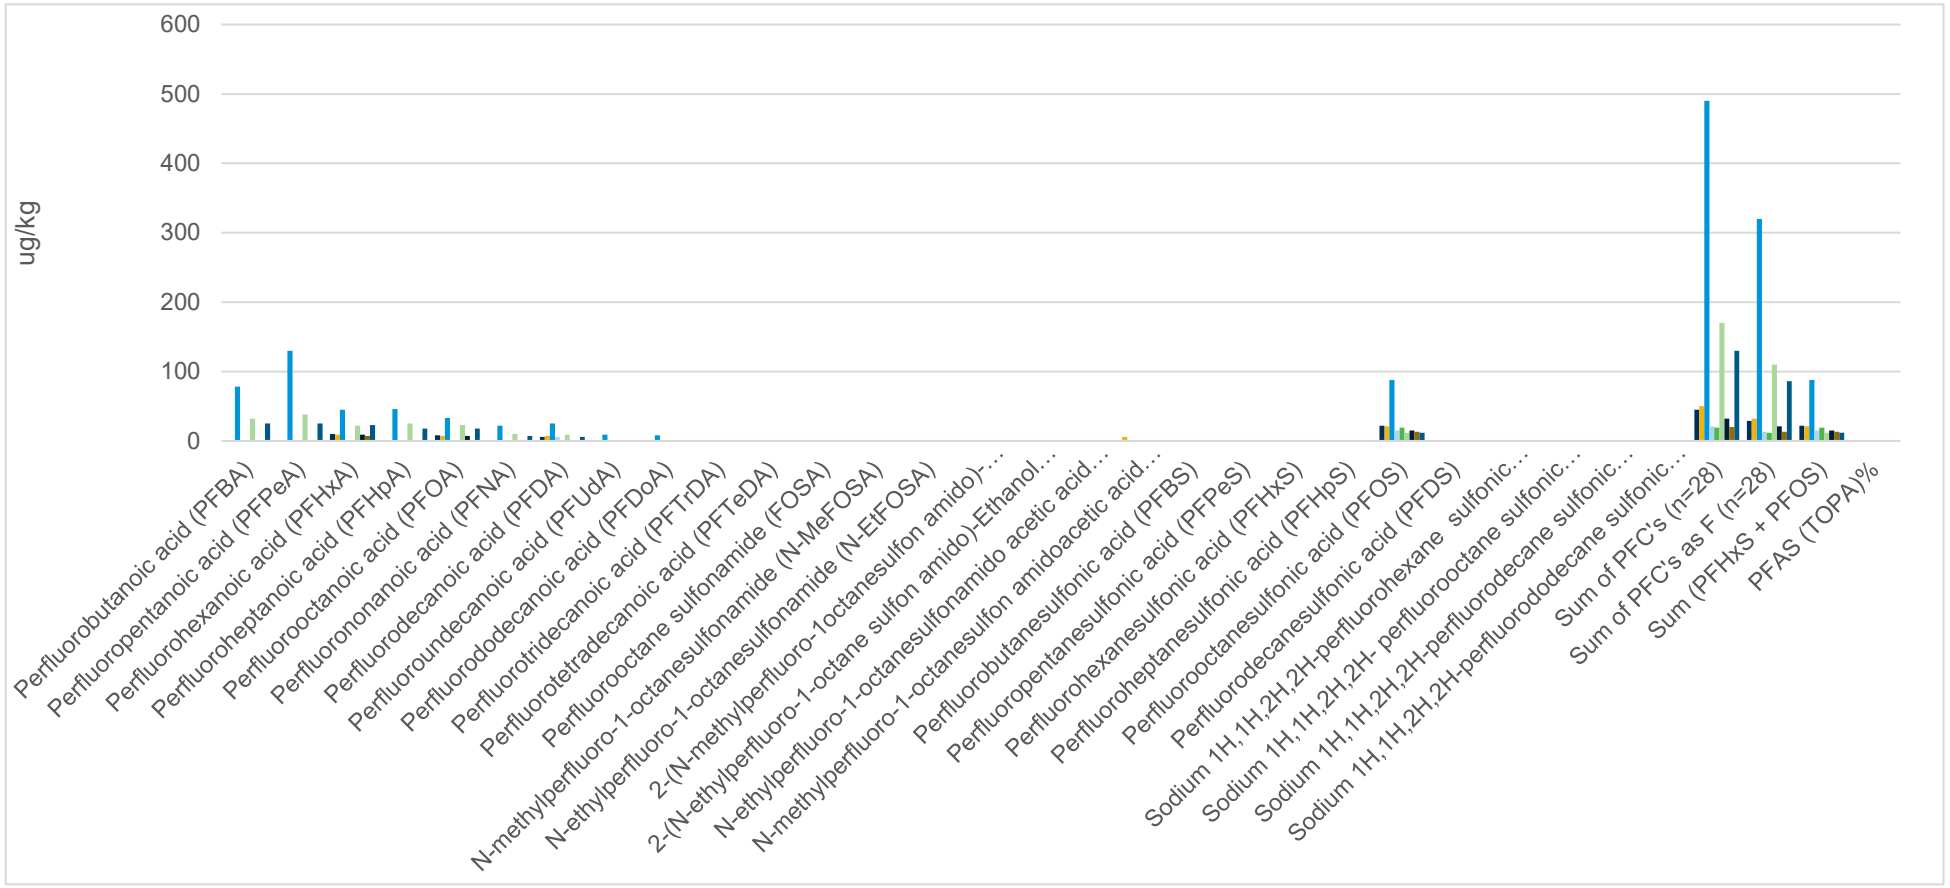

Figure 6-1: Source 1 PFAS concentrations

Figure 6-1 is an overview of the PFAS concentrations found in the biosolids from Source 1. The PFAS concentration found in these biosolids would not meet the criteria to apply to residential land with garden-accessible soil. The Source 1 biosolids average sum of PFHxS + PFOS was 17ug/kg and PFOA was 5ug/kg. Therefore, the PFAS concentration exceeds the trigger values for the use in residential areas and would need to be closely regulated.

Figure 6-2 is an overview of the PFAS concentrations found in the biosolids from Source 2.

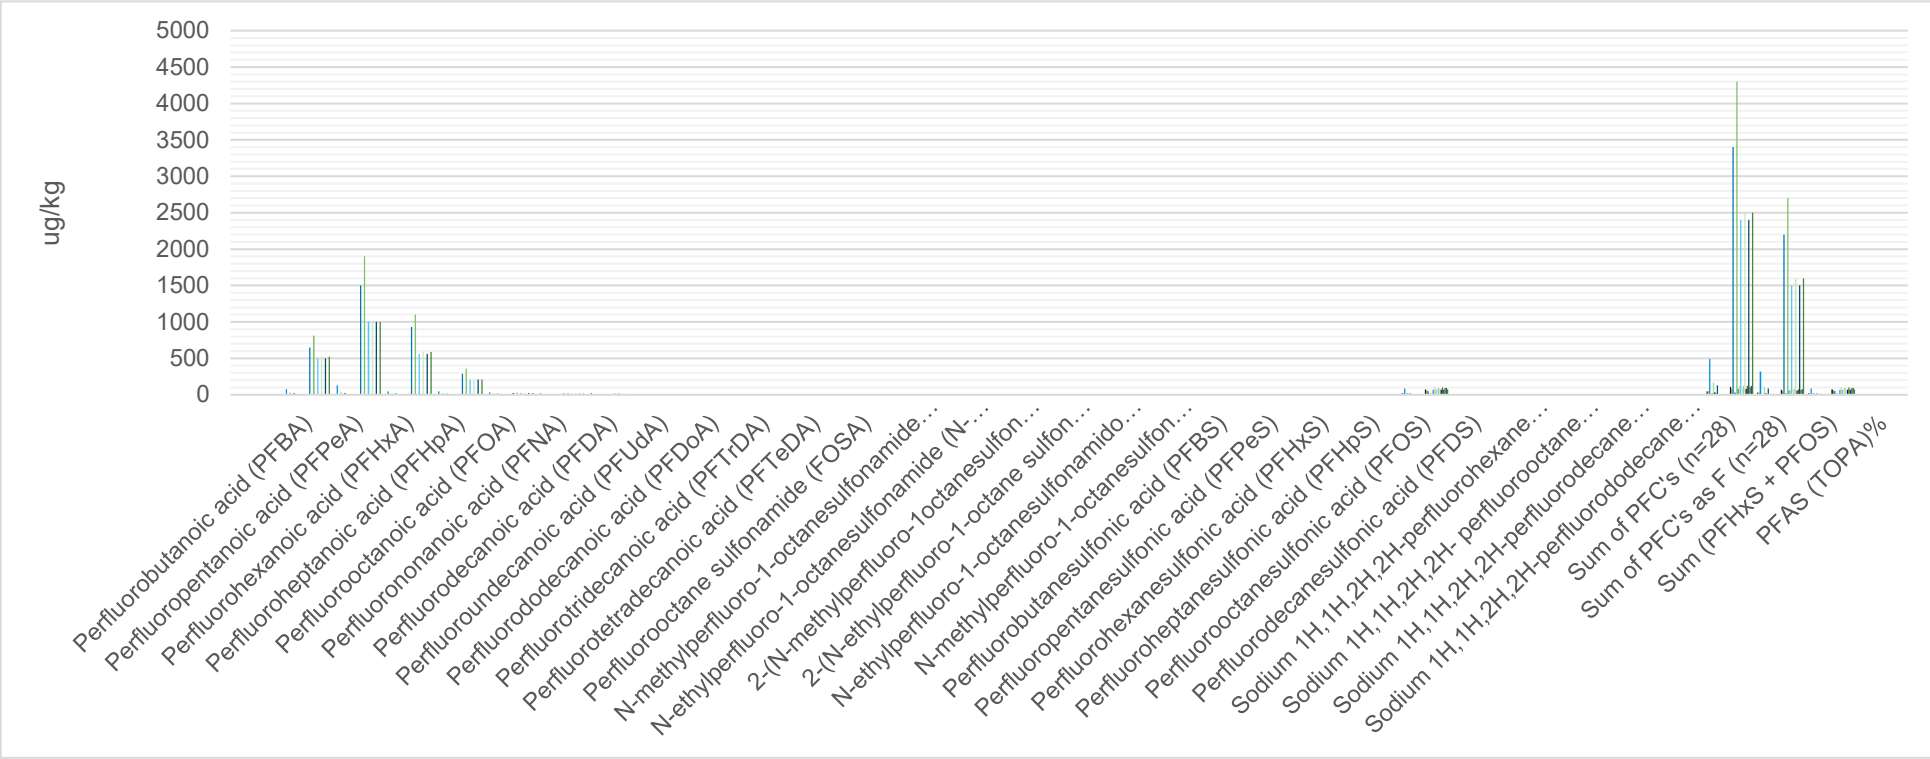

Figure 6-2: Source 2 PFAS concentration

Figure 6-2 is an overview of the PFAS concentrations found in the biosolids from Source 2. The PFAS concentration found in these biosolids would not meet the criteria to apply to residential land with garden-accessible soil. The PFAS concentrations for Source 2 biosolids are even higher than Source 1 and would not be meet the criteria to apply to public open spaces. Source 2 biosolids average sum of PFHxS + PFOS was 38ug/kg and PFOA the was <5ug/kg. Therefore, the PFAS concentration exceeds the trigger values for the use in residential areas and public open spaces and would need to be closely regulated.

6.2 Loganholme and Beenleigh WWTP PFAS concentrations

Figure 6-3 illustrates a direct comparison of biosolid samples from Loganholme and Beenleigh WWTPs.

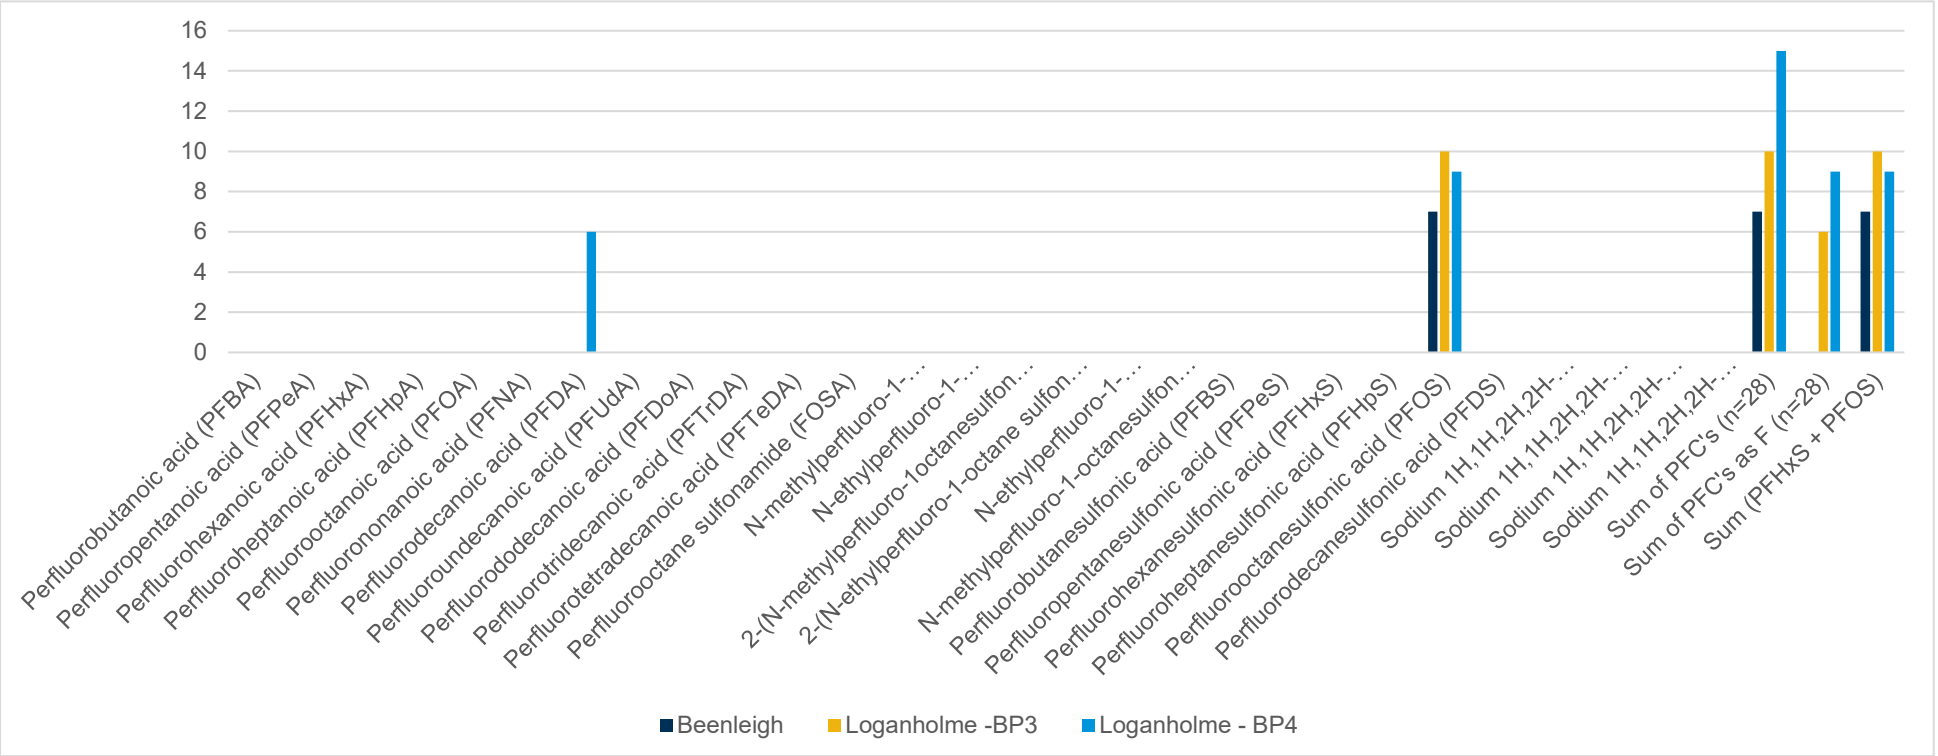

Figure 6-3: Loganholme and Beenleigh WWTP PFAS concentrations

Figure 6-3 is an overview of the PFAS concentrations found in the Loganholme and Beenleigh WWTP biosolids. The sum of PFHxS + PFOS for Loganholme WWTP belt press 3 (BP3) was 10 ug/kg and for belt press 4 (BP4) 9 ug/kg and PFOA was <5ug/kg for both sets of samples. For Beenleigh WWTP, the sum of PFHxS + PFOS was 7 ug/kg and PFOA was also <5 ug/kg. Therefore, the PFAS concentration, although within the detection levels, does not exceed the trigger values for soil application and, in its current form, is within the range for residential use.

6.3 Biochar and PFAS

Once the biochar was processed through the demonstration plant, the sum of all (PFHxS + PFOS) or PFAS TOPA% for Source 1 biosolids was <0.5ug/kg or not detectable (in four samples in total).

For Source 2, 24 biochar samples were analysed for the TOP assay method and PFHxS + PFOS was 2ug/kg and PFOA was also <0.5ug/kg. It is assumed that one of the reasons for the detection of PFAS in the biochar samples is that characteristics of the Source 2. Being processed thorough a 'pelletiser' dryer means that the biosolids are produced as spherical pellets, which are quite dense and, in some cases, have quite large particle sizes. This size is not conducive to being able to be processed and fully charred through the hearth. Sampling from the system was also difficult; however, Figure 6-4 are photos of the samples were received by the laboratory.

Figure 6-4: Source 2 pellets sizes produce biochar that is not fully charred

This is not the process that would occur in the full-scale facility due the use of the belt dryers, which produces more of a crumb rather than a pellet. All particle sizes would be within the range of 3–10mm. For corrective action, the bags of biochar were resampled two weeks later, which is out of holding time. However, but all these samples produced lower results and the average of sum was 1 ug/kg, which illustrates the importance of particle size consistency.

During the gasification process, all the PFAS compounds are made volatile in the hearth and then they progress through to the oxidiser. Therefore, the biochar does not contain PFAS at concentrations that would trigger the soil application limits and is a better overall product that will stop the bioaccumulation process in the environment.

6.4 Mass valance for PFAS

Table 6-3 is a mass balance that incorporates all data from all the sources: biosolids samples from both Source 1 and Source 2; the scrubber water (in the full-scale facility this water will return to the inlet works or be used as quenching water); and the stack (three full air emissions analyses). The oxidisers were incorporated in the air emissions analysis to give guidance on whether one or two oxidisers were required in the full-scale facility. The results show that only one oxidiser is required for each gasifier.

Table 6-3: PFAS mass balance

Perfluoroalkyl substances (PFAS) mass balance											
Analytes	**Biosolids**		**Biochar**		**Oxidisers**		**Scrubber**		**Stack**		**% Destruction**
	µg/kg	**µg/hour**	**µg/kg**	**µg/hour**	**g/min**	**µg/hour**	**µg/L**	**µg/hour**	**g/min**	**µg/hour**

	0	0	0	0	0.00000197	0.033	0	0	0.000000283	17.0079	**94**

Table 6-3 shows that the overall mass balance for PFAS destruction through the process of gasification facility, which is 94% destruction of this persistent organic pollutant. This verifies that the gasification process when carbonisation occurs of the biosolids PFAS becomes volatile and is transferred to the off gas and is then destroyed in the thermal oxidisers. There was cross contamination seen when the biosolids particles sizes were too large and dense to fully carbonise and this carry over is not expected when processed through the belt dryers in the full-scale facility.

6.5 Microplastics

Microplastics are plastics smaller than 5 mm and they fall into two broad types:

- Primary-intentionally produced plastics, for example microbeads from toothpaste or glitter from cosmetics
- Secondary-resulting plastics from the weathering of larger plastics such as microfibres, that may cause adverse effects in organisms and ecosystems.

In Australia, between 2800 and 19,000 tonnes of microplastics are applied to agro-ecosystems each year through biosolids. Figure 6-5 shows examples of microplastics found in biosolids.

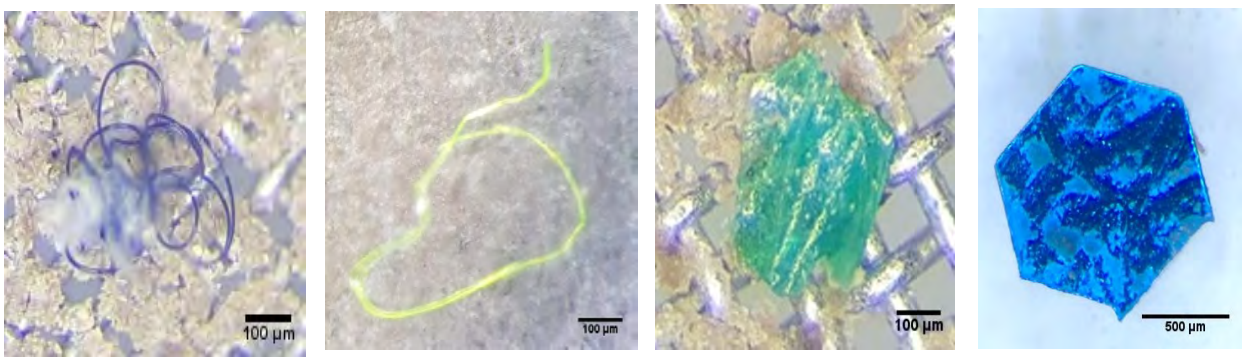

Figure 6-5: Micro and nano-plastics: microfibers, fragment (100µm), glitter (500µm)

The Source 1 biosolids contained a high proportion of microplastics. On average, the biosolids contained 8.8 particles/gram. Figure 6-6 shows the size of microplastics found in the biosolids and after they had been treated through the gasification process.

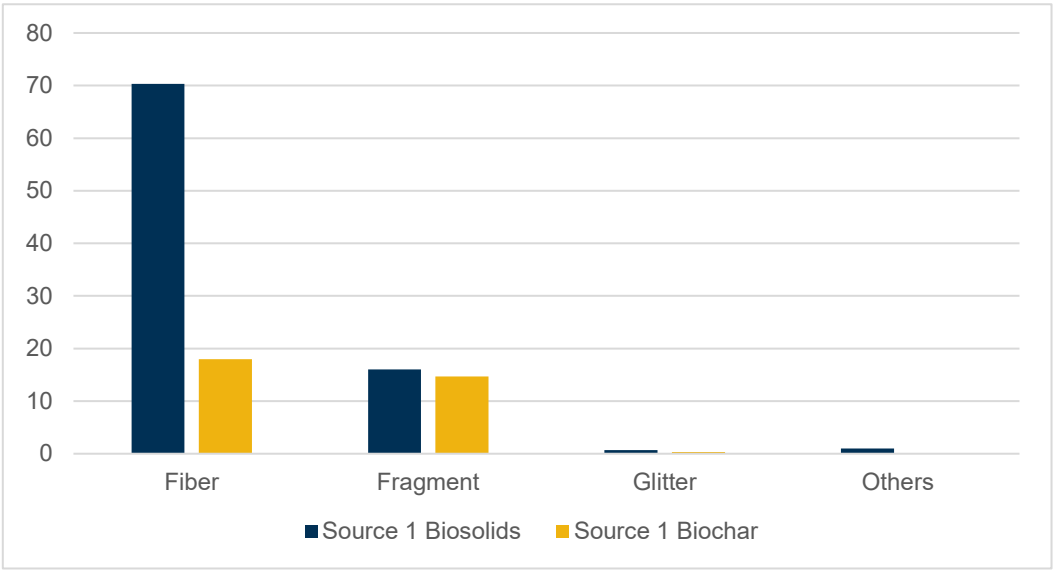

Figure 6-6: Source 1 types of microplastics in the biosolids and biochar

Figure 6-7 illustrates the particle types found in the Source 1 WWTP samples and after the treatment through the gasification system. It shows the gasification process reduces the microplastic plastic concentration; 1mm (81% less), 250µm (72% less), 150µm (60% less) and 63µm (35% less).

