The committee recommends several changes to ATSDR's guidance to ensure consistency with the findings, conclusions, and recommendations presented in this report and improve the guidance's writing, design, dissemination, and implementation:

Recommendation 7-1: The Agency for Toxic Substances and Disease Registry (ATSDR) should update its PFAS clinical guidance to make it more succinct and accord with the review of PFAS-associated health effects, exposure reduction considerations, PFAS testing recommendations and interpretation, and recommendations for clinical follow-up presented in this report. When describing the health effects of PFAS, ATSDR should avoid using terms typically used to

Copyright National Academy of Sciences. All rights reserved.

categorize toxicants, such as "endocrine disrupter" or "neurotoxin," because they are vague and not necessarily clinically meaningful. When discussing the strength of the association between PFAS and a health outcome, ATSDR should use standard categories of association (such as sufficient evidence of an association, limited or suggestive evidence of an association, inadequate or insufficient evidence of an association, and limited or suggestive evidence of no association).

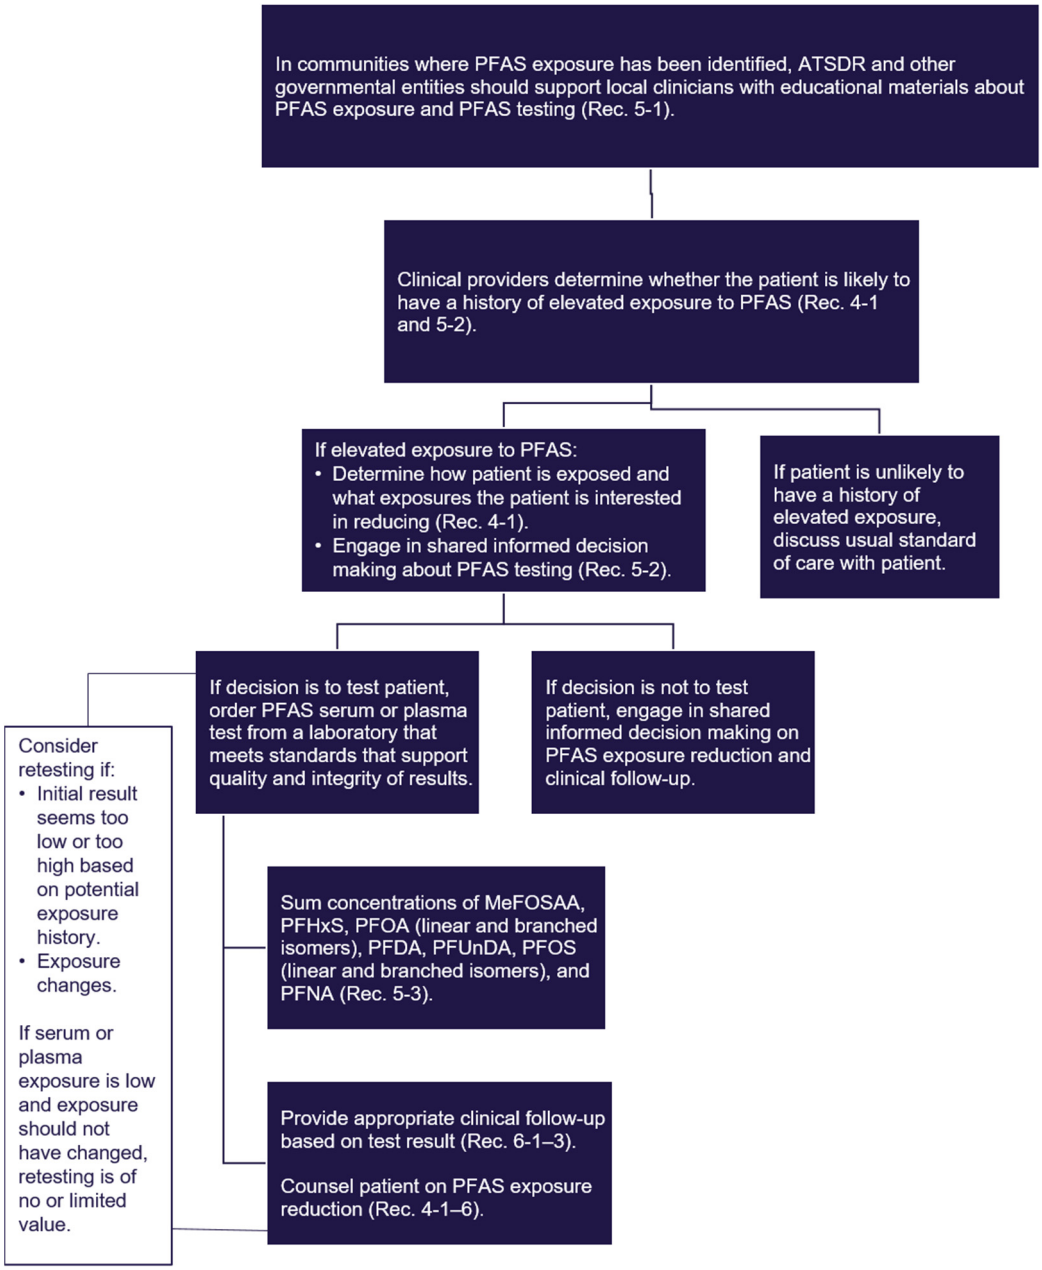

FIGURE S-7 Flow chart showing how the committee's recommendations work together in a clinical setting.
NOTE: ATSDR = Agency for Toxic Substances and Disease Registry; MeFOSAA = methylperfluorooctane sulfonamidoacetic acid; PFDA = perfluorodecanoic acid; PFHxS = perfluorohexane sulfonic acid, PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctanesulfonic acid; PFUnDA = perfluoroundecanoic acid.

Copyright National Academy of Sciences. All rights reserved.

Recommendation 7-2: The Agency for Toxic Substances and Disease Registry (ATSDR) should incorporate a reader-centered approach when developing its guidance, with the knowledge that many different audiences will turn to its clinical guidance document to prepare for discussions with their clinicians. ATSDR should also solicit feedback on the guidance from a variety of stakeholders, such as community groups, practicing clinicians, and medical associations. In addition, ATSDR should encourage clinicians to use evidence-based organizational health literacy strategies to support shared, informed decision making; patient-centered care; cultural humility; and accessible language when communicating with patients about potential health risks.