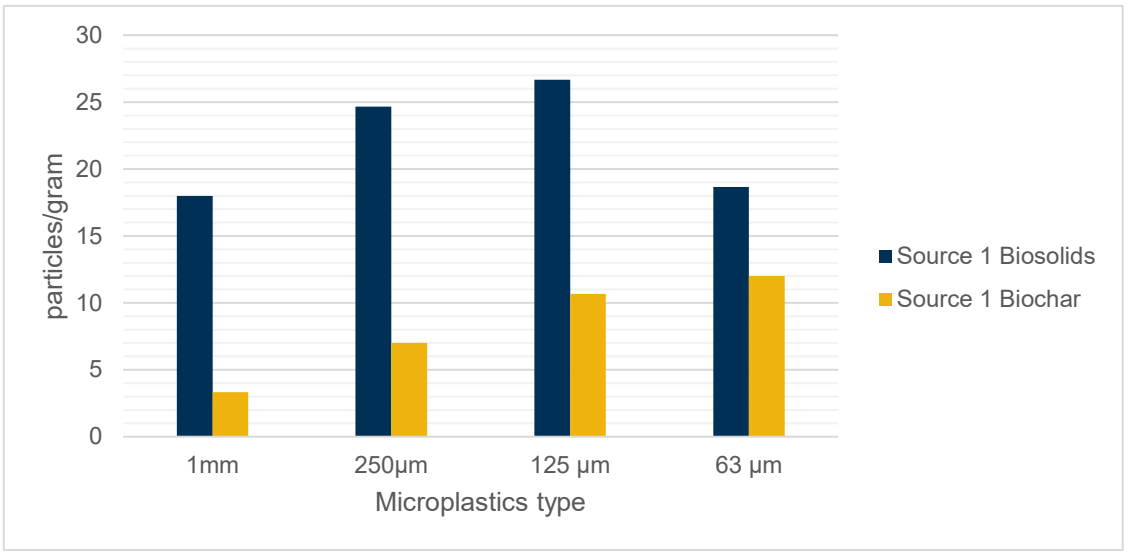

Figure 6-7: Source 1 microplastic types in the biosolids and biochar

Figure 6-7 shows that the gasification process destroys more of the fibre type microplastics with a 74% destruction rate compared with fragment (8%), glitter (50%) and others (100%). This emerging contaminate of concern can be significantly reduced through the gasification process.

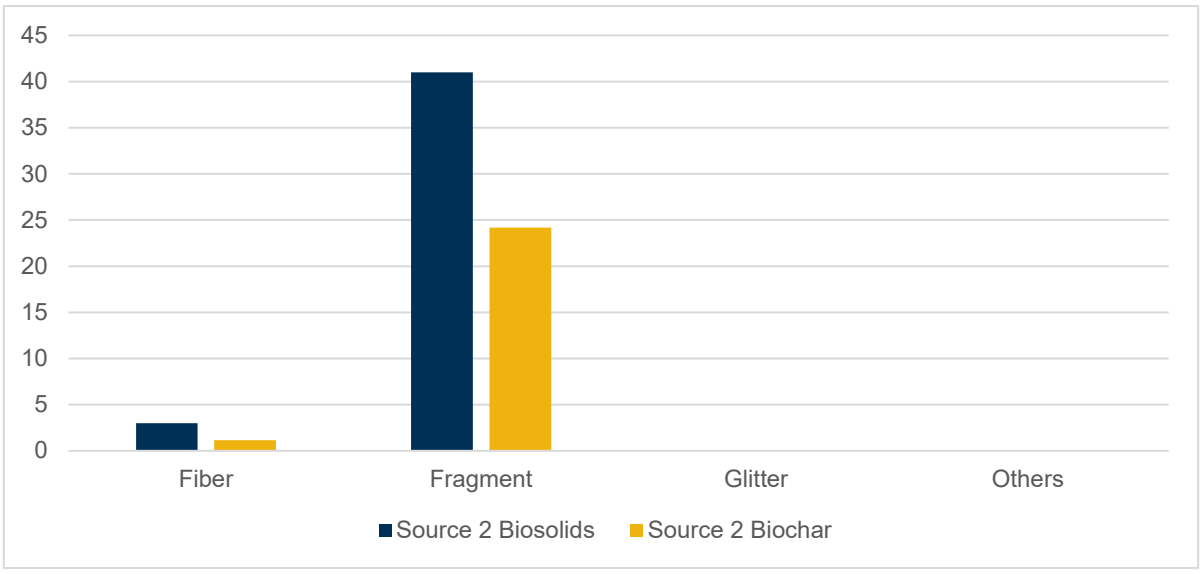

Figure 6-8: Source 2 particle size of microplastics in the biosolids and biochar

Figure 6-8 illustrates the particle types found in the Source 2 biosolid samples and after treatment through the gasification process. It shows the gasification process reduces the microplastic plastic concentration: 1mm (39% less); 250µm (48% less); 150µm (29% less); and 63µm (36% less). These destruction limits are less then Source 1, but these results are to be expected given the larger, denser particle size of Source 2 biosolids.

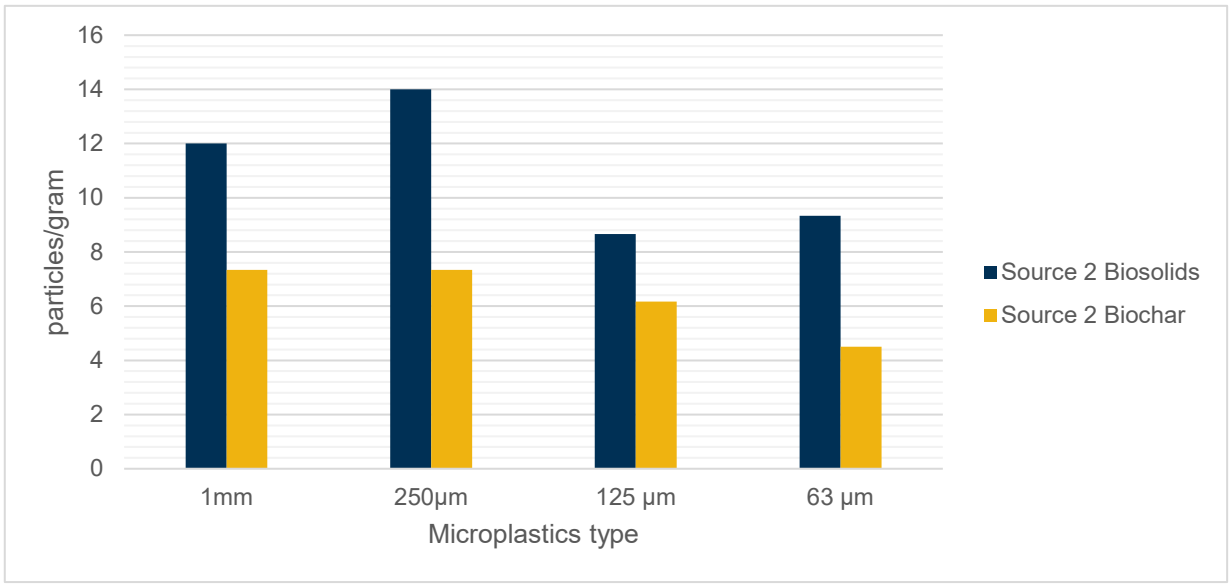

Figure 6-9: Source 2 microplastic types in the biosolids and biochar

Source 2 biosolids was small and dense because it is pelletised and not what is expected out of full-scale facility design of the belt dryers, which is more of a uniformed crumb. Also, even though the Source 2 biosolids is pelletised, they are not as dense and tightly bound and far easier to be crushed and more representative of what would be expected in the Loganholme WWTP full-scale facility. Therefore, it is expected that the microplastic destruction would be greater when processed through the belt dryer than what is illustrated in the Source 1 and 2 biosolids. Figure 6-9 shows that the gasification process does seem to destroy more of the fibre type microplastics with a 61% destruction rate compared with 41% fragment types.

The Loganholme WWTP biosolids have microplastics of around 3.3 particles/gram. Figure 6-10 shows the size and type of microplastics found in the Loganholme WWTP sludge.

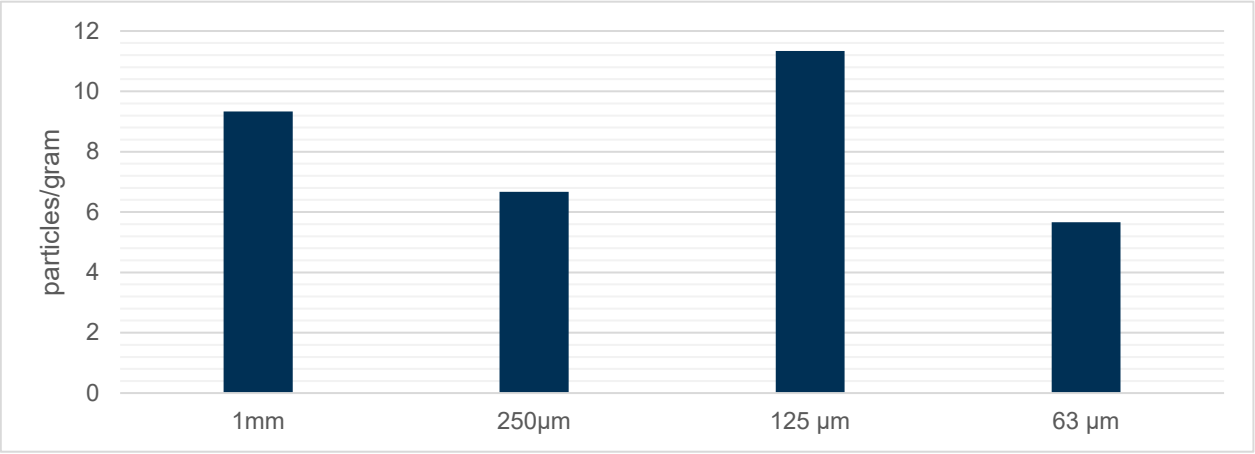

Figure 6-10: Loganholme WWTP particle size of microplastics in the biosolids and biochar

Figure 6-11 show a representative sample of biosolids from the Loganholme WWTP illustrating the types of microplastics found.

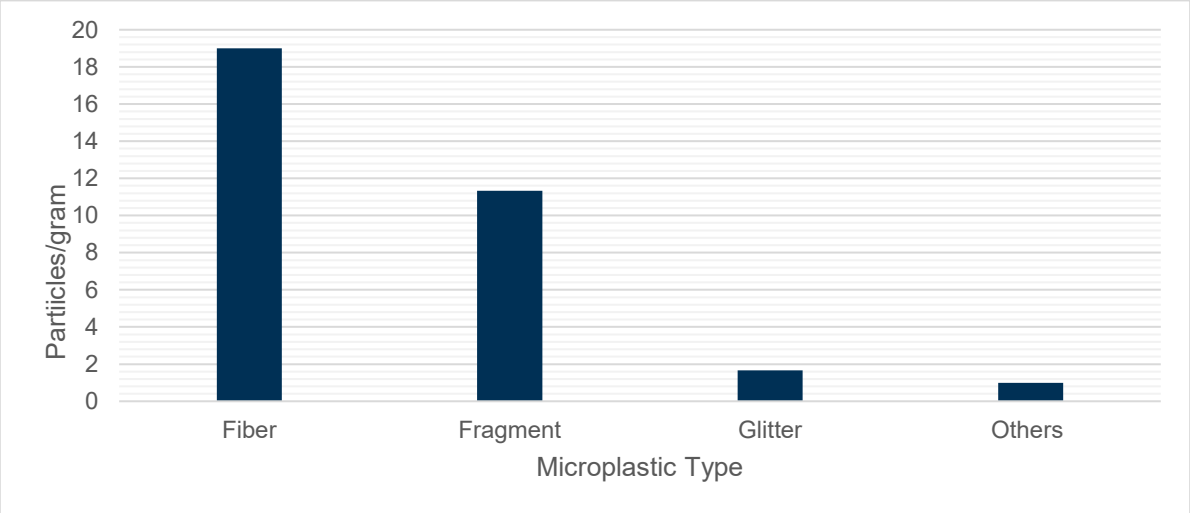

Figure 6-11: Loganholme WWTP microplastic types in the biosolids and biochar

As shown in Figure 6-11, Loganholme WWTP biosolids, like Source 1 biosolids, mostly contained fibre and fragment types of microplastic, as well as glitter. Overall, Loganholme WWTP biosolids had 63% less plastics than Source 1. This could be due to the dry concentration of the Source 1 biosolids.

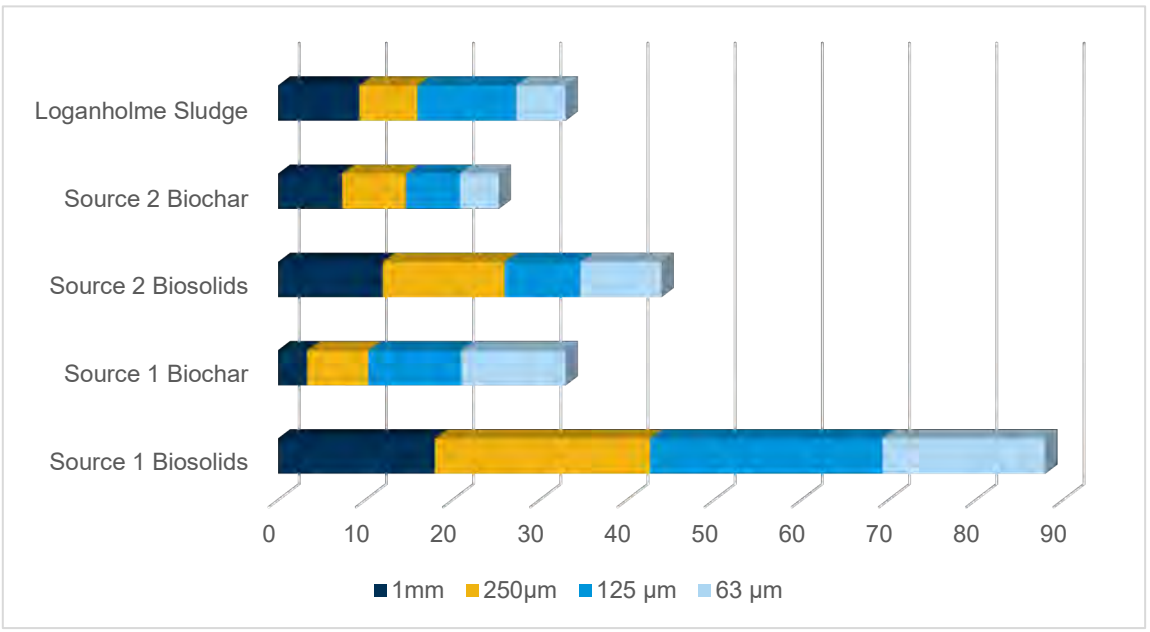

Figure 6-12: Microplastics particle size comparison across all sources of biosolids

Figure 6-12 shows that microplastics are present in the biosolids from all WWTPs; however, it also shows that Source 1 has a significant proportion compared to Loganholme WWTP and Source 2. Overall, the destruction of microplastics through the gasification process is around 60% when the source material has been through a pelletising drying process. Therefore, processing biosolids through a belt dryer that produces a less condensed source material would potentially mean a higher destruction rate of microplastics. This is an area to investigate once the full-scale facility is implemented in the Loganholme WWTP to determine the destruction rates.

7. Heat Balance

This section is an overview of how the demonstration plant addresses its objective for the heat balance for an integrated drying facility.

7.1 Background

The unit supplied for the demonstration plant incorporated a steam boiler and condensing unit to capture and measure heat generation and recovery (Pipatmonomai, Kaewluan, & Vitidsant, 2009) (Solarte-Toro, Chacon-Perez, & Cardona-Alzate, 2018). Hot flue gases from the thermal oxidiser passed through a steam boiler before being discharged to a wet scrubber.

For the demonstration plant, the steam was re-condensed via a heating coil submerged in a water bath to allow the recovered heat to be measured. Condensate was returned to the steam boiler. Plant service water used for the water bath drained back to the treatment plant. This was a controlled exercise and the scrubber water. In the full-scale facility, the flue gas will be used to heat a water circuit in a hot water generator rather than a steam boiler. The hot water set at 90–95 °C will exchange heat into a separate dryer water circuit that returns at 70–75 °C.

A key objective of the integration of dewatering, drying and gasification is that the overall process is heat-energy neutral. This effectively means that sufficient heat needs to be recovered from that produced in the gasification process to operate the dryer without the need for an additional fuel source during normal operation. The heat balance of the overall integrated drying–gasification process is mostly influenced by four parameters:

1. **Calorific value of the biosolids:** This is related to the volatile solids content of the biosolids and is inherent to the treatment plant and, therefore, not able to be adjusted in design or operation.
2. **Biosolids dewatering performance:** Mechanical removal of water via centrifugal dewatering is more efficient than evaporation and significantly impacts the heat required for drying. The initial dewatering step is designed to achieve 20% w/w dry solids (target) with 18% w/w minimum.
3. **Thermal efficiency of the dryer:** Measured as kW of heat input per tonne of water evaporated, a lower figure represents higher efficiency. This is a fundamental characteristic of the type of dryer.
4. **Operating temperature of the dryer:** A lower operating temperature allows for greater heat recovery from the gasification process flue gas as the final flue gas temperature can be reduced. The operating temperature range is inherent to the type of dryer.

Table 7-1: Calorific values for Source 2 and Loganholme and Beenleigh WWTPs

Calorific value	Unit	Loganholme WWTP	Beenleigh WWTP	Source 2
Net	MJ/kg DM	18.80	18.4	19.26
Gross	MJ/kg (calc)	2.25	2.20	2.23

Table 7-1 compares the calorific value of Source 2 biosolids to those from Loganholme WWTP and Beenleigh WWTP. Although Beenleigh WWTP is lower than Loganholme WWTP, once the sewage diversion is in place Beenleigh WWTP will be closer in value to the Loganholme WWTP values as calorific value is determined by the process stream. This shows that the Loganholme WWTP biosolids calorific value is 98% to that of Source 2 and therefore very similar results in heat energy recovery are expected. Table 7-2 is the calculated energy recovery based on the Source 2 biosolids passing through the gasification facility.

The heat balance on the Source 1 biosolids was inadequate to the extent that the radiant heat exchanger on the thermal oxidiser had to be partially disabled to allow adequate oxidiser temperatures to be maintained. The heat balance on Source 2 biosolids is outlined in Table 7-2.

Table 7-2: Summary of unit operations performance of the demonstration plant

Parameter	Value	Notes
Biosolids feed rate	480 kg/hr	85% of design feed rate (565 kg/hr) 74% of maximum continuous feed rate (650 kg/hr)
Heat recovered at radiant heat exchanger (integrated with the Thermal Oxidiser)	350 kW	Median value at 800–820 °C oxidiser temperature. Scales upwards with oxidiser temperature.
(a) Heat recovered by radiant heat exchanger scaled from 85% feed rate to 100%	0.4 MW	350 kW x 100/85
Heat recovered from flue gas heat recovery steam generator	780 kW declining to 600 kW	Median value at 540 °C inlet temperature. Declining heat transfer efficiency over 48 hours.
Flue gas heat exchanger outlet temperature (T_{out})	185 °C to 265 °C	Higher temperature reflects loss of heat transfer efficiency. Much of the loss of heat transfer efficiency occurred over a period of 24–48 hours, with a slow ongoing decline after that.
Heat recovery steam generator efficiency	66% declining to 51%	Calculated from (Tin-Tout)/Tin. Tin = 540 °C.
Heat recovered from flue gas scaled to 80% heat recovery.	941 kW	Heat recovered @ 80% = HR @ 51% efficiency x 80/51 This is a prediction based on implementation of a flue gas to hot water heat exchanger in the permanent plant with on-line soot blowing provisions to maintain performance.
(b) Heat recovered from flue gas scaled from 85% rate to 100%	1.1 MW	941 kW x 100/85
Forecast heat recovery in permanent system at design rate (565 kg/hr)	1.5MW	(a) + (b). The nominal requirement is 1.4MW per processing train. The expected performance exceeds the requirement; however, the design margin is minimal (less than 10%) and sensitive to the dewatering performance. Therefore, Pyrocal recommends the implementation of a condensing heat exchanger, located downstream of the main flue gas heat exchanger. The heat/temperature available at this point should be suitable for 150-200 kW of pre-heating for the water to the main flue gas heat exchanger. This would raise the design margin for the heat balance to 20%.

8. Operating Costs

The operating costs of the plant are dominated by the consumption of process additives for equipment protection and emissions control, and electrical consumption. The chemical additions required are an alkali such as magnesium hydroxide ($(Mg(OH)_2)$) for hot corrosion control and SOx/metals capture and an ammonia source such as urea for NOx reduction.

Electrical consumption was measured at 42–45 kW, at a power factor of -0.9 and a rate of 480 kg/hr, scaling directly with throughput at rates exceeding 33% of design throughput. This equates to 94kWh per tonne of biosolids feed.

Initially, hydrated lime ($Ca(OH)_2$) was used as the alkaline chemical additive. While this solution worked, the reliability of handling was poor in a weather-exposed environment. Hold-ups in the metering hopper were experienced. Lime powders are well known for this behaviour. In addition, accumulation of insoluble calcium compounds was observed in the scrubber and while the accumulation did not cause an operational issue, the issue could be foreseen. Therefore, a high concentration sodium hydroxide solution was trialed and then a magnesium hydroxide ($Mg(OH)_2$) slurry. Of the two, magnesium hydroxide was considered the best option because it caused no accumulation of precipitates in the wet scrubber and is safer to handle than sodium hydroxide.

A 50% urea solution was injected into the gas stream as a source of ammonia for NOx reduction. Two different addition points were trialed, with addition after the oxidiser providing the best performance.

The demonstration plant not only allowed optimisation of the choice of chemicals but also the ability to determine the final consumption rates.

8.1 Urea

When starting the demonstration plant, the urea dosing rates were around 40 L/tonne of dry biosolids of 50% w/w urea solution, subject to increases up to 180 L/tonne of biosolids if high carbonisation temperatures were used (greater than 700 °C). This was significantly optimised throughout the demonstration and Table 8-1 shows dosing rates expected for the full-scale facility.

Table 8-1: Urea dosing rates

	1 unit	2 units
Throughput	575 kg/h	1150 kg/h
Urea concentration	0.4%	0.4%
Dosing rate	2.3 kg/h	4.6kg/h
	12L/h	24 L/h
Dosing location	Spear of the inlet of the oxidisers	

Table 8-1 shows that the dosing rate has been optimised from 40–180 L/dry tonne to around 20L/dry tonne. This is a significant decrease in the amount of urea required for mitigation of NOx. Table 8-1 also shows the calculated dose rates for ultimate design capacity.

8.2 Magnesium hydroxide

Initially, the demonstration plant was consuming up to 30 litres per tonne of dry biosolids of $Mg(OH)_2$ 55% w/w slurry. This was primarily influenced by dust release rate (system throughput), i.e. higher dust rates resulted in lower alkali requirement, because the carbon dust captured in the scrubber was mildly alkaline with a pH in water of approximately 8.5. Table 8-2 calculates the dosing for ultimate design capacity.

Table 8-2: Magnesium hydroxide dosing rates

	1 unit	2 units
Throughput	575 kg/h	1150 kg/h
$Mg(OH)_2$ concentration	1.20%	1.20%
Dosing rate	6.9 kg/h	13.8kg/h
	4.5 L/h	9L/h
Dosing location	Suction of wet scrubber recirc pump (75%) Screw feeding the Hearth (25%)	

Table 8-2 illustrates that the dosing rate has been optimised from 30 L/dry tonne to around 4.5L per dry tonne. This is a significant decrease in the amount of urea required for mitigation of NOx.

8.3 Diesel

Diesel should also be accounted for in the operational. At start-up, each hearth requires around 100L per train—two gasifiers would require 200L of diesel each start-up. Overall, the full-scale facility requires continuous running for two weeks with two days shutdown. Therefore, the diesel consumption would be around 400L per month.

8.4 Boiler shield

The boiler shield is a required chemical that is used in a closed loop. However, every two weeks, 25L would have to be dosed as a top-up as part of the maintenance scheduled shutdown periods.

9. Conclusion

The Loganholme WWTP Biosolids Gasification Demonstration Plant has proven to be an innovative solution to a problem facing WWTPs that are managing biosolids: increasing energy costs, haulages rates and emerging contaminants of concern. The demonstration plant confirmed that gasification of biosolids is a reliable process that can be incorporated into a WWTP.

Each of the objectives set for the demonstration plant in terms of reliability, air emissions, persistent organic pollutants, heat balance and operating costs were achieved.

Therefore, it is recommended to proceed with the full-scale Biosolids Gasification Facility at Loganholme WWTP.

3. ESTIMATION OF LOGANHOLME CHAR QUALITY 72
4. POTENTIAL VALUE OF THE CHAR 75
5. POTENTIAL USES FOR THE CHAR 76
6. RECOMMENDATIONS 78

1. Introduction

After the successful full-scale demonstration of the Pyrocal gasification process earlier this year Logan City Council is now proceeding with a commercial gasification facility at their Loganholme WWTP. The Basis of Design (BoD) for this facility, which includes Mass and Energy Balances, has been developed by Logan Water. The full-scale demonstration work was done using dried sewage sludge from Source 1 and Source 2 WWTPs since no dried sludge was available from any of the Logan Water WWTPs. Bridle Consulting was contracted by Logan City Council to estimate char characteristics that would be generated from Loganholme biosolids, based on the data generated from the demonstration trials and comment on the potential value and uses of the char.

2. Information Provided

Logan City Water provided the following documents to Bridle Consulting to conduct this Char Reuse Review:

1. DT 007 Loganholme Biosolids Treatment Process Mass Balance, Rev 3 xlsx.
2. Excel Spreadsheet named “Copy of Merge”. This spreadsheet included analytical data of the Loganholme, Source 1, and Source 2 biosolids as well as char analytical results from the Source 1 and Source 2 gasification trials.

3. Estimation of Loganholme Char Quality

The quality of the char that will be produced from gasification of Loganholme biosolids has been estimated based on the following information:

- Loganholme biosolids analytical data provided by Logan Water,
- The design char yield of 35% as reported by Logan Water,
- The classification of NPK from biosolids to char, based on published data,
- The classification of heavy metals from biosolids to char, based on results reported by Logan Water from the gasification trials, and,
- The destruction of PFCs as reported via the gasification trials. Estimates of PFAS destruction is by Bridle Consulting.

A summary of the average gasification trial results for the four runs using Source 1 biosolids and the eighteen runs using Source 2 biosolids are shown in Table 3-1.

Table 3-1: Average gasification trial results

Parameter	Units	Source 1		Source 2	
		Biosolids	Char	Biosolids	Char
VS	%	70.7	36.3	72.3	38.3
Ash	%	29.3	63.7	27.7	61.7
Calculated char yield	%		46.00		44.9
As	mg/kg	<5	<5	8.1	4.4
Cd	mg/kg	<1	<1	<1	1.4
Cr	mg/kg	19	40.3	32.3	73.1
Cu	mg/kg	157	252.5	331	613
Pb	mg/kg	8.2	17.3	11.5	26.4
Hg	mg/kg	0.1	<0.1	0.4	<0.1
Ni	mg/kg	13.7	16	16.1	31.3
Se	mg/kg	<5	<5	<5	<5
Zn	mg/kg	360	765	569	1311
PFAS	ug/kg	22			
Total PFCs	ug/kg	32.7	<5	57	<5

The average char yield for the Source 1 and Source 2 runs are calculated because all the ash in the biosolids is conservative and is classified (transferred) to the char.

A wealth of information on the fate of heavy metals in biosolids during gasification and pyrolysis has indicated that volatile and semi-volatile metals such as mercury, arsenic and cadmium are vaporised during the process. All the mercury is vaporised and much of the cadmium and a lesser amount of arsenic are also vaporised and transferred to the syngas. All the other heavy metals are completely retained in the char.[1]

Based on this fact the theoretical char concentrations of the non-volatile heavy metals have been calculated, based on measured char yields for the Source 1 and Source 2 gasification trials and these are reported, together with measured metal values, in Table 3-2.

Table 3-2: Calculated and measured char heavy metal values

Heavy Metal	Units	Measured/Theoretical Char HM Value			
		Source 1		Source 2	
		Measured	Theoretical	Measured	Theoretical
Cr	mg/kg	40.3	41.3	73.1	71.9
Cu	mg/kg	252.5	341.3	613	737.3
Pb	mg/kg	17.3	17.8	26.4	25.6
Ni	mg/kg	16	29.8	31.3	35.9
Zn	mg/kg	765.0	782.7	1311	1267.4

[1] Bridle, T.R, Hammerton, I.F and Hertle, C.K, "Control of Heavy Metals and Organochlorines using the Oil-from-Sludge Process", Proceedings of the IAWPRC Sludge Management Conference, Los Angeles, January 1990.

As can be seen there is very good agreement between the measured and theoretical char HM values. Consequently, to estimate the expected char heavy metal concentrations from the full-scale Loganholme gasification facility the theoretical approach has been adopted.

The predicted char characteristics from the full-scale Loganholme gasification facility are shown in Table 3. These predicted char characteristics are based on the Logan Water Loganholme biosolids characteristics provided to Bridle Consulting and the following assumptions:

- A char yield of 35%, as provided by Logan Water,
- That about 55% of the biosolids N and all the P and K is classified to the char[2], and,
- Metal and contaminant classification and PFC/PFAS destruction as noted above.

It is recommended that Logan Water use these char characteristics when discussing char reuse options with Regulatory Agencies and potential char users.

Table 3-3: Predicted Loganholme Gasification Facility char characteristics.

Parameter	Units	Loganholme	
		Biosolids	Char
VS	%	81	47.2
Ash	%	19	52.8
Nitrogen	%	5	7.9
Phosphorus	%	2.3	6.6
Potassium	%	0.67	1.9
Estimated char yield	%		35
As	mg/kg	2.6	1.5
Cd	mg/kg	0.7	2.0
Cr	mg/kg	48	137
Cu	mg/kg	260	743
Pb	mg/kg	13	37
Hg	mg/kg	0.5	<0.05
Ni	mg/kg	210	600
Se	mg/kg	4.2	12
Zn	mg/kg	626	1789
PFAS	ug/kg	22	<0.2
Total PFCs	ug/kg	44.9	<0.45

4. Potential Value of the Char

The char from biosolids gasification contains many valuable components, the major valuable constituents being the following:

- Phosphorus and Potassium (P and K). These macro plant nutrients are 100% bio-available and have been speciated in a slow-release form by the thermal gasification process[3]
- Fixed Carbonised Carbon that significantly enhances soil fertility. Research by the NSW Department of Agriculture has demonstrated up to a 30% increase in broad acre crop yields when char is applied at a rate of 10 tonnes per hectare on agricultural soil
- Minor nutrients and Trace Elements such as Sulphur, Boron, Iron, Molybdenum, Zinc, Cobalt and Copper that are vital for crop growth, and,
- Energy.

The Nitrogen in the char is not plant available and thus has no agronomic value.

The most valuable components in the char are the nutrients P and K. Based on the current prices for the fertiliser's urea ($450/t), mono-ammonium-phosphate ($800/t) and potassium chloride ($380/t) the current value of P is $2,900/t and the value of K is $199/t. Based on the predicted concentrations of P and K in the Loganholme char, the value of these two nutrients is $211/t char. The estimated Fixed Carbon content of the char is 36%. It is difficult to put a value on this fixed carbon, but it is likely to be in the range of $100 to $200/t. At a value of $150/t the value of fixed carbon in the char is thus $54/t char. **Thus, the overall value of the char, for reuse in agriculture, is likely to be, at minimum, $265/t.**

The other major valuable component in char is energy. It is estimated that the Loganholme char will have and energy content of 20 GJ/t. Based on the current Australian price for coal ($56/t), with an energy content of 28GJ/t, the energy value of coal is $2/GJ. **Thus, the overall value of the char, for reuse as an energy source, is likely to be $40/t.**

This analysis strongly indicates that maximum returns from char sales will be in the agricultural sector. This reuse option also provides the best environmental outcomes.

[3] Pritchard, D, Curtin University of Technology, "Nutrient Properties of Char", Research Report prepared for Environmental Solutions International Ltd, Perth, WA, September 2003.

5. Potential Uses for the Char

A number of potential uses for char from gasification and pyrolysis of biosolids have been previously identified and these are summarised below[4]:

1. Use in agriculture as a fertiliser supplement
2. Use as a fuel in boilers, power plants and other industrial combustors
3. Use as a fuel and feedstock in cement kilns
4. Use as an ingredient to produce lightweight/insulating bricks and pavers
5. Use as an industrial adsorbent in place of Activated Carbon
6. Use as a low-grade Activated Carbon for odour control, and
7. Use as a metallurgical reductant.

Use in Agriculture as a Fertiliser/Soil Supplement

This reuse option has the highest potential economic return for Logan City Council with the best environmental outcomes. There is sufficient scientific evidence of the significant benefit that is achieved by applying char as a fertiliser supplement to agricultural soils.

The major issue for Logan City Council will be in obtaining the necessary regulatory approvals for this reuse option. The current Queensland “End of Waste Code – Biosolids” (ENEW 07359617, December 2019) stipulates the quality of biosolids that can be applied to agricultural land. Provided that the biosolids meet contaminant and pathogen reduction requirements specified in the code the biosolids are not considered as waste but rather a resource which can be reused in agriculture. There are 3 grades of quality prescribed for the 3 reuse options, namely Unrestricted Use, Restricted Use 1, and Restricted Use 2. Based on the predicted char quality as shown in Table 3, the char would not meet the Nickel quality requirement of 270 mg/kg to allow Restricted Use 2 category. Consequently, broad acre agricultural reuse for the char would NOT be permitted in Queensland. It must however be noted that the Code only applies to biosolids and thus char is unlikely to be managed by the Code. However, this should be confirmed by Logan City Council.

Thus, the most likely option for agricultural reuse would be to blend the char with other components to produce a blended or compounded fertiliser/soil supplement, like the many commercially produced and bagged products currently available at gardening centers and hardware stores. This option should be explored by Logan City Council.

Use as a Boiler/Combustor Fuel

Many industrial boilers/combustors in Queensland use fuels other than coal, oil, or gas as their primary fuel. The char would be a very suitable alternate fuel for many of these industrial boiler/combustors. As mentioned previously, the potential value of this fuel would be $40/t char. The only issue regarding this reuse option would be obtaining environmental approval from the EPA. The issue would likely be the controls required to meet heavy metal, SOx, and NOx emission limits for the facility.

Use as a Fuel/Feedstock in Cement Kilns

The char has significant inorganic constituents (Si, Al, Ca etc.) that would add to clinker formation in the kiln. This would be an added benefit of using the char to supplement the kiln energy requirements. The value of char to cement manufacturing would be at least $40/t char. Due to the likely small contribution the char would make to kiln fuel requirements it is unlikely that any emission issues would be raised. Char has been used as a kiln feedstock in Europe.

[4] Bridle, T.R, “Sludge Pyrolysis: Has its Time Arrived”. Presented at the Bioenergy Australia Conference, Fremantle, December 2006.

Feedstock for Lightweight/Insulating Bricks and Pavers

This reuse option has been demonstrated and is in use in Europe where light weight/insulating bricks are routinely used in the construction industry. The char is mixed with clay and then fired in the kilns. The organics in the char are combusted leaving small pores in the finished bricks, providing the lightweight and insulating properties. Traditionally Styrofoam pellets are used, but they are now being replaced by char.

A full-scale production trial run of light-weight brick manufacture was undertaken in Germany using 1 tonne of char produced from a demonstration sludge pyrolysis unit[4]. This trail produced bricks of essentially the same quality as when using Styrofoam pellets. A picture of a brick from this manufacturing run is shown in Figure 1.

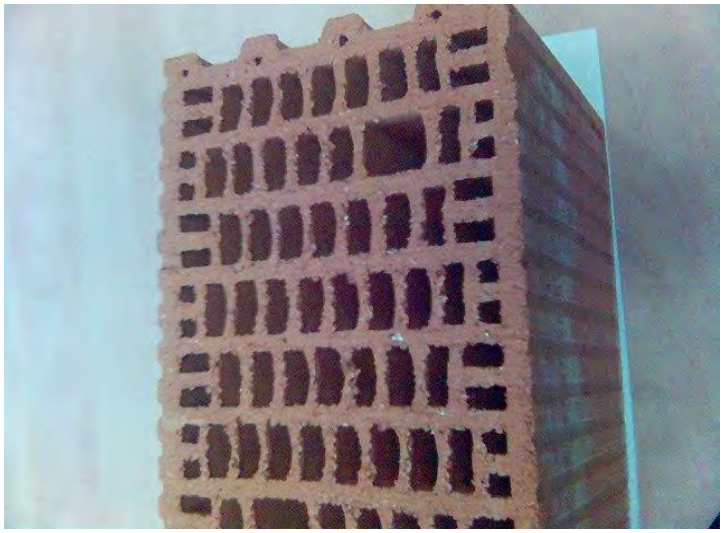

Figure 5-1: Light-weight clay brick made with char addition

Dried sludge has also been used in South Africa for the production of light-weight bricks. There is, as yet, no market for this in Australia but this reuse option is worthy of consideration by Logan City Council.

Use as a Low-grade Adsorbent to Replace Activated Carbon

Char from biosolids pyrolysis or gasification has significant adsorptive capacity and is equivalent to a low-grade activated carbon. Test-work in Germany has shown that char has a very good adsorptive capacity for heavy metals[5]. When the char was activated it had much superior adsorptive capacity for heavy metals than conventional Activate Carbon. This may be a very good use for the char, especially for treating heavy metal contaminated ground water and mining/industrial effluents.

Use as a Low-grade Activate Carbon for Odour Control

Due to its high adsorptive capacity the char would be a good alternative to conventional activated carbon for odour control applications. It would also me a good media to use in biological odour control filters commonly used in the sewage and industrial wastewater treatment industries.

Use as a Metallurgical Reductant

Char, with its relatively high carbon content could be used to replace commercial reductants used in the metallurgical processing industry. To Bridle Consulting's knowledge this, reuse option has not yet been evaluated.

6. Recommendations

Bridle Consulting recommends that Logan City Council evaluates, in more detail, the potential char reuse options identified in this report.

Reuse in the agricultural sector, as a blended soil supplement offers the maximum financial returns and also the best environmental outcomes. It is thus recommended that Logan City Council engages with the relevant Queensland Government Departments to identify any constraints on this reuse option. In addition, Logan City Council should contact the many commercial companies that operate in the blended fertiliser/soil markets to assess their interest in using char as one of the ingredients in their blended products.

rsc.li/es-water

While per- and polyfluoroalkyl substances (PFAS) are not actually generated at water resource recovery facilities (WRRFs), utilities are being forced to consider PFAS in biosolids management plans due to mounting political pressure and pending regulations. Emerging thermal technologies including pyrolysis, gasification, and super critical water oxidation have garnered recent attention for PFAS destruction. Drying, however, is a conventional technology that might also be a tool for utilities to manage PFAS in biosolids, but research on the impacts of drying on PFAS in biosolids is scarce. The objective of this research was to determine how drying affected the fate of PFAS in biosolids. Full-scale sampling was paired with lab-scale oven drying experiments to understand the impact of drying on measurable PFAS in biosolids. Overall, drying substantially reduced the total PFAS concentration in biosolids. PFAS removal during a full-scale facility's drying process matched the removal achieved when solids were taken from that facility and dried in a lab-scale oven instead, with average PFAS removal being approximately 80%. Precursors to perfluoroalkyl acids (PFAAs), primarily 5 : 3 fluorotelomer carboxylic acid (FTCA) and 6 : 2 FTCA, as well as perfluorooctane sulfonic acid (PFOS) were substantially reduced between pre-drying and post-drying triplicate samples. Additional lab-scale oven drying experiments corroborated that measurable PFAS were removed from biosolids collected from three different utilities. Drying experiments at 30 °C and 105 °C revealed that the PFAS profiles were similar, but PFAS concentrations were lower in the 105 °C samples compared to 30 °C samples. While more research is necessary to determine and validate the removal mechanism, drying could be a viable technology to reduce measurable PFAS levels in biosolids to concentrations below guidelines for land application.

Water impact

PFAS have substantially altered the biosolids management industry. Emerging technologies offer a means to reduce PFAS to non-detect levels in solid products such as biochar. Drying, however, is a widely employed technology that could sufficiently reduce PFAS levels to meet guidelines for land application.

1. Introduction

Per- and polyfluoroalkyl substances (PFAS) have altered the biosolids management landscape. Though water resource recovery facilities (WRRFs) are not actually a source of PFAS, they receive and convey PFAS because of the widespread use of PFAS in society and consumer products.[1] PFAS are abundant in a range of products including cosmetics, water-proof clothing, carpets, and fast-food wrappers.[2–5] PFAS are widely detected in people, including breastmilk, blood, and urine samples, and therefore municipal sewage also contains PFAS.[6–8] Moreover, consumer products laden with PFAS are sent to landfills where products degrade over time, and PFAS are released into leachate that is often sent to the head of a WRRF.[3,9,10] The concentration in biosolids depends on any nearby industrial sources of PFAS discharged to the WRRF as well as the unit operations used at the WRRF.[2,11–13] Some European countries, Australia, Canada, and states in the United States have set limits for PFAS concentrations in soil, and some states in the United States have set PFAS concentration limits for biosolids that can be land applied to minimize human health impacts.[7,14–20]

Biosolids management requires an understanding of how biosolids handling technologies impact the fate of PFAS. Emerging technologies, in particular thermal processes, have

KD2270

garnered attention for their potential to reduce PFAS concentrations in solids.[21,22] Indeed, pyrolysis has been shown to remove and transform PFAS at the lab and pilot scale.[23–29] Incineration, a more established technology, also removes the majority of PFAS from the solid phase.[30] Pyrolysis and gasification are still emerging technologies in the biosolids marketplace, and both of these technologies require drying first.[23,31] Drying, however, is already a widely used and established solids handling process. Aside from being useful when paired with emerging thermal technologies, drying offers the benefit of substantial mass reduction *via* removal of water. As numerous utilities already dry and land apply biosolids, it is important to understand the impacts of drying on the fate of PFAS in biosolids.

Limited studies have been conducted thus far regarding the potential impacts of drying on PFAS fate, and results have been mixed.[32–34] Indeed, heat treatment of wastewater solids at 480–650 °C led to an increase in total perfluoroalkyl acids (PFAAs) by 53%, mainly due to perfluorohexanoic acid (PFHxA) increases.[12] In another study, heat drying at 90–120 °C was found to increase PFAS concentrations, in particular the concentration of fluorotelomer phosphate diesthers (diPAPs).[32] A lab study on drying at 115 °C at 2 hours found that 6:2 diPAP approximately doubled; perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS) were similar before and after heat treatment; and perfluoropentanoic acid (PFPeA) decreased by approximately 50%.[32] One study on a full-scale dryer with a regenerative thermal oxidizer (RTO) found that 50–90% of PFAS were transferred from the biosolids to the gas phase, and 18 PFAS were detected in the gas phase headed for treatment in the RTO.[34] Despite widespread use of drying in the industry, limited studies are available that document the impacts of drying on the fate of PFAS in biosolids.

The objective of this research was to determine the impact of drying on PFAS in biosolids. As some government regulatory agencies move towards implementing concentration-based limits for PFAS in biosolids and soils, it is particularly important to know how drying processes impact measurable PFAS concentrations. This research combined sampling at a full-scale dryer with lab-scale oven drying experiments on the same full-scale pre-drying solids samples. Additionally, pre-drying solids samples provided by three different WRRFs were used for lab-scale oven drying experiments. Finally, lab-scale oven drying experiments were conducted on high moisture content (MC) samples at 30 °C and 105 °C.

2. Methods and materials

2.1. Comparison of full-scale drying to lab-scale oven drying on PFAS concentrations in biosolids

A WRRF agreed to provide pre-drying and post-drying samples from their full-scale dryer under conditions of anonymity. The average influent flow rate to this WRRF is over 50 million gallons per day (MGD). Liquid treatment steps include grit removal, primary clarification, conventional activated sludge, and chlorination. Solids undergo thickening and dewatering prior to drying. The total solids (TS) content for the pre-drying solids fed to the dryer was approximately 16% TS, and the TS content for the post-drying solids taken from the effluent of the dryer was approximately 90% TS. Triplicate pre-drying samples and triplicate post-drying samples were collected on-site from the full-scale dryer. In addition to full-scale sampling, pre-drying solids samples were dried in triplicate in a lab-scale oven at 105 °C for 5 hours to compare lab-scale oven drying to full-scale drying. All samples were sent to Eurofins Environment Testing USA (Eurofins) for PFAS extraction and analysis as described in section 2.4.

2.2. Lab-scale oven drying of solids from three different WRRFs

Solids from three different WRRFs were dried in a lab-scale oven to assess if PFAS removal was observed when drying different solids. The three WRRFs tested for this experiment were from different states than the WRRF described in section 2.1. Each WRRF requested to be kept anonymous and provided the following general information to provide context on their biosolids without revealing their identity. WRRF A receives less than 25 MGD of wastewater influent. Liquid processes include primary treatment and secondary treatment that has full nitrification and one train with anoxic zones for incidental denitrification. Primary sludge and thickened waste activated sludge (WAS) are sent to a mesophilic anaerobic digester. A portion of digested solids are sent to a screw press, and effluent samples from the screw press were collected for this work. The TS content was 18.3%. WRRF B is over 50 MGD and utilizes a two-stage anaerobic digestion process. The first stage is fed a mixture of primary sludge and WAS and has a solids retention time (SRT) of 2 days or less. The second stage has an SRT of 15–20 days. The digestate is processed through a centrifuge. Effluent samples from the centrifuge were collected for this work. The TS content was 20.8%. WRRF C is less than 10 MGD. The WRRF employs primary clarification, and solids from the primary clarifiers are pumped directly to anaerobic digesters. The WRRF employs activated sludge, and the WAS is thickened and then pumped directly to the anaerobic digesters as well. After anaerobic digestion, centrifuges are used for dewatering. Effluent samples from the centrifuges were collected for this work. The TS content was 24.2% TS.

The collected pre-drying solids samples were shipped to a laboratory at California State University-Bakersfield (CSU-B) for lab-scale oven drying. Samples were stored at 4 °C until used for the experiment. Storage was less than 7 days. "Pre-drying" refers to solids that were received from the WRRFs before undergoing any drying. "Post-drying" refers to solids after they were dried in the lab-scale oven. Approximately 20 g of pre-drying solids were placed in a drying tin. The samples were dried overnight (24 hours) at 105 °C in a conventional lab-scale oven with the fan mode on. After drying,

This journal is © The Royal Society of Chemistry 2025
KD2271

samples were transferred to containers that were provided by Eurofins for PFAS analysis. Dried samples were stored in the dark at room temperature until shipped to Eurofins. Pre-drying and post-drying samples were shipped to Eurofins for targeted analysis of PFAS as described in section 2.4.

2.3. Lab-scale oven drying experiments on high moisture content samples at 30 °C and 105 °C

High moisture content samples (99.8% MC, 0.2% TS) were dried to assess PFAS profiles in biosolids dried at two different temperatures. Triplicate biosolids drying experiments were conducted at 105 °C at the CSU-B laboratory and at the lower temperature of 30 °C. The 105 °C test was conducted overnight and the 30 °C test lasted 5 days. The 30 °C test was conducted in a lab-scale oven with the temperature lowered to 30 °C. These experiments were also conducted to assess the possibility of PFAS sticking to the drying tins. After the first set of experiments conducted in section 2.1 with results shown in section 3.1, it seemed feasible that PFAS previously associated with water could stick to the drying tin (and not the solids) as the water evaporated. This possibility was tested by employing a 'wipe kit' provided by Eurofins. This kit includes a methanol-soaked cloth that is used to wipe the tin after biosolids are completely removed for sampling following drying.