Evidence on the health effects of PFAS should be updated every 2 years, and the clinical guidance should be updated at least every 5 years. In that process, ATSDR should strive to ensure that its clinical guidance follows criteria for making guidelines trustworthy when possible. Figure S-8 provides an overview of how the process used by this committee could be applied by ATSDR to improve its clinical guidance.

Recommendation 7-3: The Agency for Toxic Substances and Disease Registry (ATSDR) should develop a process for updating its PFAS guidance that adheres to criteria for making guidelines trustworthy, such as being based on a thorough, transparent, unbiased review of the evidence and being developed by a knowledgeable panel of experts free from strong biases and conflicts of interest. A review of the evidence on the health effects of PFAS should be completed by an authoritative neutral party every 2 years, and the clinical guidance should be updated every 5 years or sooner if warranted by the evidence on the health effects of PFAS. Clinicians and members of communities with elevated PFAS exposure should be engaged to inform the problem and review updated guidance.

FIGURE S-8 Suggested framework for updating the Agency for Toxic Substances and Disease Registry's clinical guidance based on new evidence.

IMPLEMENTING THE COMMITTEE'S RECOMMENDATIONS TO IMPROVE PUBLIC HEALTH

Public health requires the use of multifaceted approaches to emerging health issues. In environmental health—the subset of public health focused on environmental factors—mitigation of potential harms associated with chemical exposures is often complicated because there is no exposure surveillance system for most chemicals. The committee's recommendations will best protect the public health if they are part of a national effort focused on increased biomonitoring, exposure surveillance, and education of clinicians and public health professionals on environmental health issues:

> **Recommendation 8-1: Laboratories conducting PFAS testing of serum or plasma should report the results to state public health authorities, following the respective states' statutes and reporting regulations. This reporting would improve PFAS exposure surveillance; it could be linked with the Centers for Disease Control and Prevention's (CDC's) environmental public health tracking network and help build capacity for improvements in the state-based national biomonitoring network.**

The people and communities with high exposures to PFAS need to be identified. As the committee looks forward, it sees a pressing need for a robust environmental health infrastructure to continue to respond to PFAS and address other complex emerging and persistent environmental challenges.