2.4. PFAS analysis

Sixty targeted PFAS analytes were measured. They are all listed by chemical class in the ESI document (ESI†), Table S1. The associated Isotope Dilution Analytes (IDAs), also known as isotopically labeled analogs, used for each PFAS analyte are also listed in ESI† Table S1. PFAS analyses were performed on a SCIEC 5500+ triple quad LC/MS/MS system operated in multiple reaction monitoring (MRM) mode. Biosolid samples were manually mixed in their collection containers and then subsampled (nominally 1 g for both pre-drying and post-drying samples). Each subsample was fortified with IDAs of the native target analytes, then extracted *via* sonication with basic methanol for one hour. The resulting extracts were re-constituted in water and then cleaned up *via* solid phase extraction (SPE) using a WAX SPE cartridge (Strata X-AW or equivalent), which retains the desired PFAS. The IDAs and target analytes were then eluted from the SPE cartridge with basic methanol and adjusted to a final extract volume of 10 ml in 80 : 20 methanol/water, after additional fortification with 13C2-PFOA as the internal standard (ISTD). Identical sample extraction procedures were applied to pre-drying and post-drying biosolid samples.

Accuracy of measurements for the reported list of 60 target analytes is ensured *via* initial and ongoing assessment of accuracy and precision *via* laboratory control sample aliquots, control sample duplicates, laboratory method blanks, method detection limit (MDL) studies, MDL verification aliquots, and performance testing studies. Each of these is performed as described in the associated laboratory Standard Operating Procedures (SOPs), and the results are monitored and validated *via* 3rd party laboratory accreditation bodies for the corresponding regulatory programs including the National Environmental Laboratory Accreditation Program and the United States Department of Defense Environmental Laboratory Accreditation Program.

Within each sample, additional measures of method performance are monitored, including IDA recovery, ISTD response, analyte retention times, analyte ion ratios, and analyte signal-to-noise ratios. Each of these sample-specific quality controls or identification elements must meet the criteria specified in the corresponding laboratory SOPs. PFAS concentrations are reported on a dry weight basis whereby dry weight is determined when moisture has been removed at 105 °C and the sample has been cooled to room temperature in a desiccator.

2.5. Analysis & Statistics

To conduct conservative statistical analyses on the fate of PFAS during drying, the reporting limits (RLs) provided in the Eurofins PFAS analysis report were used to fill in the gaps of the non-detects in the triplicate data before percent removal or significance of species removal was determined, *i.e.*, "zero" values were not used for statistics. Note that these RL data are not reflected in the figures; only species concentrations higher than the reporting limits are shown.

Statistical analysis was conducted using GraphPad Prism v10.3.1 (GraphPad Software, La Jolla, CA). The tests conducted for each experiment are listed in the ESI† Tables S5, S8, & S16. P-values < 0.05 were considered statistically significant. Concentrations of PFAS were normalized and reported in micromoles (μmol) of F per kg dry solids, where the F content stemmed from the moles of F present in the species of PFAS that were measured through targeted analysis. These concentrations were used to calculate percent removals.

3. Results

3.1. Impacts of full-scale drying and lab-scale oven drying on PFAS in biosolids

3.1.1. Full-scale dryer results. The full-scale dryer reduced the mass of detectable PFAS and changed the measurable PFAS profiles between the pre-drying and post-drying samples (Fig. 1 and ESI† Tables S2 & S3). Ten PFAS were detected across all three pre-drying samples for the full-scale dryer. The most abundant species in the pre-drying samples was 5 : 3 fluorotelomer carboxylic acid (FTCA), and 6 : 2 FTCA was the third most abundant species. These FTCA compounds are common precursors to short-chain PFAAs; 'precursors' are chemical species known to degrade and transform into other species of PFAS.[35–37] PFOS was the second most abundant PFAS overall in the pre-drying samples, and the most abundant PFAA. Of the ten PFAS detected across all three pre-drying samples, seven were detected above RL in all three post-drying samples. 7 : 3 FTCA was detected in two of the three post-drying samples, perfluorodecanoic acid (PFDA) was detected in one of the three post-drying samples, and 6 : 2 FTCA was not detected in any of

the post-drying samples (Fig. 1 and ESI† Tables S2 & S3). Two PFAAs, specifically perfluoropentanoic acid (PFPeA) and perfluorohexane sulfonic acid (PFHxS), were detected across all three post-drying samples, but not in any of the pre-drying samples. These two PFAAs were present at concentrations in the post-drying samples that were below the RLs for the pre-drying samples (ESI† Tables S3 & S4). Therefore, it is not possible to know if these two PFAAs appeared during the drying process due to a reaction or if they were already present in the pre-drying samples but could not be detected.[12,38] In general though, the PFAS fraction attributed to precursor compounds, *i.e.*, FTCA, fluorotelomer sulfonic acids (FTS), perfluorooctane sulfonamido acetic acids (FOSAA), and perfluorooctane sulfonamido ethanols (FOSE), decreased significantly during drying (ESI† Fig. S1, Tables S7 & S8).[35–37]

3.1.2. Lab-scale oven drying results. The solids samples collected before entering the full-scale dryer were also dried in a lab-scale oven at 105 °C to compare the impacts of lab-scale oven drying to full-scale drying on the PFAS profile in biosolids. The lab-scale oven data reflected similar trends as the full-scale dryer data. Total PFAS were reduced and the profile changed (Fig. 2). Of the ten PFAS detected across all three pre-drying samples, four were detected above RL in all three post-drying samples (ESI† Tables S3 & S4). One species, PFHxS, a terminal PFAA, appeared in all three lab-scale oven post-drying samples despite not being detected in the pre-drying samples. Similar to the full-scale dryer post-drying samples, PFOS was detected in all three lab-scale oven post-drying samples and was the second most abundant species detected after 5 : 3 FTCA. Together, 5 : 3 FTCA and PFOS accounted for, on average, more than half of the molar F as PFAS concentration in the lab-scale oven post-drying samples and full-scale dryer post-drying samples. There was no significant difference between the concentrations of these two species from the two drying methods (ESI† Table S5). Lab-scale oven drying also decreased the ratio of precursor species to total PFAS in biosolids (ESI† Fig. S1, Tables S7 & S8), which is consistent with the full-scale dryer sample data.

Overall, the full-scale dryer and lab-scale oven drying experiments revealed substantial reductions in measurable PFAS in the biosolids (Fig. 3). The average PFAS removal in the full-scale dryer was 84.9% and the average PFAS removal in the lab-scale oven was 81.9% (ESI† Table S9). Average removal of total PFAS was not significantly different between the full-scale dryer and the lab-scale oven (ESI† Table S8). These results indicate that drying biosolids could be a viable option to reduce the measurable PFAS concentration in biosolids, and, for these particular systems, the lab-scale oven setup can be used to help estimate removal percentage for the majority of detectable PFAS in biosolids in a full-scale system.

On a PFAS mass concentration basis, pre-drying total PFAS concentrations ranged from approximately 100–150 μg kg^{-1} (ESI† Table S3). The full-scale dryer post-drying samples had a wider range of concentrations than the lab-scale oven post-drying samples. The full-scale dryer post-drying samples total PFAS concentration ranged from 13–31 μg kg^{-1}, and the lab-scale oven post-drying samples ranged from 16–23 μg kg^{-1}. Some states have employed interim guidelines for land application of biosolids that set 20 μg kg^{-1} of PFOS and PFOA as a threshold wherein any concentrations below this level can be land applied.[40] The pre-drying biosolids samples had PFOS and PFOA concentrations already below this threshold.

3.2. Impact of lab-scale oven drying on PFAS in biosolids from three different utilities

Biosolids samples were collected anonymously from three WRRFs that were unique from the WRRF that provided samples for the results presented in section 3.1 above. The biosolids samples were collected from different WRRFs with varying

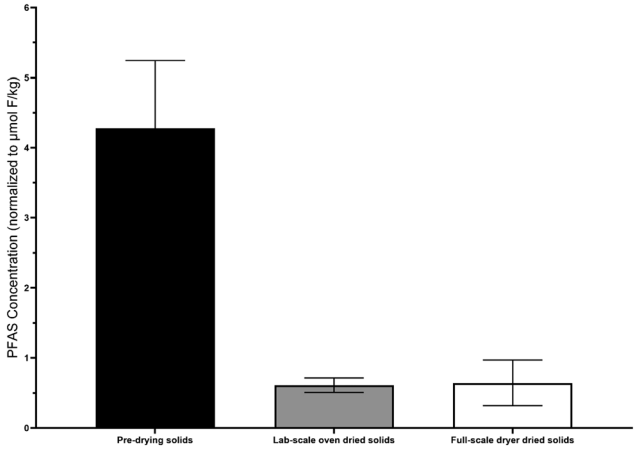

Fig. 3 Average total PFAS concentration (normalized to µmol F kg^{-1}) across pre-drying solids, lab-scale oven post-drying solids, and full-scale dryer post-drying solids. Samples taken in triplicate (n = 3) and error bars represent standard deviation. Reprinted with permission. © The Water Research Foundation.[39]

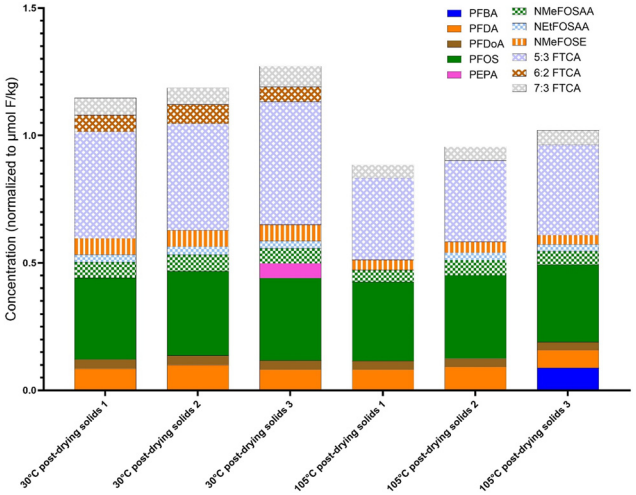

Fig. 5 Drying at 105 °C decreased total PFAS concentration by 16% compared to drying at 30 °C. Water content of pre-drying solids was 99.8%. 30 °C and 105 °C drying of samples were conducted in triplicate (n = 3). Reprinted with permission. © The Water Research Foundation.[39]

influent flow rates and unit operations as described in the methods section. Regardless of biosolids sample, the total sum of measurable PFAS decreased after drying (Fig. 4, ESI† Tables S10 & S11). For all three pre-drying samples, 5 : 3 FTCA was the first or second most abundant PFAS. PFOS was one of the three most abundant PFAS in each pre-drying sample as well. These two PFAS were still detected in post-drying samples, but their concentrations decreased. Average PFAS removal across the three samples was 76% (ESI† Table S13). These results indicate that drying can reduce measurable PFAS in biosolids, but drying does not completely remove PFAS from biosolids.

3.3. Impact of drying temperature on PFAS profiles in samples with high moisture content

High moisture content samples (99.8%) were dried at 30 °C and 105 °C. Overall, the PFAS fingerprint and concentration profiles were similar for samples dried at 30 °C and samples dried at 105 °C (Fig. 5), but temperature did have some effect on PFAS profiles in the dried biosolids. Four of the eight PFAS detected in both post-drying samples across all triplicates (5 : 3 FTCA, 7 : 3 FTCA, *N*-methyl perfluorooctane sulfonamido ethanol (NMeFOSE), and perfluorododecanoic acid (PFDoA)) were significantly lower in biosolids dried at 105 °C compared to biosolids dried at 30 °C (ESI† Tables S14–S16). Similar to the other data sets, 5 : 3 FTCA and PFOS were the first and second most abundant PFAS in every sample (Fig. 5 and ESI† Tables S14 & S15). Overall, the total PFAS concentration was 16% lower in the 105 °C post-drying sample than the 30 °C post-drying sample, with a statistically significant p-value of 0.0058. A wipe kit was provided by Eurofins to wipe the drying tins and test for residual PFAS. The reporting limit was 1 ng PFAS per wipe. No PFAS detections were observed for any of the six wipes tested (three tins at each temperature). Either there were no residual PFAS in the tins, or the wipes were not able to absorb residual PFAS that may have been left in the tins. This test was conducted to observe any major experimental artifacts of PFAS residual in tins that could be absorbed with a methanol wipe.

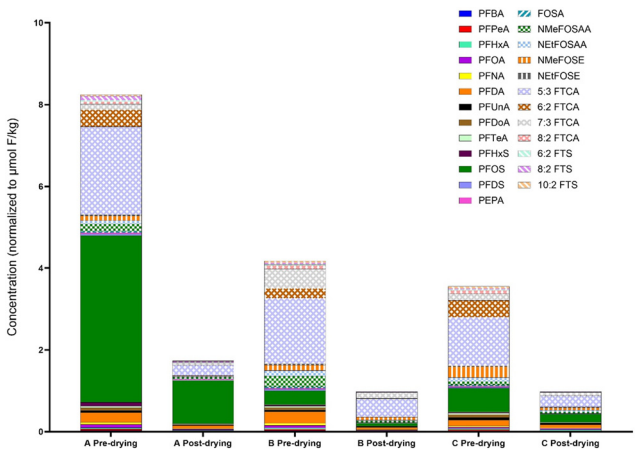

Fig. 4 Lab-scale oven drying reduced measurable PFAS in samples from three different WRRFs. Reprinted with permission. © The Water Research Foundation.[39]

3.4. Impact of moisture content on PFAS removal

Across the full-scale dryer and lab-scale oven data sets, moisture content was weakly correlated to total PFAS removal (Fig. 6, ESI† Table S18). The potential role of water in PFAS removal is discussed in more detail in the discussion section below. While certainly more data from a range of biosolids types and moisture contents are needed to validate this correlation, these data indicate that further study on the role of moisture content during drying of biosolids is warranted.

KD2274

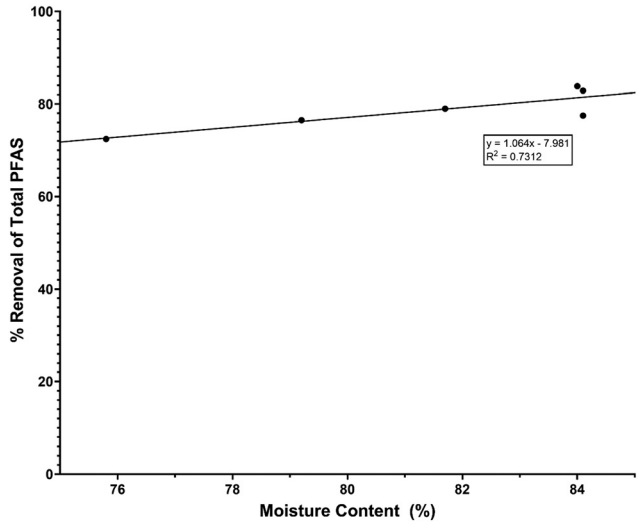

Fig. 6 Moisture content correlated to PFAS removal across sample sets. Reprinted with permission. © The Water Research Foundation.[39]

4. Discussion

The effect of drying on the PFAS profile of biosolids has been largely overlooked in literature.[34] Due to the recognized thermal stability of PFAS and their high boiling points as pure substances, it has been posited that temperatures around 100 °C would be insufficient to remove them from biosolids.[33] The following three sections discuss possibilities to explain the observed PFAS removal with recognition that more research is required to determine the removal mechanism.

4.1. Potential role of water and removal with aerosols

It has been established that PFAS readily partition to the air–water interface (AWI), and, in fact, a reduction in the aqueous concentration of PFAS increases this tendency of PFAS to partition to the AWI.[41–43] In the case of water-bearing biosolids, an accurate assessment of the AWI partitioning tendency of PFAS is complicated by the potential presence of air bubbles formed during the drying process as the temperature approaches 100 °C, at which point the water begins to boil.[44] As the boiling bubbles burst upon reaching the surrounding atmosphere of the biosolids, small water droplets may be flung into the air in what is referred to as the "bubble microtome effect"; these droplets, having existed as underwater pockets of air before bursting, may harbor significant quantities of PFAS that partitioned to their surface.[44] Furthermore, Hoff *et al.* suggest that the organic solutes most apt to partition to the interface of air bubbles have low vapor pressure and low solubility in water, and are typically polar; with polar functional groups and low Henry's constants, this characterization may apply to some PFAS, including PFAAs.[44,45] In this way, the drying of biosolids may provide an avenue by which non-volatile PFAS may escape wet biosolids, *i.e.*, *via* attachment to bubbles that form during drying and subsequent release (and removal from biosolids) attributed to the bubble microtome effect.

Additionally, recent research by Nguyen *et al.* revealed that PFAS can be removed from wastewater aeration basins *via* attachment to aerosols.[46] Indeed, PFOS removal was over 75%, and the concentration of PFOS associated with aerosols was 100 to 1000-fold greater than the PFOS associated with the wastewater.[46] PFOA also exhibited similar removal *via* association with aerosols.[46] This finding is important for two reasons. First, the removal of PFAS to aerosols occurred at 20 °C, a temperature well below the boiling point of water as well as lower than the temperatures reported for volatilization of PFAS, indicating that it is possible for PFAS to leave a water matrix without volatilizing.[46–50] Second, the PFAS that were removed *via* association to aerosols were not classically defined 'volatile' PFAS, *e.g.*, fluorotelomer alcohols (FTOH), that have been reported in landfill gas, for example.[45,51] Therefore, this aerosol removal mechanism does not require a phase change of PFAS. As the agitation of water due to aeration within aeration basins may catalyze the aerosolization of water, the tendency of PFAS to partition to the AWI may increase their susceptibility to removal with these water molecules.[43,52] This phenomenon of aerosolization of PFAS could also likely occur during tumbling of biosolids in rotary dryers.

In addition to these more nuanced potential mechanisms of removal, Hakeem *et al.* highlighted the need for more research to understand the impact of water vaporization on the fate of PFAS during the drying of biosolids; due to the complexity of interactions at the AWI, it may also be prudent to explore the impact of water content on removal.[33] As the PFAS concentration in the drying biosolids decreases, their tendency to partition to the AWI may increase, which may perpetuate the cycle of their removal during the above processes, despite the fact that they may occur at temperatures lower than the PFAS' boiling points.[43,47–50] In order to validate this claim, an analysis of the atmospheres of the drying environments (both lab-scale ovens and full-scale dryers), as well as of any water droplets generated and expelled during heating processes would be necessary.[45,53] Moreover, variations in moisture content may affect the consistency of PFAS extraction methods from solid samples due to the complex partitioning behavior of PFAS in multi-phase media. Further investigation on extraction methods and experimental artifacts is prudent for understanding the entire scope of the observed results.

4.2. Potential role of pure chemical volatilization

While PFAS are used in non-stick pans and fire-fighting foams because of their resistance to degradation, they still can volatilize as temperatures increase.[49] Sasi *et al.* observed PFOA weight loss at 100 °C *via* thermal gravimetric analysis (TGA), raising the possibility that some PFOA could be lost during drying *via* volatilization.[49] However, in the pure chemical studies by Sasi *et al.*, PFOS weight loss was not observed until temperatures were

This journal is © The Royal Society of Chemistry 2025
KD2275

above 400 °C.[54] The drying temperatures in these studies were below 400 °C, yet PFOS removal was still observed, indicating that loss *via* volatilization was unlikely, or at the least not the major removal mechanism.[49,54]

4.3. Potential role of biotransformation

In addition to the concentration of PFAS changing during drying, the fingerprint, *i.e.* the specific PFAS present in each sample, changed after drying. FTCAs are a common class of precursors, and it is possible that biological enzymes converted FTCA precursors to terminal short-chain PFAAs such as perfluorobutanoic acid (PFBA), PFPeA, or PFHxA.[55] Research has been reported on the degradation of 5:3 FTCA to PFPeA and the more general theory that *n*:2 fluorotelomer carboxylic acids, *N*-alkyl perfluoroalkane sulfonamido acetic acids, and perfluoroalkane sulfonamido ethanols (*i.e.* 6:2 FTCA, NEtFOSAA, NMeFOSAA, and NMeFOSE) transform into perfluoroalkyl carboxylic acids (PFCAs) and perfluoroalkyl sulfonic acids (PFSAs).[35–37] The fraction of total PFAS attributed to precursors decreased after drying for the majority of experiments (ESI† Fig. S2). To confirm biotransformation, microbial activity assays and microbial community analyses would need to be conducted. If transformation were the only mechanism occurring, then total targeted PFAS measurements would increase as undetectable precursors were converted to detectable terminal species. The total sum of PFAS went down, implying that other mechanisms are at play even if transformation partially explained a change in PFAS profiles.

5. Conclusions

Biosolids management plans that incorporate PFAS management considerations are imperative while regulatory agencies weigh risk assessments for allowable PFAS concentrations that are safe for land application of biosolids. Source reduction is still the most important and effective way to mitigate PFAS in wastewater solids. It is essential to recognize the impact that all treatment processes may have on altering the PFAS profile of biosolids. Current treatment technologies could be leveraged to achieve compliance. Drying of biosolids may serve as a method by which PFAS contaminated biosolids are treated and made to achieve regulatory compliance for land-application. However, it is essential to recognize that the reduction in concentration of PFAS in biosolids during drying might result in air-borne PFAS associated with water droplets. Additional studies are needed to assess the fate of PFAS to assist the industry and regulators in establishing appropriate management and treatment protocols. Both lab-scale oven drying and full-scale drying processes had significant impacts on the measurable PFAS profile of biosolids, thereby suggesting that drying is indeed an effective process for altering the PFAS profile of biosolids. Drying is a technology already widely used in the industry. While drying does not completely remove PFAS to below reporting limits, it does substantially reduce measurable PFAS concentrations. Future research is needed to confirm if PFAS are emitted with the gas phase or if other mechanisms are responsible for these changes observed during drying.

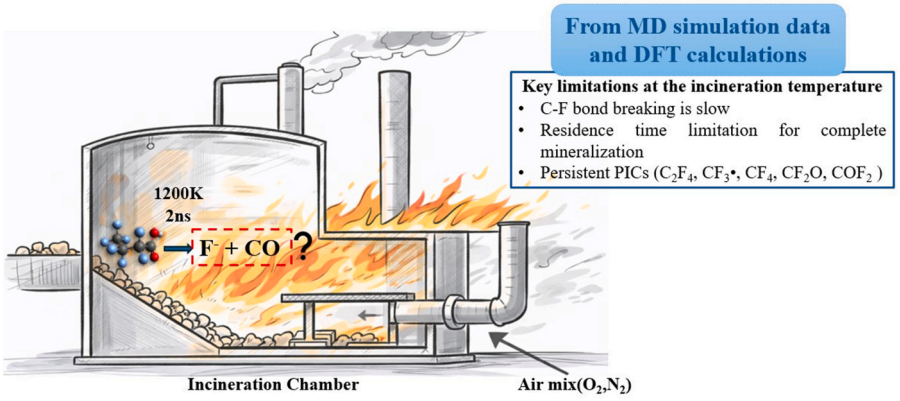
Incineration of PFBA with temperature: Reaction mechanisms, kinetics, and residence time from molecular level simulations



Jay N. Meegoda *, Targol Teymourian, Duwage C. Perera **

John A. Reif, Jr. Department of Civil and Environmental Engineering, New Jersey Institute of Technology, Newark, NJ, 07102, USA

HIGHLIGHTS

- PFBA degradation under incineration conditions were resolved by reactive MD and DFT.
- DFT shows defluorination of C2F4, CF2O & CF4 is kinetically inaccessible at 1200 K.
- Residence-time analysis shows, fluorocarbon intermediates outlast incinerator times.
- Molecular-level insights explain incomplete combustion & guide PFAS thermal treatment.

ABSTRACT

Per- and polyfluoroalkyl substances (PFAS) are thermally stable organofluorine compounds whose complete destruction by incineration is difficult due to strong C–F bonds, radical stabilization, and formation of toxic intermediate products. In this research, atomistic degradation pathways of perfluorobutanoic acid (C_3F_7COOH) were investigated using a combined molecular dynamics (MD) and density functional theory (DFT) to quantify bond dissociation, intermediate formation, and kinetic limits under regular incineration temperature (1200 K). High-temperature MD simulations revealed that thermal cleavage of the C–C bond between the perfluoroalkyl chain and carboxyl group is the dominant initial reaction, generating $C_3F_7^{\bullet}$ radicals and CO_2. Subsequent pathways involve β-scission, $O\bullet/O_2$ addition, and radical recombination to produce intermediates such as C_2F_4, $CF_3^{\bullet}$, CF_2, $CF_3C(O)F$ and COF_2. The DFT transition-state calculations provide activation energies from 40 to 513 kJ mol^{-1}, enabling estimation of rate constants and residence times from transition-state theory. At 1200 K temperature, early fragmentation step occurs over micro-to millisecond timescales, whereas C_2F_4 defluorination, COF_2 decomposition, and CF_4 breakdown calculations show residence times exceeding seconds to hundreds of seconds well above typical incinerator gas-phase residence times. These findings provide quantitative evidence that PFAS incineration proceeds through complex multistep of degradation pathways and that kinetically

persistent products of incomplete combustion result primarily from slow defluorination steps. The mechanistic and kinetic trends identified here provide molecular-level guidance for optimizing incineration conditions to improve PFAS mineralization.

1. Introduction

Per- and polyfluoroalkyl substances (PFAS) are a large class of synthetic organofluorine compounds widely used for their thermal stability, chemical resistance, and surfactant properties. These characteristics arise from strong C–F bonds and fully fluorinated carbon backbones, which also make PFAS highly persistent in natural and engineered environments (Perera and Meegoda, 2024; Sznajder-Katarzyńska et al., 2019; Xu et al., 2021; Buck et al., 2011; Jin et al., 2020; Lin et al., 2022; Murphy and Warner, 2022; Sunderland et al., 2019; Zuccaro et al., 2022). PFAS have been widely detected in groundwater, soils, biota, and even remote polar ecosystems, raising concerns about long-term exposure risks and the difficulty of achieving complete remediation (Roy et al., 2025; Sadia et al., 2023)

Incineration is currently the only full-scale technology used for PFAS destruction. Hazardous-waste incinerators typically operate above 1000 °C, where PFAS are expected to thermally decompose to CO_2 and HF. However, field and pilot-scale studies show that degradation is often incomplete, producing intermediates such as perfluoroolefins, COF_2, perfluoroacyl fluorides, and stable fluorocarbons (e.g., C_2F_4, CF_4, C_2F_6) through complex radical-mediated pathways and limited residence time or oxidizing conditions. (Baranovskii and Skorobogatov, 2016). Short-chain PFAS, such as perfluorobutanoic acid (PFBA), are particularly challenging during combustion because their high volatility and mobility can hinder complete destruction and promote the formation of ultrashort-chain perfluoroalkyl acids (PFAs)(Altmeyer Mendes et al., 2025; Bharti, 2025; Blotevogel et al., 2023; Kovacs et al., 2025; Yu et al., 2025).

Although macroscopic emission data show that temperature and residence time strongly influence PFAS destruction efficiency, the underlying atomistic mechanisms remain poorly understood. Thermal cleavage of C–C and C–F bonds, radical stabilization, recombination, and competing oxidation pathways determine whether incineration leads to complete mineralization or formation of fluorinated byproducts. Experimental studies confirm that PFAS decomposition depends on temperature, residence time, reactor material, and oxidizing conditions. For example, Weber et al. (2024) reported that PFOS decomposes to HF, CO_2, and SO_2 above 850 °C in the presence of water vapor, while pyrolysis under inert conditions forms intermediates such as CF_2 and C_2F_4(N. (2025) Weber et al., 2024). Rocchio et al. (2025) reported that incomplete combustion of PFOA in a pilot-scale incinerator can regenerate smaller PFAS (C_2–C_6) through competing α-lactone and C–C cleavage pathways (Rocchio et al., 2025). These results indicate that PFAS degradation proceeds through complex multistep reactions rather than direct oxidation. Although macroscale incineration studies provide temperature and emission data, molecular-level mechanisms remain poorly understood, highlighting the need for atomistic investigations of PFAS thermal.

Molecular dynamics (MD) and density functional theory (DFT) are powerful computational tools that provide complementary insights into PFAS degradation mechanisms during incineration. MD simulations capture the time-dependent atomic behavior of PFAS under reactive conditions, enabling the identification of bond cleavage, radical formation, and reaction pathways. Reactive force fields such as ReaxFF allow bond formation and dissociation, making it possible to simulate complex degradation networks. For example, Bezerra de Souza et al. (2025) used MD to investigate PFAS degradation under ultrasonic cavitation and showed that chain length and headgroup structure influence the onset of C–F bond cleavage and radical formation (de Souza and Meegoda, 2024). Similarly, Loganathan and Wilson (2022) used MD simulations to study PFAS adsorption and diffusion on kaolinite, showing that short-chain PFAS exhibit higher mobility and weaker interfacial binding than long-chain analogues. (Loganathan and Wilson, 2022).

In contrast, density functional theory (DFT) provides a quantum mechanical description of electronic structure and is widely used to determine reaction pathways, activation barriers, and transition states in PFAS decomposition. DFT calculations help identify charge transfer and bond weakening processes that initiate PFAS degradation (Mohamed et al., 2024). Moreover, DFT-based kinetic models have shown that PFAS pyrolysis proceeds through HF and SO_2 elimination, followed by fragmentation of perfluoroalkyl chains into smaller radicals such as CF_2 and CF_3 (Altarawneh, 2021). Integrating DFT with MD provides a comprehensive view of PFAS incineration, where DFT determines reaction energetics and MD captures the dynamic molecular evolution under high-temperature conditions.

This study employs a multiscale computational approach to investigate the thermal degradation of perfluorobutanoic acid (PFBA). High-temperature MD simulations identify dominant fragmentation pathways and radical intermediates, while DFT calculations determine transition states, activation barriers, and rate constants for key reactions. These atomistic insights help evaluate whether typical incineration conditions can achieve complete PFAS destruction or if kinetic limitations lead to persistent byproducts.

2. Materials and methods

2.1. MD simulation approach

As the initial step, the MD simulation was performed using the periodic simulation box was set to 383.57 Å × 383.57 Å × 383.57 Å (see Fig. S01). Perfluorobutanoic acid (PFBA or $C_4HF_7O_2$) was selected as a representative short-chain perfluorocarboxylic acid to investigate thermal degradation under incineration-relevant conditions utilizing the ReaxFF force field (Senftle et al., 2016; Van Duin et al., 2001). PFBA captures the key structural characteristics of perfluoroalkyl acids while reducing computational cost relative to longer-chain analogues. All simulations were carried out in the gas phase to mimic the high-temperature combustion zone of incinerators, where PFAS degradation occurs primarily through thermal excitation and radical reactions in an oxidative environment containing O_2 and N_2, with no water molecules present.

The simulation box containing 10 PFBA molecules, 750 N_2 molecules, and 250 O_2 molecules was constructed to an approximate oxidizing combustion atmosphere. Each system underwent an initial energy minimization, followed by equilibration in canonical (NVT) ensemble at 373.15 K and 1 atm. After equilibration, production runs were performed in a NVT ensemble spanning the temperature from 373.15 K to 1200 K. Simulations were performed at 1200 K, a representative high-temperature combustion condition within the range typically used in PFAS thermal decomposition and incineration studies (1000–1500 K) (Altarawneh et al., 2022a; Blotevogel et al., 2023).

All MD simulations were carried out using the LAMMPS package[17]. Molecular structures were constructed and geometry-optimized using Avogadro, and trajectory visualization and analysis were performed using OVITO (Stukowski, 2010).

2.2. Details of DFT calculation

All electronic structure calculations were performed using ORCA

KD2280

6.0.1 as the quantum chemistry software package (Neese et al., 2020) using the long-range corrected hybrid functional wB97X-D3BJ in combination with the def2-TZVP basis set for all atoms. Geometry optimizations of all reactants, intermediates, products, and transition states were carried out in the gas phase without symmetry constraints, using the TightSCF convergence criteria and the resolution-of-identity approximation (RIJCOSX) with the def2/J auxiliary basis to accelerate the Coulomb and exchange integrals. Empirical dispersion interactions were treated with the D3(BJ) correction as implemented in ORCA.

For each elementary step in the PFAS decomposition network, the reactant and product geometries were fully optimized to local minima and characterized by vibrational frequency analyses. Transition state (TS) structures were located either by constrained scans followed by OptTS optimizations or by NEB-TS searches using the optimized reactant and product structures as endpoints. All TS candidates were confirmed by a single imaginary frequency corresponding to motion along the desired reaction coordinate.

Temperature-dependent rate constants for unimolecular decomposition reactions were estimated using Arrhenius kinetics based on the activation energies obtained from DFT calculations. For unimolecular homolytic bond-cleavage reactions, the pre-exponential factor was approximated as 1.0×10^{15} s^{-1}, consistent with values predicted by transition-state theory for radical dissociation reactions and commonly reported in combustion-kinetics literature. The resulting k(T) values were then used to compute characteristic residence times at incineration temperatures, providing a direct link between atomistic reaction mechanisms and macroscopic PFAS destruction requirements in thermal treatment systems.

The expected uncertainty of activation energies at the wB97X-D3BJ/def2-TZVP level of theory is typically on the order of ±10–20 kJ mol^{-1} for fluorinated systems. While direct benchmarking with experimental rate constants was not performed, the predicted reaction intermediates and degradation pathways are consistent with products reported in laboratory and field-scale PFAS incineration studies. The reaction coordinates were visualized using Avogadro 1.2.0 software (Hanwell et al., 2012).

3. Results and discussion

3.1. Analyzing possible reaction pathways

3.1.1. Primary decomposition pathways of C_3F_7COOH

High-temperature molecular dynamics simulations were performed to identify the earliest bond-cleavage events, dominant dissociation pathways, and transient radical intermediates formed during thermal breakdown of PFBA under simulated incineration conditions. The simulation cell contained 10 PFBA molecules, 750 N_2 molecules, and 250 O_2 molecules, representing an oxidizing gas-phase combustion environment (Fig. S01). After equilibration at 373.15 K, the system was heated to 1200 K, where PFAS degradation is experimentally observed to begin within millisecond timescales.

Across independent trajectories, the first decomposition event consistently involved cleavage of the C–C bond between the perfluoroalkyl tail and the –COOH group, producing the highly stable $C_3F_7^{\bullet}$ radical and a carboxyl fragment $COOH^{\bullet}$. This is consistent with those reported in the literature suggesting that perfluoroacyl C–C bonds are thermally weaker than internal C–F bonds at incineration temperatures.

This observation is consistent with previous theoretical studies of PFAS thermal degradation. For example, Altarawneh et al. (2022) reported through kinetic modeling and quantum chemical calculations that PFCA decomposition is initiated by decarboxylation reactions that generate perfluoroalkyl radicals, followed by β-scission and fragmentation of the fluorinated carbon chain (Altarawneh et al., 2022a). Similarly, Krug et al. (2022) demonstrated through kinetic modeling and combustion experiments that PFAS decomposition proceeds through radical-mediated fragmentation producing intermediates such as $CF_3\bullet$, C_2F_4, and smaller fluorocarbon species. The agreement between these earlier studies and the MD trajectories observed here provides additional support for the proposed radical-driven degradation mechanism (Krug et al., 2022).

Following initial fragmentation, rapid decarboxylation of $COOH^{\bullet}$ to $CO_2 + H^{\bullet}$ was observed, in agreement with expected gas-phase thermolysis behavior. Fig. 1 shows results from the MD simulation for 55ns period. Detailed species information is recorded in Table S04 in the SI document. The $C_3F_7\bullet$ radical underwent several competing pathways, including.

- C–F bond homolysis yielding $C_3F_6 + F\bullet$,
- H-abstraction from $COOH^{\bullet}$ or O_2-derived radicals, producing C_3F_7H,
- Addition of $O^{\bullet}$ or O_2, leading to $C_3F_7O^{\bullet}$ and subsequently $CF_3C(O)F + {}^{\bullet}CF_3$

In addition to the radical C–C cleavage pathway, an alternative HF elimination pathway (Reaction 1D, However, this pathway likely represents a secondary or less favorable route under gas-phase thermal conditions) was also identified, producing C_3F_6, CO_2, and HF. This pathway is consistent with previously reported PFCA thermal decomposition mechanisms involving HF elimination and formation of fluorinated intermediates.

Importantly, MD trajectories demonstrated the formation of ultrashort-chain fluorocarbons (e.g., CF_4, C_2F_6, C_2F_4) and perfluoroacyl fluorides, which are experimentally recognized products of incomplete combustion. The MD simulations therefore provide mechanistic evidence that radical-driven cascades, not direct one-step fragmentation, dominate PFAS thermal breakdown. Fig. 2 illustrates the proposed reaction pathways.

The role of oxygen was also apparent in this simulation. Although the gas mixture contained 25% O_2, many of the first fragmentation events occurred before O_2 participation. Oxygen addition occurred later in the radical cascade, often stabilizing or oxidizing intermediates rather than driving primary bond scission. This implies that initial PFAS decomposition under incineration is governed largely by thermal excitation, while oxidation becomes dominant only after primary fragmentation has created reactive radicals.

3.1.2. Molecular geometries and transition state analysis

To validate and quantify the MD-identified pathways, key reaction steps were examined using DFT with the wB97X-D3BJ/def2-TZVP. All reactants, intermediates, products, and transition states were optimized using the wB97X-D3BJ/def2-TZVP. Transition states for bond-cleavage, β-scission, and O/O_2 addition steps were obtained either through NEB-TS searches or by scanning the relevant reaction coordinate to locate a maximum. All TS structures were verified by observing a single imaginary vibrational frequency, corresponding to the expected C–C, C–F, or O-insertion motion.

3.1.3. Fate of C_3F_7 radical

Once generated by the primary C–C bond cleavage of PFBA (Reaction 1A), the $C_3F_7\bullet$ radical becomes the central branching point of the entire thermal degradation network. Its subsequent reactions determine whether breakdown proceeds toward (i) oxidative fragmentation, (ii) short-chain PFAS formation, or (iii) stable fluorocarbon by-products. Under desired incineration conditions (1200 K), three major thermochemical pathways compete.

(I) **β-scission to form $CF_3\bullet$ and C_2F_4 (Reaction 2; E_a = 175 kJ/mol):** This β-scission pathway represents the most kinetically accessible C–C bond cleavage of the $C_3F_7^{\bullet}$ radical, producing $CF_3^{\bullet}$ and C_2F_4 (tetrafluoroethylene). The $CF_3^{\bullet}$ fragment subsequently participates in secondary reactions leading to CF_4, COF_2 (or CF_2O), while C_2F_4 an exceptionally stable short-chain fluorocarbon tends to persist because further C–F bond cleavage

KD2281

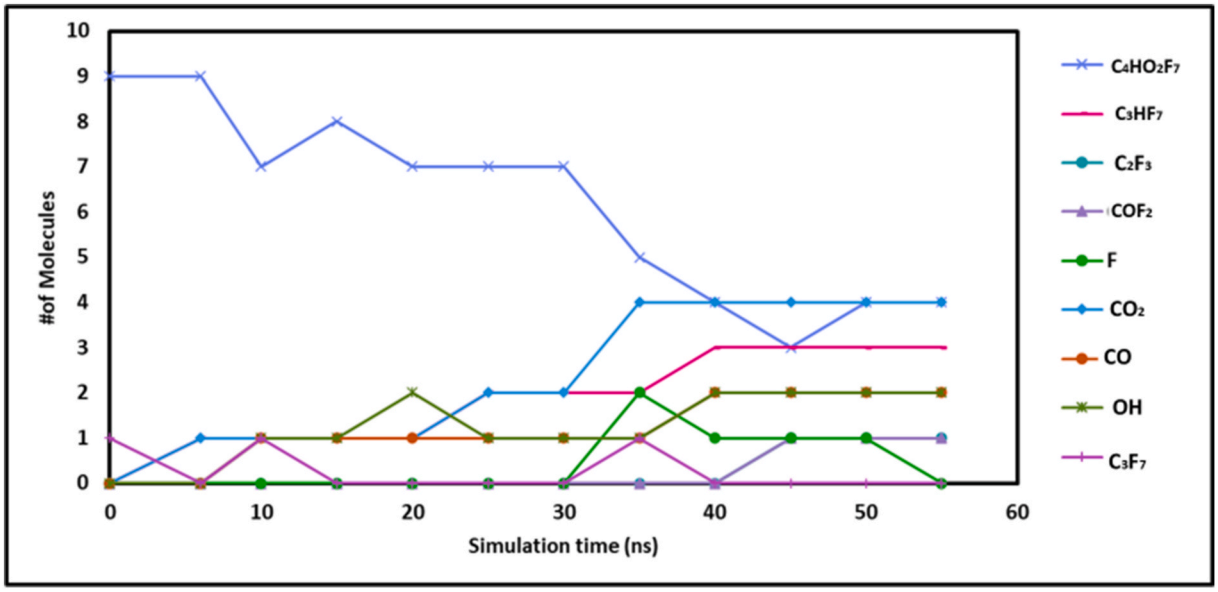

Fig. 1. Time evolution of PFAS fragments and radicals during reactive molecular dynamics (MD) simulation of PFBA thermal decomposition at 1200 K. Colored curves represent the number of molecules of each species (PFBA, C_3HF_7, C_2F_3, COF_2, F, CO_2, CO, OH, and C_3F_7) as a function of simulation time (ns). Additional fragment details are provided in Table S04 of the Supporting Information document.

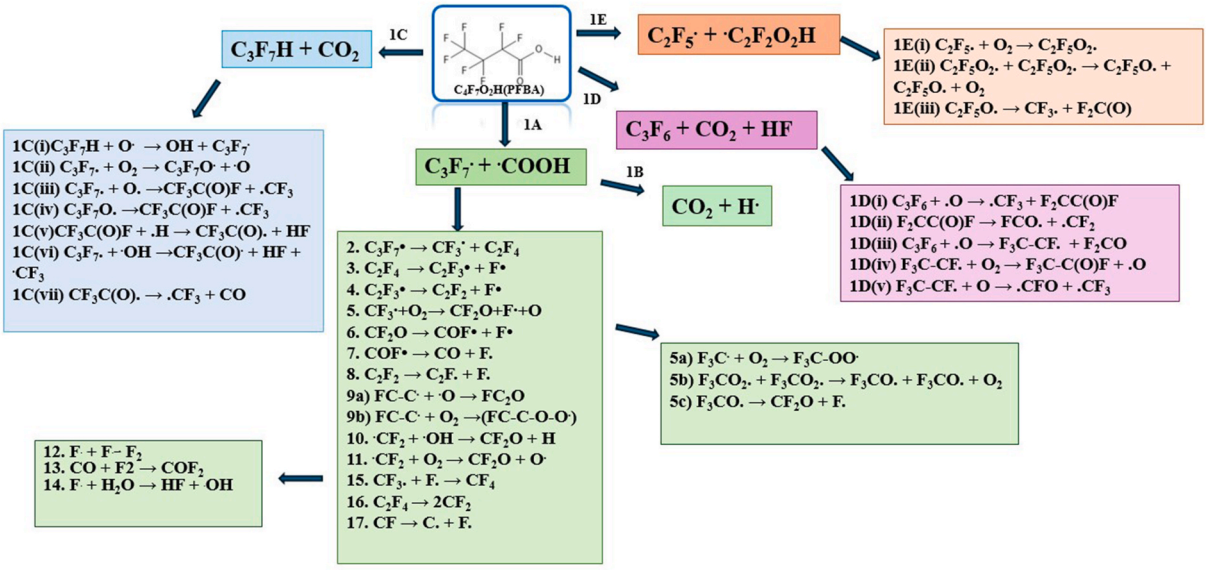

Fig. 2. Schematic illustration of proposed reaction mechanism pathways.

requires a much higher activation energy (E_a = 513 kJ/mol, Reaction 3). As a result, this pathway directs PFAS degradation toward stable, shorter-chain fluorocarbons and explains why C_2F_4 is frequently observed as an intermediate or byproduct during PFAS incineration.

(II) **Oxygen-driven degradation (Reactions 1C(ii)–1C(iv); Ea = 176–262 kJ/mol):** In oxidizing environments, the C_3F_7• radical readily undergoes additional reactions with O_2 to form $C_3F_7O_2$• or with atomic oxygen to generate C_3F_7O•, followed by β-scission of these fluorinated alkoxy intermediates to yield $CF_3C(O)F$ and •CF_3. These steps produce perfluoroacyl fluorides such as $CF_3C(O)F$, which are well-documented intermediates during PFAS combustion. The β-scission of C_3F_7O• (Ea = 262 kJ mol^{-1}) liberates CF_3•, further feeding the sequence of short-chain fluorocarbon fragments. Overall, this oxidative pathway steers the system toward formation of carbonyl species including COF_2, CO, and CO_2, marking the progression toward oxidative mineralization.

(III) **Hydrogen abstraction reactions (Reactions 1C(i) and 1C(v)–1C(vi)):** When H• or OH• radicals are present, C_3F_7• can participate in hydrogen-abstraction reactions or be regenerated through radical exchange. For instance, reaction of C_3F_7H with O• produces OH• and reforms C_3F_7•, while interaction of $CF_3C(O)F$ with H• yields $CF_3C(O)$• and HF, although this process requires a large activation barrier (~500 kJ mol^{-1}) and is therefore kinetically unfavorable at 1200 K. Additionally, reaction between C_3F_7• and OH• generates HF and perfluoroacyl radicals, and the absence of a stable transition state indicates that this step proceeds through a barrierless radical–radical capture mechanism. Collectively, these pathways account for the early formation of

KD2282

HF during incineration when hydrogen-containing species become available.

3.1.4. Formation and fate of toxic products of incomplete combustion (PIC)

Incomplete combustion of PFAS generates a suite of toxic and highly persistent intermediate species, commonly referred to as products of incomplete combustion (PICs). In this research, MD simulations and DFT results show that several PICs, most notably C_2F_4, CF_3•, CF_4, CF_2O, COF_2, and perfluoroacyl fluorides (e.g., $CF_3C(O)F$), emerge naturally along the thermal degradation pathway. These species form when primary PFBA fragmentation produces C_3F_7• radicals, which subsequently undergo β-scission to generate C_2F_4 and CF_3•, both of which are well-documented fluorocarbon PICs reported in experimental PFAS combustion and pyrolysis studies (Altarawneh et al., 2022a; Krug et al., 2022; N. H. Weber et al., 2024).

C_2F_4 is particularly problematic due to its high C–F bond strength and large activation barrier for further cleavage, allowing it to survive typical incineration residence times. CF_3• can also be oxidized or decomposed to COF_2 (carbonyl intermediate) or further react with F• and O• to yield COF_2 (carbonyl fluoride, also known as difluorophosgene), a highly reactive and toxic fluorinated gas. Perfluoroacyl fluorides such as $CF_3C(O)F$ are another important class of PICs; they form through oxygen-driven fragmentation pathways and can subsequently decompose to CF_3• and CO. Although many PICs are thermally stable, their fate ultimately depends on the availability of oxidizing radicals (O•, OH•, O_2), which convert them into final mineralization products CO_2, CO, HF, and inorganic fluoride at sufficiently high temperature and residence time. Altogether, these results highlight that PFAS incineration does not proceed directly to complete mineralization; instead, it passes through a complex network of PICs whose persistence and toxicity underscore the need for sufficiently high temperatures, long residence times, and optimized oxidation conditions to prevent their atmospheric release.