Introduction

More than a decade ago, the United Nations General Assembly passed Resolution 64/292, recognizing that safe and clean drinking water is a human right and is essential to realizing all human rights. Yet today, drinking water in thousands of communities across the United States is contaminated with chemicals known as per- and polyfluoroalkyl substances (PFAS) (Hu et al., 2016) (see Box 1-1). PFAS do not occur in nature and are manufactured for a wide range of purposes, from nonstick cookware, to stain-resistant fabrics and carpets, to firefighting foams and protective gear. PFAS constitute a large class of up to 12,000 different chemicals (EPA, 2020). They are commonly used in thousands of products because they have desirable chemical properties that impart oil and water repellency, friction reduction, and temperature resistance (ITRC, 2017). PFAS as a class have a wide variety of distinct chemical properties and toxicities; for example, some PFAS can accumulate and persist in the human body and the environment, while others transform relatively quickly. The PFAS that do transform, however, will become one or more other PFAS, because the carbon–fluorine bond they contain does not break naturally. It is for this reason that PFAS are termed "forever chemicals."

In the most rudimentary sense, PFAS can be thought of as either polymer or nonpolymer. Nonpolymer PFAS, such as perfluroalkyl acids (PFAAs), are more commonly detected in the environment and are often considered highly persistent and mobile (Blum et al., 2015; ITRC, 2021). By contrast, many polymer PFAS, such as polytetrafluoroethylene (PTFE), are insoluble, less bioavailable, and often considered less of a direct concern, with respect to human or ecological health (Lohmann et al., 2020; ITRC, 2021). Nonetheless, the production of fluoropolymers requires other PFAS chemicals, such as PFAAs. For example, the nonpolymer PFAS perfluorooctanoic acid (PFOA) was used as a surfactant in the emulsion polymerization of fluoropolymers.[1]

BOX 1-1
What Are PFAS?

What are PFAS? A consensus definition does not exist. Buck and colleagues (2011) define PFAS as fluorinated substances that "contain 1 or more C atoms on which all the H substituents (present in the nonfluorinated analogues from which they are notionally derived) have been replaced by F atoms, in such a manner that they contain the perfluoroalkyl moiety $C_nF_{2n+1}-$" (p. 513).

The Organisation for Economic Co-operation and Development (OECD) defines PFAS as "fluorinated substances that contain at least one fully fluorinated methyl or methylene carbon atom (without any H/Cl/Br/I atom attached to it), that is, with a few noted exceptions, any chemical with at least a perfluorinated methyl group (–CF3) or a perfluorinated methylene group (–CF2–) is a PFAS" (OECD, 2021, p. 7).

BOX 1-1 Continued

The U.S. Environmental Protection Agency's (EPA's) (2020) CompTox Chemicals Dashboard includes all substances that contain a specific set of substructural elements. The Dashboard says that "there is no precisely clear definition of what constitutes a PFAS substance" and PFAS lists include "partially fluorinated substances, polymers, and ill-defined reaction products" (EPA, 2020, para. 1).

What are PFAS used for? PFAS have desirable chemical properties such as oil and water repellency, temperature resistance, and friction reduction. Since the late 1940s, PFAS have been used in numerous applications, such as firefighting, chrome-plating, lubricants, and insecticides, as well as coating and treating of such surfaces as carpeting, packaging, and cookware (ATSDR, 2021).

How long do PFAS stay in the human body following exposure? PFAS levels in people's bodies will persist unless exposure ceases, and will continue to persist even after exposure ends. Half-life estimates based on repeated serum measurements range from days (e.g., PFBA) to years (e.g., PFOA, PFOS). It is generally assumed that it takes five half-lives to eliminate PFAS after exposure has ceased (ATSDR, 2021).

What are the potential hazards of PFAS? Health effects associated with PFAS include altered immune function, elevated cholesterol, thyroid disease, hypertension during pregnancy, testicular cancer, and kidney cancer (ATSDR, 2021; Fenton et al., 2021; Steenland et al., 2020).