Fig. 3 summarizes the intrinsic C–F bond dissociation energetics for three representative fluorocarbon fragments formed during PFAS degradation. In all cases $C_2F_4 \rightarrow C_2F_3$• + F• (Fig. 4a), $F_2C_2 \rightarrow FC_2$• + F• (Fig. 4b), and CF → C• + F• (Fig. 4c) the potential energy scans reveal extremely high activation barriers (ΔEa ~536–762 kJ mol^{-1}), reflecting the exceptional thermodynamic stability of the C–F bond. The steep rise in energy prior to bond rupture indicates that unimolecular C–F cleavage is not kinetically favorable under typical incineration temperatures (1200 K), meaning that PFAS fragments such as C_2F_4 and CF_3 radicals can persist long enough to act as PICs(Altarawneh et al., 2022b; Krug et al., 2022).

These calculated barriers align with experimental reports showing that perfluoroolefins and fluorinated radicals resist further decomposition unless strong oxidizing species (O•, OH•, O_2) are present to drive alternative pathways such as HF elimination, oxidation, or radical recombination (N. H. Weber et al., 2024). Overall, Fig. 3 shows that PFAS do not decompose through direct C–F bond scission; instead, thermal treatment produces a network of radical intermediates whose fate is strongly governed by oxygen-assisted pathways that determine whether PICs accumulate or mineralize (Altarawneh et al., 2022b; N. H. Weber et al., 2024). These results are consistent with literature values reporting similarly large C–F bond dissociation energies in fluorocarbons (typically 500–750 kJ mol^{-1})(Giannetti, 2005).

Although DFT provides a computationally efficient way to explore PFAS fragmentation pathways, the extremely large dissociation barriers predicted for direct C–F bond dissociation barriers (ΔEa = 536–762 kJ mol^{-1}) require further validation using higher-level wavefunction methods. Coupled-cluster theory (CCSD and CCSD(T)) is the benchmark for thermochemistry and bond dissociation energies, particularly in fluorinated systems where electron correlation plays a critical role. CCSD(T) single-point energies on DFT-optimized structures will be employed in future research to refine the activation barriers and reaction energetics. Because reaction rate constants depend exponentially on activation energy, even moderate corrections (10–20 kJ mol^{-1}) can lead to differences of several orders of magnitude in predicted residence times at 1200 K. Accurate CCSD(T)-based energetics are therefore essential for determining whether specific PFAS fragmentation channels are kinetically accessible during incineration or whether the predicted residence times (hours to days) reflect methodological limitations of DFT-based scans rather than intrinsic chemical behavior.

The recombination of CF_3• + F• → CF_4 (Reaction#15) represents a kinetically favorable radical pathway during PFAS incineration. DFT calculations show that this reaction proceeds with an extremely low activation energy ($E_a \approx 0.13$ kJ mol^{-1}), making it effectively barrierless under thermal conditions. At incineration temperatures (1000–1400 °C), CF_3• and F• radicals generated from C–C and C–F bond scission can recombine rapidly to produce CF_4, a highly stable perfluorocarbon. However, in combustion environments containing hydrogen sources such as water vapor, CF_3• may also preferentially react with H•

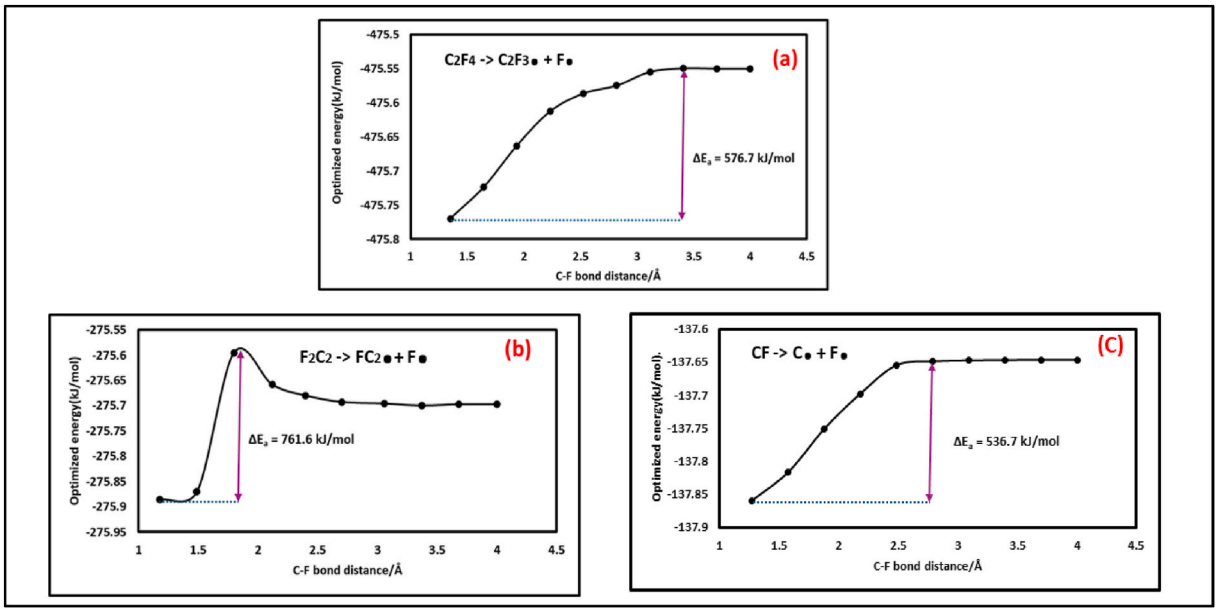

Fig. 3. Energy diagram of (a) $C_2F_4 \rightarrow C_2F_3$. + F., (b) $F_2C_2 \rightarrow FC_2$. + F. and (c) CF → C. + F. calculated using the wB97X-D3BJ/def2-TZVP level of theory.

KD2283

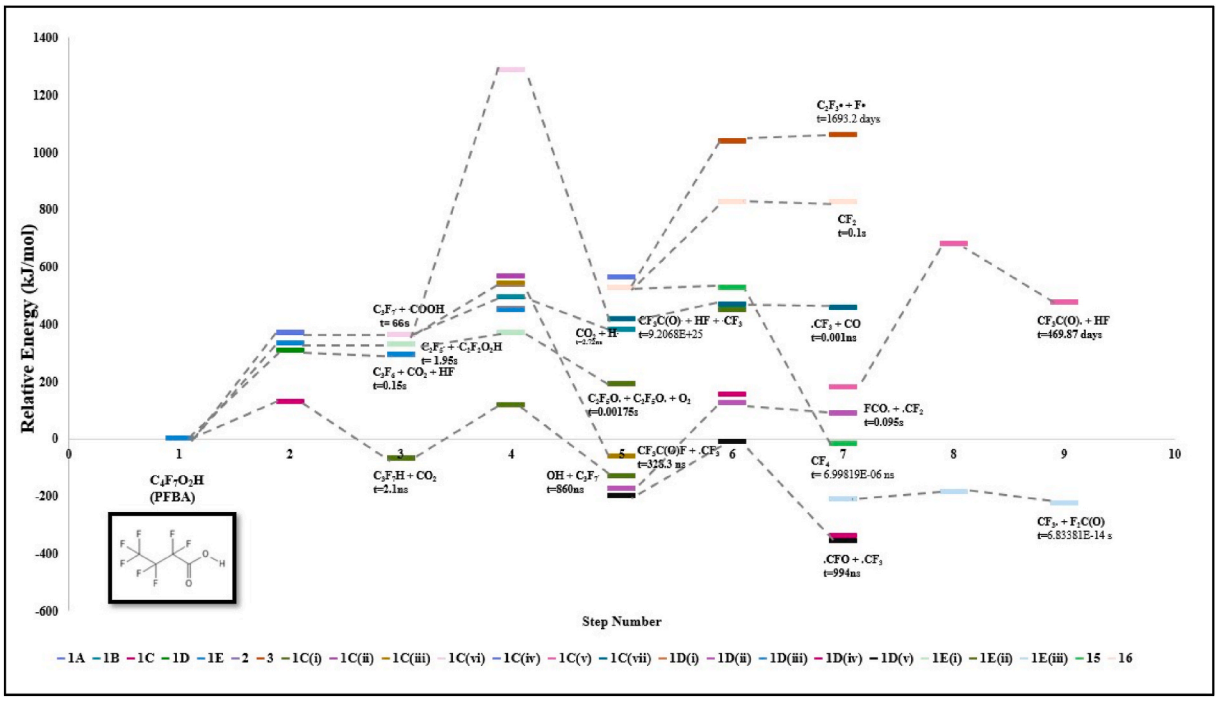

Fig. 4. Schematic diagram of the residence time profile calculated using the rate constant for each reaction step.

to form fluoroform (CHF_3). Therefore, the formation of CF_4 is not inevitable and depends on the availability of hydrogen and the overall combustion conditions.

Conversely, the reverse reaction, $CF_4 \rightarrow CF_3\bullet + F\bullet$, requires overcoming a large barrier (Ea ~542.35 kJ mol^{-1}), reflecting the exceptional thermodynamic stability of CF_4. Even at 1200 K, this barrier is far larger than the available thermal energy, making CF_4 essentially non-decomposable under typical incineration of residence times. Thus, once formed, CF_4 behaves as a terminal product rather than a reactive intermediate.

This large asymmetry between forward and reverse barriers has important implications for PFAS destruction. Any process generating $CF_3\bullet$ and $F\bullet$ radicals whether through β-scission, HF elimination, or fragmentation of perfluoroolefins inevitably channels a fraction of the reaction flux toward CF_4 formation. Because the conversion to CF_4 is kinetically favored and thermodynamically downhill, its breakdown is prohibitively slow and CF_4 accumulates as a product of incomplete combustion (PIC). This mechanistic insight helps explain why CF_4 is consistently detected in laboratory and pilot-scale incineration studies, even at temperatures exceeding 1000 °C, and why complete mineralization of PFAS requires not only high temperatures but also sufficiently long residence times and oxidizing conditions to suppress radical recombination.

3.2. Kinetic modelling, rate constant and residence time calculation

Activation energies (E_a) were calculated as the electronic energy difference between the optimized transition state and reactant structures obtained from DFT calculations. These E_a values (see Table S01 in the SI for details) were then used to estimate temperature-dependent rate constants, k(T), using the Arrhenius expression:

$$k(T) = A.\exp\left(\frac{-E_a}{RT}\right) \quad (1)$$

Where A is the pre-exponential factor estimated from unimolecular transition-state theory and R is the gas constant (0.008314 kJ/mol. K). Rate constants were calculated at the incineration temperature of 1200 K. All calculated rate constants for the individual reaction steps are provided in Table S02 in the SI document.

Assuming pseudo-first-order kinetics for high-temperature PFAS decomposition, degradation follows:

$$\frac{C}{C_0} = e^{-k(T)t} \quad (2)$$

A destruction efficiency of 99.9%, consistent with hazardous-waste combustion standards, corresponds to a remaining fraction:

$$\frac{C}{C_0} = 0.001 \quad (3)$$

Solving for t gives:

$$t_{99.9\%} = \frac{\ln(1000)}{k(T)} \quad (4)$$

Equation (4) was applied to each elementary reaction step to determine the minimum residence time required to achieve 99.9% conversion at incineration temperatures. Reactions with high activation energies (e.g., late-stage formation or destruction of CF_4, C_2F_6) exhibited extremely small k values at 1200 K, resulting in residence times that exceed to minutes, far longer than typical incinerator gas-phase residence times (0.5–2 s). In contrast, early PFBA fragmentation and oxygen-addition steps proceed rapidly (<μs), indicating that the major kinetic bottlenecks are the final defluorination and destruction of ultra-stable fluorocarbons, not the initial PFAS decomposition.

Table S02 summarizes the calculated activation energies (ΔEa), unimolecular rate constants k (1200 K), and corresponding residence times required to reach 99.9 percent conversion ($t_{99.9}$) for each elementary step in the proposed C_3F_7COOH degradation network calculated using the A value (Bao et al., 2016; Choi et al., 2023; Cobos et al., 2013; Confer et al., 2020; Harvey, 2013; Harvey et al., 2012) as $1.00*10^{15}$. The residence time is reported in seconds, nanoseconds, and days to highlight processes that are relevant on the incinerator timescale (milliseconds to a few seconds) versus those that are effectively frozen at 1200 K.

Overall, the data show that the initial decomposition of C_3F_7COOH is very fast at 1200 K. Decarboxylation to $C_3F_7\bullet$ + •COOH (Reaction 1A)

KD2284

has a moderate barrier (ΔE_a ~224 kJ mol^{-1}) but still proceeds with k ~ 1.7 × 10^5 s^{-1}, corresponding to $t_{99.9}$ ~ 4 × 10^{-5} s. Subsequent fragmentation of •COOH to CO_2 + H• (Reaction 1B) and the alternative decarboxylative hydrogen transfer channel $C_3F_7COOH \rightarrow C_3F_7H + CO_2$ (Reaction 1C) are even faster (ΔE_a ~126–129 kJ mol^{-1}, k ~ 10^9 s^{-1}, $t_{99.9}$ on the order of 10^{-9} s). Thus, the parent PFBA is essentially consumed instantaneously compared to typical gas-phase residence times in hazardous waste incinerators.

Once C_3F_7• is formed, its reactions with O, O_2 and OH proceed within microsecond to sub-millisecond timescales. Steps 1C(i)–1C(iii) and 2, which include $C_3F_7H + O$•, C_3F_7• + O_2, C_3F_7• + O• and C_3F_7• → CF_3• + C_2F_4, all have ΔE_a in the range of 176–203 kJ mol^{-1} and rate constants of 10^6–10^7 s^{-1}, giving $t_{99.9}$ values between about 10^{-7} and 10^{-6} s. Rearrangement of C_3F_7O• to $CF_3C(O)F + CF_3$• (Reaction 1C(iv)) is somewhat slower (ΔE_a ~262 kJ mol^{-1}, $t_{99.9}$ ~ 1.7 × 10^{-3} s), but still easily completed within a 2s incinerator residence time. Direct HF elimination to C_3F_6 (Reaction1D) and C2 fragment formation (Reaction 1E) are slower than the radical pathways but remain kinetically accessible at 1200 K, with $t_{99.9}$ of about 0.15s and 0.59s, respectively.

In contrast, several downstream fragmentation steps and PIC decomposition reactions are orders of magnitude slower. The hydrogen abstraction from $CF_3C(O)F$ by H• (Reaction 1C(v)) and the unimolecular decomposition of C_2F_4 to C_2F_3• + F• (step 3) and COF_2 to COF• + F• (step 6) have very high barriers (ΔE_a ~485–513 kJ mol^{-1}) and extremely small rate constants at 1200 K. The corresponding $t_{99.9}$ values are on the order of 10^7–10^{8}s, which translates from tens to thousands of days. C_2F_4 can undergo relatively rapid dissociation to CF_2 (16), its subsequent transformation depends on oxidation pathways not fully captured within the unimolecular framework considered here. In contrast, COF_2 exhibits intrinsic kinetic persistence due to its slow unimolecular decomposition. Additionally, OH-mediated oxidation, if available, may provide an alternative depletion pathway for CF_2O; however, it is not explicitly included in the present framework. Therefore, C_2F_4 is more appropriately described as a reactive intermediate reservoir, whereas COF_2 represents a kinetically persistent fluorinated product within the present reaction network. By comparison, many radical recombination or low barrier steps, such as C_2F_5• + O_2 (Reaction 1E(i)), FC–C• + O (Reaction 9A), CO + F_2 (Reaction 13), and F• + H_2O (Reaction 14), exhibit very small ΔE_a (0–40 kJ mol^{-1}), rate constants on the order of 10^{13}–10^{15}s^{-1}, and $t_{99.9}$ in the picosecond or sub-nanosecond regime, indicating that they are essentially diffusion controlled.

Table S02 shows a clear separation of timescales. Primary PFAS decomposition and most radical propagation steps are much faster than a 2 s (s) residence time at 1200 K, which explains efficient disappearance of the parent C_3F_7COOH. However, a small subset of high barrier steps that control the breakdown of C_2F_4, COF_2 and related fragments are far too slow to reach completion under typical incineration conditions. These slow steps constitute the kinetic bottlenecks that allow persistent fluorocarbon PICs to survive and be emitted even when PFAS destruction efficiencies appear high.

Fig. 4 is a schematic illustration of the energy and the residence time profile for selected reactions. The residence time data for all the proposed reactions are in Table S03 in the SI document.

Table 1 presents the calculated activation energy (ΔE_a = 512.9 kJ mol^{-1}), temperature-dependent rate constants, and corresponding residence times for the $C_2F_4 \rightarrow C_2F_3$• + F• dissociation. Because reaction rates follow the Arrhenius relationship, even small increases in temperature have an exponential effect on k(T). As a result, the residence time required for 99.9% conversion ($t_{99.9\%}$) decreases dramatically as temperature increases.

At low to moderate temperatures (500–1200 K), the rate constant remains exceedingly small (k ~ 10^{-39} –10^{-8}s^{-1}), resulting in residence times on the order of years to thousands of seconds. Such long timescales confirm that direct C–F bond dissociation is kinetically inaccessible under typical incineration conditions, where gas residence times rarely exceed 1–2s.

However, once temperatures exceed ~3000 K, the rate constant increases sharply (k ~ 10^6–10^{8}s^{-1}), and the corresponding residence times collapse into the nanosecond regime ($t_{99.9\%}$ ~10^{-6}–10^{-8}s). At 5000 K, $t_{99.9\%}$ is on the order of 1–2 s for 99.9% decomposition, with characteristic times of nanoseconds for single-molecule events. These extremely short times reflect the fact that, at such high temperatures, the thermal energy (RT) approaches the magnitude of the activation barrier, placing the system in a regime where bond dissociation becomes statistically probable within ultrashort time windows.

Residence times of minutes to days at these temperatures explain why C_2F_4 and related PFAS fragments persist and behave as PICs. Such temperatures are far above those reached in practical waste-incineration systems but can occur during shock heating, plasma treatment, or ultrasonic cavitation hot-spots, consistent with experimental observations of transient PFAS fragmentation under those conditions. Overall, kinetic calculations reported here demonstrate that thermal decomposition of PFAS cannot rely on unimolecular C–F cleavage, and must instead proceed through lower-energy radical, oxidative, or stepwise pathways. The $t_{99.9\%}$ values shifting from days to nanoseconds as temperature increases encapsulate this fundamental kinetic limitation.

Fig. 5 shows the temperature-dependent residence time required for 99.9% conversion of $C_2F_4 \rightarrow C_2F_3$• + F• based on transition-state-derived rate constants. Below ~1500 K, the predicted residence time exceeds practical incineration scales (>10^3–10^8 days), indicating that direct C–F scission is kinetically inaccessible. Only at temperatures above ~3500 K does the reaction occur on sub-second timescales, highlighting that unimolecular dissociation cannot drive PFAS destruction under conventional combustion conditions.

Fig. 6 illustrates the temperature dependence of PFBA decomposition obtained from reactive MD simulations over 10ns time limit. The detailed species list is shown in Table S04 ((a)-(f)) in the SI document. At 500 and 1000 K, the number of intact PFBA molecules remains nearly constant over the simulation time, indicating negligible thermal degradation. In contrast, at 2000 K and above, PFBA undergoes rapid fragmentation, with the intact molecule population declining sharply within the first few nanoseconds. At 3000 K and higher, complete PFBA decomposition occurs almost instantaneously on the MD timescale. This behavior demonstrates that increasing temperature significantly accelerates PFBA breakdown, reflecting the exponential temperature dependence of bond dissociation and radical-driven degradation

pathways.

3.3. Comparison with the experiment and field scale data

The mechanistic and kinetic insights obtained from MD and DFT simulations align closely with observations from laboratory-scale thermal degradation and full-scale incineration studies. Experimental investigations have shown that PFAS degradation does not occur in a single step but proceeds through a sequence of intermediate products of incomplete combustion (PICs), including C_2F_4, CF_3•, CF_2O, COF_2, and perfluoroacyl fluorides, which matches the intermediate species identified in the MD trajectories and reaction pathways predicted in this study. Similar intermediates have been reported in experimental and kinetic studies of PFAS thermal decomposition and combustion chemistry (Altarawneh et al., 2022a; Krug et al., 2022; N. H. Weber et al., 2024).

Field-scale incinerator measurements have similarly detected short-chain fluorocarbons and acid fluorides under suboptimal operating conditions, supporting the conclusion that degradation pathways involving β-scission of perfluoroalkyl radicals and formation of perfluoroacyl fluorides are kinetically favored at high temperature (Rocchio et al., 2025).

KD2286

These qualitative agreements with experimental observations provide indirect validation of the computational reaction mechanisms and kinetic trends predicted in this study.

In addition, calculated activation barriers provide a mechanistic explanation for the persistence of certain fluorinated species in real systems. For example, the high Ea for C_2F_4 defluorination (~513 kJ/mol) is consistent with experimental findings that tetrafluoroethylene can survive typical residence times in rotary kilns and fluidized-bed incinerators. Similarly, the predicted formation of COF_2 follows established combustion chemistry, and both compounds have been reported in laboratory pyrolysis and smoldering tests (Krug et al., 2022; N. H. Weber et al., 2024).

Residence-time estimates derived from Arrhenius-based rate constants in this study likewise agree with engineering data: while early fragmentation steps proceed rapidly, complete destruction of stable PICs such as COF_2 and C_2F_4 requires residence times longer than those commonly used in conventional municipal or hazardous-waste incinerators. These findings are consistent with experimental combustion studies demonstrating that PFAS destruction efficiency depends strongly on temperature, residence time, oxidizing conditions, and reactor design (Altarawneh et al., 2022a; Krug et al., 2022; N. H. Weber et al., 2024).

Overall, computational results provide a mechanistic foundation that explains, and, in several cases, predicts the intermediates, byproducts, and destruction of efficiencies observed in experimental studies and full-scale thermal treatment systems.

4. Conclusions

This work provides molecular-level insight into the thermal breakdown of PFAS using combined MD simulations and DFT-based reaction kinetics. By systematically resolving elementary decomposition steps of PFBA and quantifying activation barriers, this study demonstrates that PFAS destruction during high-temperature treatment does not occur through direct C–F bond cleavage. Instead, early decomposition is controlled by rapid decarboxylation and β-scission steps that generate highly persistent intermediates such as C_2F_4, $CF_3\bullet$, and COF_2. These radicals and fluorinated fragments form within microsecond timescales, well within typical incineration residence times; however, their subsequent defluorination transitions exhibit activation energies more than 480–520 kJ mol^{-1} and residence times ranging from seconds to several days at 1200 K. Kinetic modeling clearly distinguishes fast, thermally accessible reactions from rate-limiting defluorination events. While initial PFBA dissociation and oxidative propagation reactions rapidly proceed toward intermediate fluorocarbon formation, the slow unimolecular breakdown of C_2F_4 and COF_2 acts as the dominant kinetic bottleneck. These findings provide a mechanistic basis for the recurrence of these species as products of incomplete combustion in laboratory and full-scale incineration studies. Moreover, the asymmetry in energetics such as essentially barrierless recombination of $CF_3\bullet + F\bullet \rightarrow CF_4$ contrasted with the very slow decomposition of CF_4 explains the accumulation of terminal perfluorocarbons even at elevated combustion temperatures.

Overall, the atomistic framework developed here based on the unimolecular intrinsic reaction kinetics quantitatively links reaction energetics to residence-time requirements and suggested that complete mineralization of fluorinated intermediates may require longer residence time than reported for conventional incineration.

Although PFBA was used as a representative short-chain PFCA in this study, the mechanistic framework developed here can be extended to other PFAS classes, since many PFAS share similar perfluoroalkyl backbones and radical-driven fragmentation pathways during thermal decomposition. The findings highlight the need for either extended high-temperature exposure, enhanced oxidizing environments, plasma/electrical heating zones, or catalytic interventions to accelerate terminal defluorination steps. The mechanistic insights and kinetic thresholds established in this research provide a scientific foundation for optimizing incineration design and preventing emission of persistent fluorocarbon combustion products. Unlike thermal treatment, which requires extended residence times to overcome large activation barriers, ultrasonication produces microsecond-duration hotspots exceeding 3000 K, enabling complete PFAS mineralization in a significantly shorter time.

The **National Academy of Sciences** was established in 1863 by an Act of Congress, signed by President Lincoln, as a private, nongovernmental institution to advise the nation on issues related to science and technology. Members are elected by their peers for outstanding contributions to research. Dr. Marcia McNutt is president.

The **National Academy of Engineering** was established in 1964 under the charter of the National Academy of Sciences to bring the practices of engineering to advising the nation. Members are elected by their peers for extraordinary contributions to engineering. Dr. John L. Anderson is president.

The **National Academy of Medicine** (formerly the Institute of Medicine) was established in 1970 under the charter of the National Academy of Sciences to advise the nation on medical and health issues. Members are elected by their peers for distinguished contributions to medicine and health. Dr. Victor J. Dzau is president.

The three Academies work together as the **National Academies of Sciences, Engineering, and Medicine** to provide independent, objective analysis and advice to the nation and conduct other activities to solve complex problems and inform public policy decisions. The National Academies also encourage education and research, recognize outstanding contributions to knowledge, and increase public understanding in matters of science, engineering, and medicine.

Consensus Study Reports published by the National Academies of Sciences, Engineering, and Medicine document the evidence-based consensus on the study's statement of task by an authoring committee of experts. Reports typically include findings, conclusions, and recommendations based on information gathered by the committee and the committee's deliberations. Each report has been subjected to a rigorous and independent peer-review process and it represents the position of the National Academies on the statement of task.

Proceedings published by the National Academies of Sciences, Engineering, and Medicine chronicle the presentations and discussions at a workshop, symposium, or other event convened by the National Academies. The statements and opinions contained in proceedings are those of the participants and are not endorsed by other participants, the planning committee, or the National Academies.

Rapid Expert Consultations published by the National Academies of Sciences, Engineering, and Medicine are authored by subject-matter experts on narrowly focused topics that can be supported by a body of evidence. The discussions contained in rapid expert consultations are considered those of the authors and do not contain policy recommendations. Rapid expert consultations are reviewed by the institution before release.

Reviewers

This Consensus Study Report was reviewed in draft form by individuals chosen for their diverse perspectives and technical expertise. The purpose of this independent review is to provide candid and critical comments that will assist the National Academies of Sciences, Engineering, and Medicine in making each published report as sound as possible and to ensure that it meets the institutional standards for quality, objectivity, evidence, and responsiveness to the study charge. The review comments and draft manuscript remain confidential to protect the integrity of the deliberative process.

We thank the following individuals for their review of this report:

Andrea Amico, Testing for Pease
Dean Baker, University of California, Irvine
Linda Birnbaum, National Institute of Environmental Health Sciences and National Toxicology Program (retired)
Julia Brody, Silent Spring Institute
Courtney Carignan, Michigan State University
Ellen Chang, Center for Health Sciences at Exponent, Inc.
Nicholas Chartres, University of California, San Francisco
Alan Ducatman, West Virginia University School of Public Health and School of Medicine
Baruch Fischhoff, Howard Heinz University
Philippe Grandjean, Harvard University
Alex John London, Carnegie Mellon University
Donald Mattison, University of South Carolina
Joseph V. Rodricks, Ramboll
Carlos Santos-Burgoa, The George Washington University
Susan L. Santos, Veterans Biomedical Research Institute
Annie St-Amand, Health Canada
Heather M. Stapleton, Duke University
John Washington, U.S. Environmental Protection Agency

Although the reviewers listed above provided many constructive comments and suggestions, they were not asked to endorse the conclusions or recommendations of this report, nor did they see the final draft before its release. The review of this report was overseen by **Joshua Sharfstein**, Johns Hopkins Bloomberg School of Public Health, and **Susan Brantley**, The Pennsylvania State University. They were responsible for making certain that an independent examination of this report was carried out in accordance with the standards of the National Academies and that all review comments were carefully considered. Responsibility for the final content rests entirely with the authoring committee and the National Academies.

Acknowledgments

Many people were critical in helping the committee accomplish its charge. The committee gratefully acknowledges the work of the community liaisons who provided insight and viewpoints pertinent to planning for our public meetings. In particular, we thank Andrea Amico, Emily Donovan, Patrick Elder, Ayesha Khan, Kristen Mello, and Laura Olah, who provided helpful insights on the perspectives and experiences of their communities that informed our community engagement methods. This engagement ensured that our public meetings would include the relevant perspectives, which allowed us to learn about the social, environmental, public health, and medical challenges central to our charge. In addition, we found the information and perspectives provided by the presentations and discussions at our public meetings immensely helpful in informing our deliberations (see Appendix C).

The committee's work was enhanced by the technical expertise; writing contributions; data evaluation, visualization, and extraction; and other support provided by Cary Haver, Jordan Kuiper, Judy Lakind, Kate Marquess, Melissa Miller, Josh Naiman, Anna Ruth Robuck, and Lauren Tobias, who served as consultants. We would also like to acknowledge the U.S. Environmental Protection Agency's Office of Water and Office of Research and Development for sharing publicly available abstracted data from some of the epidemiologic studies included in our literature review, as well as Scott M. Bartell and Nicholas Cuvelier from the University of California, Irvine, for calculating percentiles of per- and polyfluoroalkyl (PFAS) exposure.

Importantly, the committee heard from a number of individuals who shared their personal stories about and experiences with PFAS exposure, testing, and clinical follow-up. These discussions helped ground our work in the lived experiences of the complex issues that had to be tackled in this report, and we are extremely grateful for their courage in sharing those experiences in a public forum.

The committee thanks the staff of the National Academies of Sciences, Engineering, and Medicine who contributed to producing this report, especially the extraordinary, creative, and tireless study staff: Kaley Beins, Elizabeth Boyle, Clifford Duke, Kathryn Guyton, Rose Marie Martinez, Alexandra McKay, Marilee Shelton-Davenport, and Alexis Wojtowicz. Thanks as well go to other staff in the Division on Earth and Life Studies who provided additional support, including Tamara Dawson, Eric Edkin, Elizabeth Eide, Lauren Everett, Nancy Huddleston, Radiah Rose, and Maggie Walser. This project also received important assistance from Megan Lowry (Office of News and Public Information) and Matthew Anderson (Office of Financial Administration). Valuable research assistance was provided by Christopher Lao-Scott, senior research librarian in the National Academies Research Center. Finally, a thank you is extended to Rona Briere and Allison Boman, who assisted the committee with editing the report.

Preface

The creation of the U.S. Environmental Protection Agency (EPA) in 1970 signaled public recognition of industrial impacts on the environment. The government subsequently acknowledged that three elements essential for life—air, water, and food—could be contaminated by industrial activity and threaten human health. In 1980, two steps were taken in response to the government's concern: passage of the Comprehensive Environmental Response, Compensation, and Liability Act and creation of the Agency for Toxic Substances and Disease Registry (ATSDR).

The mission of ATSDR is to prevent or mitigate the adverse impacts on human health and diminished quality of life resulting from exposure to hazardous substances in the environment. The earliest contaminants of concern included pesticides; heavy metals from mining; asbestos; munitions and their manufacturing by-products (including radioactive substances); petrochemicals, including solvents; and products and by-products associated with oil and gas extraction, refinement, and use. Over time, additional industrial products with significant potential to affect the population's health have been identified, including the class of chemicals known as per- and polyfluoroalkyl substances, or PFAS. PFAS have useful properties, such as oil and water repellency, temperature resistance, and friction reduction. For decades, they have been used in numerous applications and products, such as firefighting; chrome-plating; lubricants; insecticides; and coatings and treatments for such surfaces as carpeting, packaging, and cookware. As a result of the production and use of PFAS, many sites across the country are contaminated with PFAS, which in turn can result in contamination of soils and drinking water.

ATSDR faces a critical challenge in protecting people from the potential health impacts of PFAS exposures. Data from the National Health and Nutrition Examination Survey show that nearly 100 percent of people in the United States are exposed to at least one PFAS, but at what level of exposure do harms to human health occur? What PFAS-associated health outcomes might benefit from clinical follow-up or care? Would there be any benefit in testing people to know their PFAS exposure level? What clinical follow-up can help protect people from PFAS-associated harms?

Answering these questions requires bridging approaches used for chemical hazard assessments, such as those carried out by the EPA; public and community health benefits, such as those laid out in the Community Guide to Preventive Services; and medical care health benefit assessments, such as those of the U.S. Preventive Services Task Force. Chemical hazard assessments are conducted to determine whether a chemical exposure causes harm; public health assessments address the impact on and interventions to mitigate threats to the health of a population or community; and medical care health benefit assessments evaluate the effects of medical interventions, including their beneficial effects and potential adverse outcomes. One challenge with blending these different approaches is that in medical care health benefit assessments, the "gold standard" for informing clinical risk/benefit decisions for medical interventions is the randomized controlled trial (RCT). However, RCTs are typically impossible for chemical hazard assessments, for both ethical and practical reasons. For example, most environmental chemicals are not developed to improve human health, making intentional exposures in an RCT unethical. Chemical exposures also vary and may or may not be significant depending on the agent's toxicity, which sometimes makes controlled trials infeasible. And public health assessments, in which comparative studies are still required to support evidence-based recommendations, usually require many years of data and are challenged by the long-standing and often-lamented separation of health care and public health.

In 2010, researchers Stephen Rappaport and Martyn Smith reported that "70 to 90% of disease risks are probably due to differences in environments" and made the case for a more comprehensive approach to evaluating environmental exposures in order to understand the causes of and contributors to

Copyright National Academy of Sciences. All rights reserved.

chronic disease.[2] Such an approach has, as in the case of lead, and will, for chemicals such as PFAS, ultimately depend on breaking down the barriers between environmental public health and the clinical care setting. These two health sectors have had some limited success in bridging the gap for infectious disease outbreaks and epidemics. Identifying environmental exposures, measuring exposure levels in patients, and providing indicated medical follow-up are elements of a critical frontier that could and should bring the two disciplines closer together to improve the health of those in the nation's communities.

Another challenge for the study committee was the critical need to include community voices in the study process as an important and credible source of evidence to inform guidance recommendations. To meet that challenge, this study included the testimony of more than 30 people who live in or work with a community impacted by PFAS contamination. Community members provided the committee with much needed data based on their lived experiences with PFAS contamination, and moved the committee's work from an academic exercise to a personal reality. The committee used the presentations of community members to inform frameworks within the report and to gain an understanding of the social context that the committee's recommendations will inform.

Atmospheric chemist Susan Solomon has suggested that successfully addressing environmental challenges requires making the problem personal, perceptible, and practical. The voices of affected individuals in contaminated communities make the PFAS issue personal, while the scientists researching the associations with human health make the impacts of PFAS exposure perceptible. In this report, the committee has endeavored to provide practical recommendations that can aid policy makers, state and federal environmental and public health agencies, clinicians, and concerned individuals in addressing this important health problem.

Summary[1]

Perfluoroalkyl and polyfluoroalkyl substances (PFAS) are a class of chemicals that includes more than 12,000[2] different compounds with various chemical properties. PFAS are commonly used in thousands of products, from nonstick cookware to firefighting foams and protective gear, because they have desirable chemical properties that impart oil and water repellency, friction reduction, and temperature resistance. PFAS as a class have a wide variety of distinct chemical properties and toxicities; for example, some PFAS can bioaccumulate and persist in the human body and the environment, while others transform relatively quickly. The PFAS that do transform, however, will become one or more other PFAS because the carbon–fluorine bond they contain does not break naturally. It is for this reason that PFAS are termed "forever chemicals."

STUDY CONTEXT

Public concern about the impact of PFAS contamination on human health and the environment began in the late 1990s when perfluorooctanoic acid (PFOA) water contamination was identified in Parkersburg, West Virginia. As a result, 3M, a primary PFAS manufacturer initiated a voluntary phase-out of some PFAS (PFOA, perfluorooctanesulfonic acid [PFOS], and perfluorohexanesulfonic acid [PFHxS]). The contamination in Parkersburg also led to a class action lawsuit that identified several health effects related to PFAS exposure and led to the establishment of a medical monitoring program in 2013. Shortly thereafter, the U.S. Environmental Protection Agency (EPA) began requiring all community water systems serving more than 10,000 people to test for certain PFAS, which led to more communities learning that their water was contaminated. In 2016, researchers found that the drinking water supply for Wilmington, North Carolina, was contaminated with a chemical called "GenX," a PFOA replacement. This finding led to public concern about the potential health effects of replacement PFAS (see Figure S-1).

Organizations such as the International Agency for Research on Cancer (IARC), the Agency for Toxic Substances and Disease Registry (ATSDR), and the EPA have linked exposure to PFAS (particularly PFOA and PFOS) to multiple cancers, thyroid dysfunction, small changes in birthweight, and high cholesterol. Gaining a complete picture of the threat can be difficult, however, because of the chemical and toxicological differences among individual PFAS and uncertainty about the exposure level at which their adverse effects may occur. In addition, many of the chronic diseases associated with PFAS exposure have myriad causes.

An estimated 2,854 U.S. locations (in all 50 states and two territories) have some level of PFAS contamination (see Figure S-2). Although not all of the contamination represents exceedances of health advisories, the pervasiveness of the contamination is alarming. Furthermore, almost 100 percent of the U.S. population is exposed to at least one PFAS. Although exposures to the phased-out PFAS have been decreasing (see Figure S-3), people are still exposed to those PFAS from site contamination, occupational uses of stored products, and breakdown of PFAS polymer products that are found in homes. Carpeting, for example, is often treated with fluorotelomer-based polymers that can biodegrade to form phased-out PFAS, such as PFOA. Exposures also occur to the PFAS chemicals used to replace those that have been phased out. Although the harms of the replacement PFAS are less well understood, they may have

comparable or more serious toxicity than the PFAS they have replaced. The state of New Jersey, for example, recently set a groundwater standard for a replacement PFAS that is an order of magnitude lower than drinking water standards for other PFAS. The New Jersey maximum contaminant levels of perfluorononanoic acid (PFNA), PFOA, and PFOS in drinking water are 13, 14, and 13 nanograms per liter (ng/L), respectively,[3] while the groundwater standard for the replacement PFAS, chloroperfluoropolyether carboxylates, is 2 ng/L.[4]

FIGURE S-2 PFAS contamination across the United States.
NOTES: According to the Environmental Working Group (EWG), "locations represented on the map are approximate and intended to portray the general area of a contamination site or a community water system. Locations were mapped using the best data available from official records, including data provided by tests of public drinking water systems, the Safe Drinking Water Information System and the Department of Defense report *Addressing Perfluorooctane Sulfonate (PFOS) and Perfluorooctanoic Acid (PFOA)*, and Department of Defense public records, among others. Data on contaminated industrial and military sites was current as of October 2021." Furthermore, "EWG has worked to ensure the accuracy of the information provided in this map. The map is dynamic. This contaminant site, results, suspected sources and other information in the database may change based on evolving science, new information or other factors. Please be advised that this information frequently relies on data obtained from many sources, and accordingly, EWG cannot guarantee the accuracy of the information provided or any analysis based thereon."

The people who live, work, and play in environments where PFAS contamination exceeds standards do not know how to protect themselves from the health risks of exposure. Many have been exposed to PFAS for decades and may continue to be exposed in their homes or workplaces. Some members of communities that have discovered that their exposures exceed health advisory levels are calling for a medical program to prevent, lead to early detection of, or treat diseases related to the health risks they may face. Developing such a program is challenging, however, because of the uncertainties about the health effects of PFAS and potential harms from additional medical treatments; moreover, many of these diseases are not preventable or even treatable, and many clinicians lack information about what they can and should do for these patients.

To help clinicians[5] respond to patient concerns about PFAS exposure, ATSDR published *PFAS: An Overview of the Science and Guidance for Clinicians on Per- and Polyfluoroalkyl Substances.*[6] This guidance summarizes general information about PFAS and PFAS health studies and suggests answers to example patient questions. However, the ATSDR guidance does not provide specific recommendations on when to test for PFAS, how to order the tests, how to interpret the results, or what clinical follow-up based on PFAS exposure might look like. Interpretation of PFAS blood or urine results is challenging because the specific level of exposure at which harms may occur is unknown, and the science on the potential health effects of exposure to PFAS is advancing quickly, making it difficult to provide advice to clinicians about what follow-up tests might be helpful.

STUDY CHARGE AND APPROACH

ATSDR and the National Institute of Environmental Health Sciences (NIEHS) asked the National Academies of Sciences, Engineering, and Medicine to form an ad hoc committee to advise on PFAS testing and clinical care for patients exposed to PFAS. The Statement of Task asked the committee to

- develop principles for biological testing and clinical evaluation, given substantial scientific uncertainty about the health effects or the value of such measures in informing care,
- review the human health literature for the health effects of PFAS, and
- characterize human exposure pathways and develop principles for exposure reduction.

The Statement of Task asked the committee to recommend

- options and considerations to guide decision making for PFAS testing in a patient's blood or urine,
- PFAS concentrations that could inform clinical care of exposed patients, and
- appropriate patient follow-up and care specific to PFAS-associated health endpoints for those patients known or suspected to be exposed to PFAS.

The committee also was asked to provide advice on changes to ATSDR's clinical guidance. The committee was not asked for community prevention guidance or advice on policies that would reduce exposure to PFAS.

Figure S-4 summarizes the committee's approach to the Statement of Task. A critical component of the approach was community engagement because people who live with potentially harmful exposures have knowledge from experiential learning that precedes scientific findings. The study's community engagement consisted of a panel of community liaisons, three town halls (summarized in Appendix B),

[5] The committee uses "clinician" throughout this report to refer to "a healthcare professional qualified in the clinical practice of medicine. Clinicians may be physicians, nurses, pharmacists, or other allied health professionals" as defined by the Centers for Medicare & Medicaid Services (https://www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/MMS/QMY-Clinicians [accessed June 14, 2022]).

[6] See https://www.atsdr.cdc.gov/pfas/docs/clinical-guidance-12-20-2019.pdf (accessed June 14, 2022).

community speakers at every public committee meeting, open sign-up for public testimony at every public meeting, and encouragement for written testimony throughout the data collection phase of the study. The following sections provide descriptions of the remaining components of the study approach and the committee's associated recommendations.

COMMITTEE'S PRINCIPLES FOR DECISION MAKING UNDER UNCERTAINTY

Providing clear advice to clinicians on clinical follow-up for PFAS-exposed patients is challenging. The questions in the Statement of Task all have some degree of uncertainty. First, clinicians need to know what the health consequences of PFAS exposure are. If everyone is exposed, what exposure level warrants follow-up? What actions can be taken to reduce exposure or prevent disease? What are the harms of those actions? Answering all of these questions requires making ethical judgments. Building on the work of other experts and evidence-to-decision frameworks, the committee developed five principles to guide decision making under uncertainty for use throughout this report and by ATSDR when updating the guidance for clinicians: proportionality, justice, autonomy, feasibility, and adaptability (see Box S-1). In the clinical setting, these principles converge under the principle of autonomy; thus, shared, informed decision making between clinician and patient is the practical way to incorporate the principles into a clinical encounter.

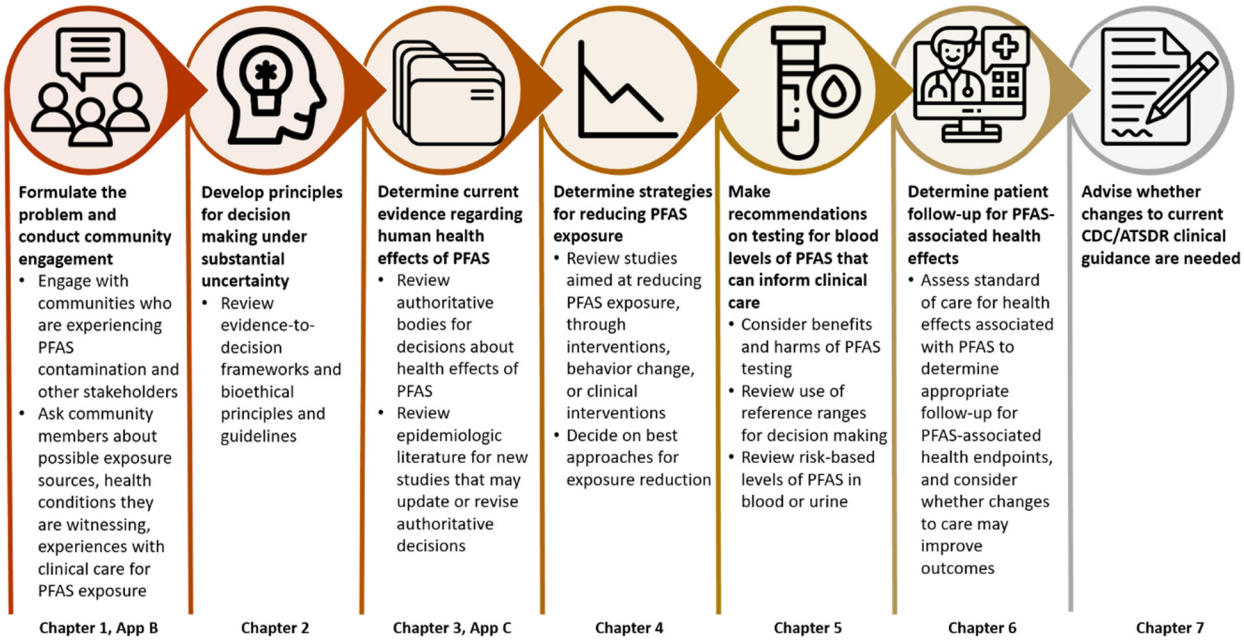

FIGURE S-4 The committee's approach to the Statement of Task and the chapters and appendixes where the topics are discussed.
NOTE: ATSDR = Agency of Toxic Substances and Disease Registry; CDC = Centers for Disease Control and Prevention; PFAS = per- and polyfluoroalkyl substances.

BOX S-1
Principles for Decision Making Under Uncertainty Used in This Report

Proportionality: Decisions should balance plausible harms and benefits proportionally, meaning that the harms and benefits are considered together and weighed based on a qualitative assessment of their potential likelihoods and magnitudes.

Justice: Decisions should be informed by an emphasis on promoting justice, including by balancing benefits and harms fairly across the population of at-risk individuals, advancing health equity, and respecting human rights. In addition, justice requires consideration of sociohistorical context, stakeholders, existing structural inequalities, and issues of agency (the power a community has to advocate for itself in conflicts).

Autonomy: Decisions should be based on informed decision making by individuals and reflect respect for their values.

Feasibility: Decisions should take into account resource availability, including follow-up services.

Adaptability: Decisions should respond to new information about harms, benefits, and other relevant considerations (e.g., health equity and feasibility).

POTENTIAL HEALTH EFFECTS OF PFAS

To recommend PFAS levels that should inform clinical care, the committee conducted a literature review to determine health effects or conditions associated with PFAS. The Statement of Task limited this review to human studies of those PFAS included in the Centers for Disease Control and Prevention's (CDC's) *National Report on Human Exposure to Environmental Chemicals* (see Table S-1). Other PFAS may also cause harm, though they do not all have the same biological persistence and toxicity. Most people are exposed to mixtures of PFAS such that specific effects are difficult to disentangle. Considering these issues, and recognizing that some PFAS are infrequently measured, the committee provided one strength-of-evidence determination for all PFAS for each health effect, recognizing that providing one conclusion across PFAS may not account for the distinct physical, chemical, and toxicological properties of each type of PFAS.