SOCIOHISTORICAL TIMELINE OF PFAS

Public concern about the impact of PFAS contamination on human health and the environment began in the late 1990s when PFOA water contamination was identified in Parkersburg, West Virginia.[2] In response, 3M, a primary PFAS manufacturer, initiated a voluntary phase-out of some PFAS (PFOA, perfluorooctanesulfonic acid [PFOS], and perfluorohexanesulfonic acid [PFHxS)]) (ITRC, 2017). The contamination in Parkersburg also led to a class action lawsuit that identified several health effects related to PFAS exposure and subsequently to the establishment of a medical monitoring program (see Box 1-2). Shortly thereafter, the U.S. Environmental Protection Agency (EPA) began requiring all community water systems serving more than 10,000 people to test for certain PFAS, which led to more communities learning that their water was contaminated.[3] In 2016, researchers found that the drinking water supply for Wilmington, North Carolina, was contaminated with a chemical called "GenX," a PFOA replacement.[4] This finding led to public concern about the potential health effects of replacement PFAS (see Figure 1-1).

An estimated 2,854 U.S. locations (in all 50 states and two territories) have some level of PFAS contamination (see Figure 1-2). Although not all of the contamination represents exceedances of health advisories, the pervasiveness of the contamination is alarming. Furthermore, almost 100 percent of the U.S. population is exposed to at least one PFAS. Although exposures to the phased-out PFAS have been decreasing (see Figure 1-3), people are still exposed to those PFAS from site contamination, occupational uses of stored products, and breakdown of PFAS polymer products that are found in homes. Carpeting, for example, is often treated with fluorotelomer-based polymers that can biodegrade to form phased-out PFAS, such as PFOA (Washington and Jenkins, 2015). Exposures also occur to the PFAS chemicals used to replace those that have been phased out. Although the harms of the replacement PFAS are less well understood, they may have comparable or more serious toxicity than the PFAS they have replaced (Kwiatkowski et al., 2020). The state of New Jersey, for example, recently set a groundwater standard for

a replacement PFAS (chloroperfluoropolyether carboxylates) that is an order of magnitude lower than drinking water standards for other PFAS. The New Jersey maximum contaminant levels of perfluorononanoic acid (PFNA), PFOA, and PFOS in drinking water are 13, 14, and 13 nanograms per liter (ng/L), respectively,[5] while the groundwater standard for the replacement PFAS, chloroperfluoropolyether carboxylates, is 2 ng/L.[6]

A reason PFAS contamination became well known only recently, after decades of their use, is that they can be difficult to detect. The physical and chemical properties that make PFAS persistent and mobile in the environment also make them particularly challenging to analyze (Guelfo et al., 2021). Analytical methods sensitive enough to detect environmentally relevant concentrations became widely available in the early 2010s. Although analyte lists continue to expand, currently available methods still allow identification of only a small fraction of the thousands of PFAS that have reportedly been created and used since the 1950s. As existing analytical methods improve, additional PFAS and new release sites will likely be identified (De Silva et al., 2021; Guelfo et al., 2021).