TABLE S-1 PFAS Species Currently Included in the Centers for Disease Control and Prevention's *National Report on Human Exposure to Environmental Chemicals*

Abbreviated Name	Full Name	CAS Registry No.
MeFOSAA	Methylperfluorooctane sulfonamidoacetic acid	2355-31-9
PFHxS	Perfluorohexanesulfonic acid perfluorohexane sulfonic acid	355-46-4
n-PFOA (linear isomer), Sb-PFOA (branched isomers)	Perfluorooctanoic acid	335-67-1*
PFDA	Perfluorodecanoic acid	335-76-2
PFUnDA	Perfluoroundecanoic acid	2058-94-8
n-PFOS (linear isomer), Sm-PFOS (branched isomers)	Perfluorooctanesulfonic acid	1763-23-1*
PFNA	Perfluorononanoic acid	375-95-1

NOTES: CAS = Chemical Abstracts Service. * = CAS number refers to linear isomer only. Previous survey years have also included perfluorobutane sulfonic acid (PFBS), perfluoropentanoic acid (PFpA), perfluorododecanoic acid (PFDoDA), perfluorooctane sulfonamide (FOSA), and 2-(N-ethyl-perfluorooctane sulfonamido)acetate (EtFOSAA), according to Patrick N. Breysse's presentation to the committee on February 4, 2021.

The committee began its review by identifying decisions of other authoritative bodies regarding PFAS exposure and any human health effects. The committee then considered more recent human studies, both systematic reviews and published epidemiologic research articles, that could inform updates to those decisions. This approach improved efficiency while minimizing the risk of excluding scientific findings that could inform the committee's conclusions.

The committee considered animal studies discussed in ATSDR's *Toxicological Profile for Perfluoroalkyls* and in systematic reviews to aid in its interpretation of the human studies. The committee synthesized the available evidence into four categories of association used by other National Academies committees: sufficient evidence of an association, limited or suggestive evidence of an association, inadequate or insufficient evidence of an association, and limited or suggestive evidence of no association (see Figure S-5). All associations between PFAS and a health outcome were considered inadequate or insufficient by default unless available evidence from all aspects of the committee's review warranted placing the evidence in another category of association.

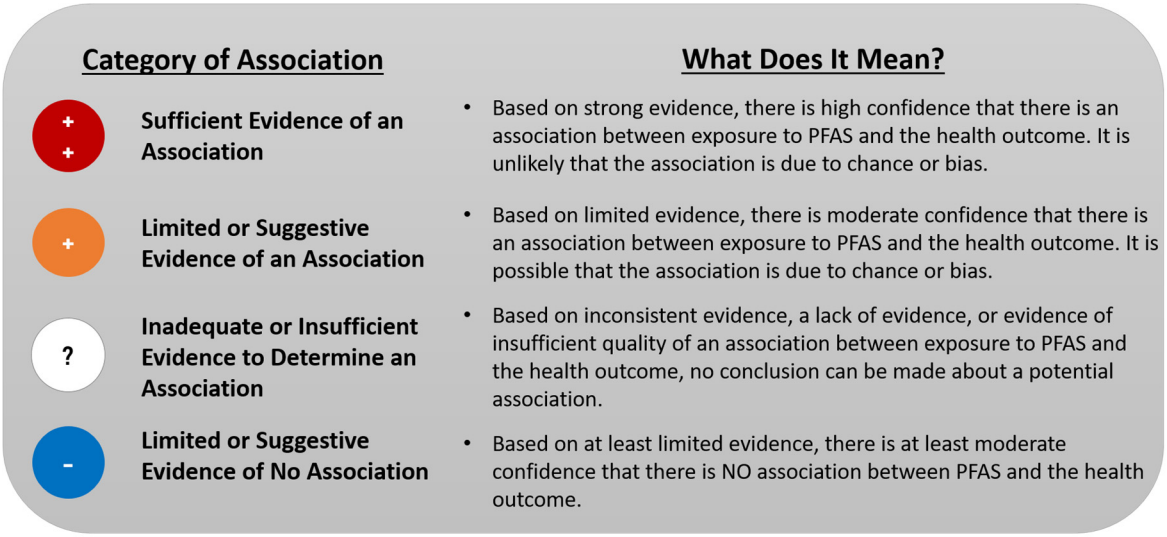

FIGURE S-5 Categories of association used in this report.
NOTES: The categories of association only describe how strong the evidence is between PFAS and the health outcome. The risk of developing an outcome from exposure to PFAS for things in the same category can vastly differ and are dependent on whether an individual has other risk factors for developing the outcome.

The committee found sufficient evidence of an association for the following diseases and health outcomes:

- **decreased antibody response (in adults and children),**
- **dyslipidemia (in adults and children),**
- **decreased infant and fetal growth, and**
- **increased risk of kidney cancer (in adults).**

The committee found limited or suggestive evidence of an association for the following diseases and health outcomes:

- **increased risk of breast cancer (in adults),**
- **liver enzyme alterations (in adults and children),**

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- **increased risk of pregnancy-induced hypertension (gestational hypertension and preeclampsia),**
- **increased risk of testicular cancer (in adults),**
- **thyroid disease and dysfunction (in adults), and**
- **increased risk of ulcerative colitis (in adults).**

The committee observed gaps in the evidence, rendering the evidence inadequate or insufficient, for many health effects including the following:

- immune effects other than reduced antibody response, and ulcerative colitis;
- cardiovascular outcomes other than dyslipidemia;
- developmental outcomes other than small reductions in birthweight;
- cancers other than kidney, breast, and testicular;
- reproductive effects other than hypertensive disorders of pregnancy;
- hepatic effects other than liver enzyme levels;
- endocrine disorders other than those involving thyroid hormone levels;
- respiratory effects;
- hematological effects;
- musculoskeletal effects, such as effects on bone mineral density;
- renal effects, such as renal disease; and
- neurological effects.

For some outcome categories, the research spanned many different tests or measures of effect, all of which assessed slightly different health outcomes, making the evidence difficult to synthesize and use to draw strong conclusions. The committee found this issue most apparent when reviewing the literature on neurodevelopmental effects, such as effects on learning and behavior. Another research issue is that most studies reviewed by the committee were not conducted among people known to have high exposures to PFAS, indicating a gap in understanding the effects of PFAS among those highly exposed.

PFAS EXPOSURE REDUCTION

Some people may be interested in reducing their exposure to PFAS. The primary route to PFAS in nonoccupational settings is likely ingestion, which may include drinking contaminated water; eating seafood from contaminated water; or consuming other contaminated foods, such as vegetables, game, or dairy products. PFAS are often used in materials that come in contact with food, such as microwave popcorn bags or packaging used for fast foods or processed foods. Exposure may also occur when dust containing PFAS is ingested. Inhalation is the most common route in occupational settings, and is a route of exposure for people living near fluorochemical plants or incinerators. PFAS transfer to the fetus during pregnancy and in early life during lactation. Dermal exposure is understudied.

If PFAS are in drinking water, switching to consumption of water lower in PFAS will reduce exposure. In general, however, it is difficult to reduce exposure to PFAS through personal behavior modifications.

For clinicians, based on its review of the evidence on PFAS exposure reduction, the committee makes the following recommendations:

Recommendation 4-1[7]: Clinicians advising patients on PFAS exposure reduction should begin with a conversation aimed at first determining how they might be exposed to PFAS

[7] The committee's recommendations are numbered according to the chapter of the main text in which they appear.

Copyright National Academy of Sciences. All rights reserved.

(sometimes called an environmental exposure assessment) and what exposures they are interested in reducing. This exposure assessment should include questions about current occupational exposures to PFAS (such as work with fluorochemicals or firefighting) and exposures to PFAS through the environment. Known environmental exposures to PFAS include living in a community with PFAS-contaminated drinking water, living near industries that use fluorochemicals, serving in the military, and consuming fish and game from areas with known or potential contamination.

Recommendation 4-2: If patients may be exposed occupationally, such as by working with fluorochemicals or as a firefighter, clinicians should consult with occupational health and safety professionals knowledgeable about the workplace practices to determine the most feasible ways to reduce that exposure.

Recommendation 4-3: Clinicians should advise patients with elevated PFAS in their drinking water that they can filter their water to reduce their exposure. Drinking water filters are rated by NSF International, an independent organization that develops public health standards for products. The NSF database can be searched online for PFOA to find filters that reduce the PFAS in drinking water included in the committee's charge. Individuals who cannot filter their water can use another source of water for drinking.

Recommendation 4-4: In areas with known PFAS contamination, clinicians should advise patients that PFAS can be present in fish, wildlife, meat, and dairy products and direct them to any local consumption advisories.

There are fewer evidence-based, exposure-reduction recommendations for patients without known sources of exposure:

Recommendation 4-5: Clinicians should direct patients interested in learning more about PFAS to authoritative sources of information on how PFAS exposure occurs and what mitigating actions they can take. Authoritative sources include the Pediatric Environmental Health Specialty Units (PEHSUs), the Agency for Toxic Substances and Disease Registry (ATSDR), and the U.S. Environmental Protection Agency (EPA).

Recommendation 4-6: When clinicians are counseling parents of infants on PFAS exposure, they should discuss infant feeding and steps that can be taken to lower sources of PFAS exposure. The benefits of breastfeeding are well known; the American Academy of Pediatrics, the American Academy of Family Physicians, and the American College of Obstetricians and Gynecologists support and recommend breastfeeding for infants, with rare exceptions. Clinicians should explain that PFAS can pass through breast milk from a mother to her baby. PFAS may also be present in other foods, such as the water used to reconstitute formula and infant food, and potentially in packaged formula and baby food. It is not yet clear what types and levels of exposure to PFAS are of concern for child health and development.

Additionally, there is a critical need for more data to understand PFAS exposure among breastfed infants:

Recommendation 4-7: Federal environmental health agencies should conduct research to evaluate PFAS transfer to and concentrations in breast milk and formula to generate data that can help parents and clinicians make shared, informed decisions about breastfeeding.

PFAS TESTING AND CONCENTRATIONS TO INFORM CLINICAL CARE OF EXPOSED PATIENTS

Decisions about PFAS testing require shared informed decision making between patient and clinician. Clinicians should explain that exposure biomonitoring may provide important information about an individual's exposure levels that might guide clinical follow-up. At the same time, this information cannot indicate or predict the likelihood that an individual will end up with a particular condition. Allowing people the opportunity to determine whether they will undergo PFAS testing shows respect for patient values. Discussions about PFAS testing should always include information about how PFAS exposure occurs, potential health effects of PFAS, limitations of PFAS testing, and the benefits and harms of the testing (see Box S-2).

BOX S-2
Potential Harms and Benefits of PFAS Testing

Potential Harms

- Fear of blood draw
- Small risk of injury or infection at draw site
- Difficulties in interpreting results
- Stress or concern about the health effects of exposure
- Decreased property values resulting from identifying property contamination
- Social isolation
- Clinical consequences from medical follow-up as a result of exposure

Potential Benefits

- Increased awareness of exposure so it can be reduced
- Empowerment of communities to respond to contamination
- Relief from the stress of not knowing one's exposure level
- Identification of the potential risk for health conditions associated with PFAS exposure, informing subsequent preventive care
- Help in monitoring whether efforts to reduce exposure are working through the conduct of baseline and follow-up tests

The German Human Biomonitoring Commission has risk-based guidance levels for two PFAS chemicals—PFOS and PFOA. The European Food Safety Authority has one guidance level for the sum of PFOA, PFOS, PFHxS, and PFNA. No individual values are available for PFHxS and PFNA, and the committee could find no values for methylperfluorooctane sulfonamidoacetic acid (MeFOSAA), PFDA, and perfluoroundecanoic acid (PFUnDA). Based on its review of the evidence for PFAS testing, the committee recommends:

Recommendation 5-1: As communities with PFAS exposure are identified, government entities (e.g., Centers for Disease Control and Prevention [CDC]/Agency for Toxic Substances and Disease Registry [ATSDR], public health departments) should support clinicians with educational materials about PFAS testing so that they can discuss testing with their patients. These educational materials should include the following information:

Copyright National Academy of Sciences. All rights reserved.

- **How people can be exposed to PFAS: Exposure routes include occupational exposures and work with fluorochemicals or as a firefighter; consumption of contaminated drinking water in communities that obtain their water from sources near commercial airports, military bases, fluorochemical manufacturing plants, wastewater treatment plants, landfills, or incinerators where PFAS-containing waste may have been disposed of or farms where sewage sludge may have been used; and consumption of contaminated fish or game if fishing or hunting occurs in contaminated areas. Individuals living near fluorochemical plants may also be exposed via inhalation of air emissions.**
- **Potential health effects of PFAS exposure and strategies for reducing exposure.**
- **Limitations of PFAS blood testing: PFAS blood testing does not identify the sources of exposure or predict future health outcomes; it only assesses body burden at the time of sample collection. For example, a person with low blood levels today may have had higher levels in the past.**
- **The benefits and harms of PFAS testing.**

Recommendation 5-2: Clinicians should offer PFAS testing to patients likely to have a history of elevated exposure. In all discussions of PFAS testing, clinicians should describe the potential benefits and harms of the testing and the potential clinical consequences (such as additional follow-up), related social implications, and limitations of the testing so that patient and clinician can make a shared, informed decision. Patients who are likely to have a history of elevated exposure to PFAS include those who have

- **had occupational exposure to PFAS (such as those who have worked with fluorochemicals or served as a firefighter);**
- **lived in communities where environmental and public health authorities (Centers for Disease Control and Prevention [CDC], Agency for Toxic Substances and Disease Registry [ATSDR], U.S. Environmental Protection Agency [EPA], state and local environmental or health authorities), or academic researchers have documented PFAS contamination; or**
- **lived in areas where PFAS contamination may have occurred, such as near facilities that use or have used fluorochemicals, commercial airports, military bases, wastewater treatment plants, farms where sewage sludge may have been used, or landfills or incinerators that have received PFAS-containing waste.**

Recommendation 5-3: Clinicians should use serum or plasma concentrations of the sum of PFAS* to inform clinical care of exposed patients, using the following guidelines for interpretation:

- **Adverse health effects related to PFAS exposure are not expected at less than 2 nanograms per milliliter (ng/mL).**
- **There is a potential for adverse effects, especially in sensitive populations, between 2 and 20 ng/mL.**
- **There is an increased risk of adverse effects above 20 ng/mL.**

*** Simple additive sum of MeFOSAA, PFHxS, PFOA (linear and branched isomers), PFDA, PFUnDA, PFOS (linear and branched isomers), and PFNA in serum or plasma. Caution is warranted when using capillary blood measurements as levels may differ from serum or plasma levels.**

Copyright National Academy of Sciences. All rights reserved.

The cutoff levels should be updated as additional information becomes available. The committee also noted that children younger than 12 years are not routinely included in the *National Report on Human Exposure to Environmental Chemicals*, nor are pregnant people included in large numbers. More reference- and risk-based values are needed, for other PFAS and other biological matrices, but given the expansiveness of the class, this gap can best be addressed with relative potency factor approaches rather than the development of risk-based levels for each PFAS.

Recommendation 5-4: The National Health and Nutrition Examination Survey should begin collecting and sharing more data on children younger than 12 years of age and pregnant people to generate reference populations for those groups.

Testing for PFAS, although expensive, offers an opportunity to identify people who may need to reduce their PFAS exposure and are at increased risk of certain health outcomes. It is important to recognize, however, that race, age, and other social and demographic characteristics already have disadvantaged many patients with respect to accessing clinical preventive services, such as PFAS testing. The disadvantage would be compounded as PFAS testing services should be linked to counseling on steps to mitigate exposure and its impacts. Therefore, encouraging testing primarily among people with relatively stable access to care could have the unintended effect of aggravating disparities in exposure to PFAS absent a funded, national PFAS testing program with a counseling component.

APPLICATION OF THE COMMITTEE'S PRINCIPLES TO PATIENT FOLLOW-UP FOR PFAS-ASSOCIATED HEALTH EFFECTS

Many health outcomes or conditions that the committee found to be associated with PFAS exposure are common in the general population. All have multiple known risk factors. The committee categorized the strength of the evidence for an association between PFAS and various health outcomes, and concluded that all conditions with an adequately supported association should be considered for patient follow-up. The committee then used its established cutoff levels to determine appropriate follow-up based on PFAS exposure level. Risks from PFAS likely increase with exposure, and PFAS levels of 3 ng/mL and 19 ng/mL do not represent the same risk even though they are listed in the same category. Clinical providers should use judgment and shared, informed decision making in making follow-up decisions based on PFAS exposure and other risk factors. Figure S-6 suggests that clinicians engage in shared decision making with their patients regarding follow-up care for PFAS-associated health endpoints.

Recommendation 6-1: Clinicians should treat patients with serum PFAS concentration below 2 nanograms per milliliter (ng/mL) with the usual standard of care.

Recommendation 6-2: For patients with serum PFAS concentration of 2 nanograms per milliliter (2 ng/mL) or higher and less than 20 ng/mL, clinicians should encourage PFAS exposure reduction if a source of exposure is identified, especially for pregnant persons. Within the usual standard of care clinicians should:

- **Prioritize screening for dyslipidemia with a lipid panel (once between 9 and 11 years of age, and once every 4 to 6 years over age 20) as recommended by the American Academy of Pediatrics (AAP) and the American Heart Association (AHA).**
- **Screen for hypertensive disorders of pregnancy at all prenatal visits per the American College of Obstetricians and Gynecologists (ACOG).**

Copyright National Academy of Sciences. All rights reserved.

- **Screen for breast cancer based on clinical practice guidelines based on age and other risk factors such as those recommended by the U.S. Preventive Services Task Force (USPSTF).**

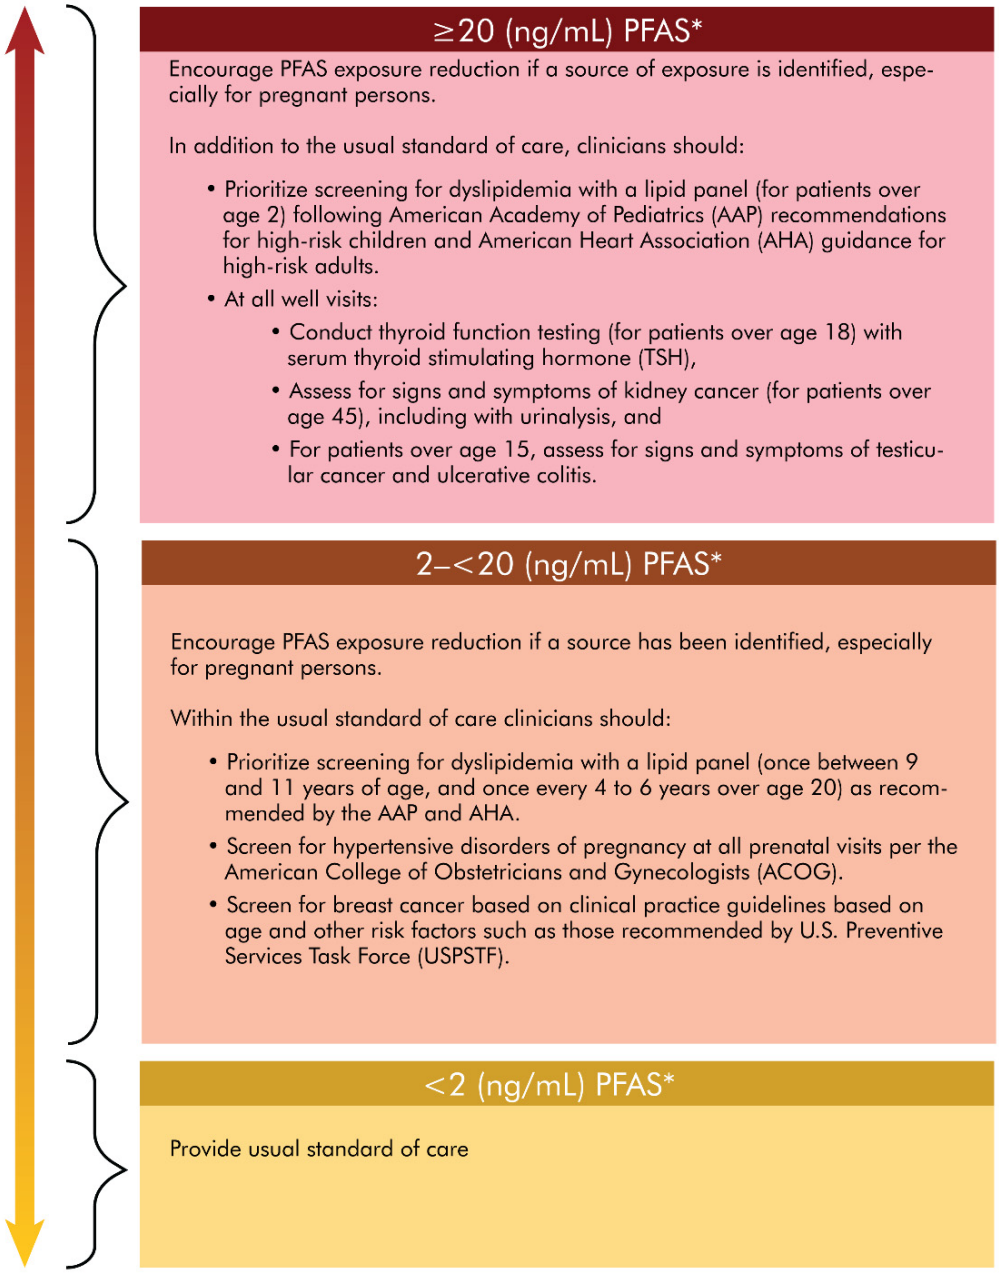

FIGURE S-6 Clinical guidance for follow-up with patients after PFAS testing.

Copyright National Academy of Sciences. All rights reserved.

Recommendation 6-3: For patients with serum PFAS concentration of 20 nanograms per milliliter (ng/mL) or higher, clinicians should encourage PFAS exposure reduction if a source of exposure is identified, especially for pregnant persons. In addition to the usual standard of care, clinicians should:

- **Prioritize screening for dyslipidemia with a lipid panel (for patients over age 2) following American Academy of Pediatrics (AAP) guidelines for high-risk children and American Heart Association (AHA) guidance for high-risk adults.**
- **At all well visits:**
  - **conduct thyroid function testing (for patients over age 18) with serum thyroid stimulating hormone (TSH),**
  - **assess for signs and symptoms of kidney cancer (for patients over 45), including with urinalysis, and**
  - **for patients over 15, assess for signs and symptoms of testicular cancer and ulcerative colitis.**

APPLYING THE COMMITTEE'S EXPOSURE, TESTING, AND CLINICAL FOLLOW-UP RECOMMENDATIONS

The committee created a flow chart summarizing PFAS education, exposure assessment, and clinical follow-up (see Figure S-7). In communities where PFAS exposure has been identified, ATSDR and other government entities should support local clinicians with educational materials about PFAS exposure and testing. Clinicians should then determine whether a particular patient is likely to have a history of elevated exposure to PFAS. If so, the clinician should offer PFAS testing and make a shared, informed decision on that testing. If testing is chosen, the labs should be ordered (Test Code 39307 Current Procedural Terminology [CPT] code 82542). Test results should be interpreted by summing the concentrations of MeFOSAA, PFHxS, PFOA (linear and branched isomers), PFDA, PFUnDA, PFOS (linear and branched isomers), and PFNA. The laboratory may not report results for all PFAS considered by the committee or may include different PFAS in its panel. In that case, the sum of PFAS should include only the PFAS in the analyte list that the committee considered. For example, if the lab tests for PFOA, PFOS, PFHxS, PFNA, and perfluorobutane sulfonic acid (PFBS), the summation should include PFOA, PFOS, PFHxS, and PFNA. Differing analytes lists may cause some variation in response. Still, as long as PFOA, PFOS, PFHxS, and PFNA are included in the analyte list, the results may not vary too greatly as these four analytes are most commonly detected in the United States. If any analyte is below the limit of detection, the clinician should calculate the analyte limit of detection divided by the square root of 2 and use this value in the summation. The sum thus derived should be compared against Figure S-6 to determine an appropriate clinical follow-up plan based on shared, informed decision making between patient and clinician.

REVISING ATSDR'S PFAS CLINICAL GUIDANCE