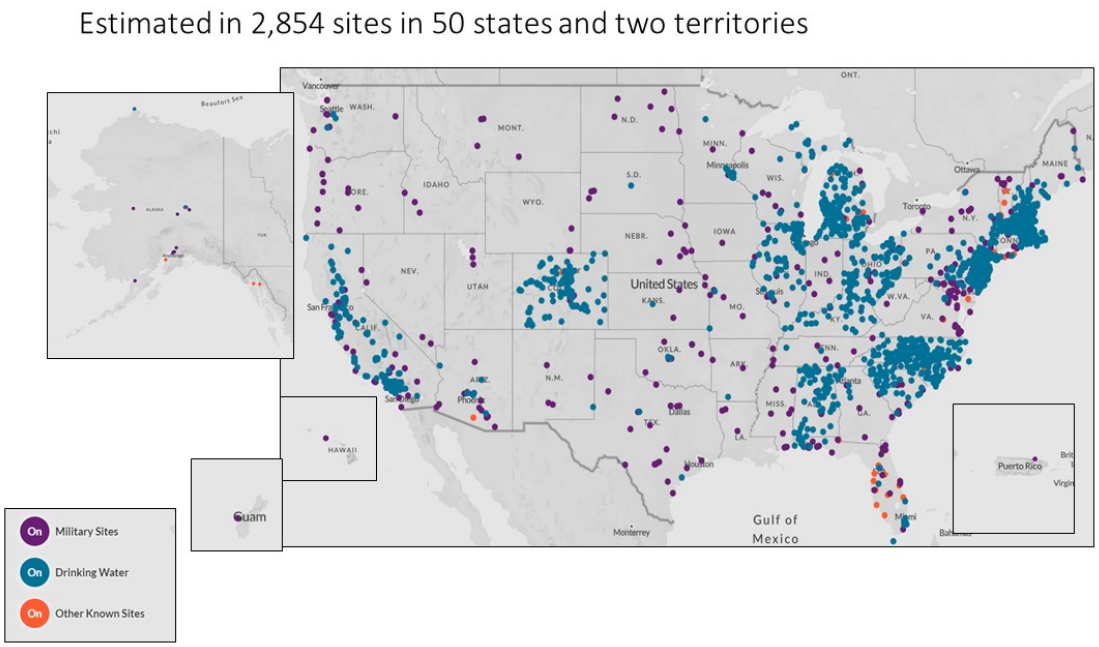

FIGURE 1-2 PFAS contamination across the United States.
NOTES: According to the Environmental Working Group (EWG), "locations represented on the map are approximate and intended to portray the general area of a contamination site or a community water system. Locations were mapped using the best data available from official records, including data provided by tests of public drinking water systems, the Safe Drinking Water Information System and the Department of Defense report *Addressing Perfluorooctane Sulfonate (PFOS) and Perfluorooctanoic Acid (PFOA)*, and Department of Defense public records, among others. Data on contaminated industrial and military sites was current as of October 2021." Furthermore, "EWG has worked to ensure the accuracy of the information provided in this map. The map is dynamic. This contaminant site, results, suspected sources and other information in the database may change based on evolving science, new information or other factors. Please be advised that this information frequently relies on data obtained from many sources, and accordingly, EWG cannot guarantee the accuracy of the information provided or any analysis based thereon."

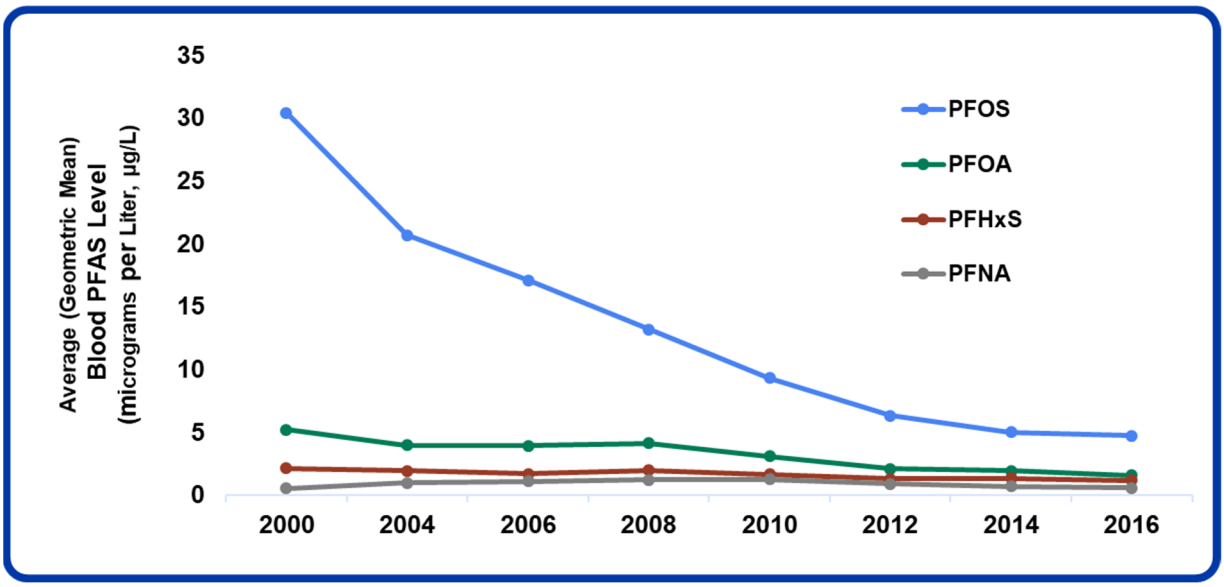

FIGURE 1-3 Blood (serum) levels of PFAS, United States, 2000–2016.
NOTE: Average = geometric mean.
SOURCE: Patrick N. Breysse's presentation to the committee on February 4, 2021. DATA SOURCE: Centers for Disease Control and Prevention (2019, January). *Fourth Report on Human Exposure to Environmental Chemicals*, updated tables. Atlanta, GA: U.S. Department of Health and Human Services.

The people who live, work, and play in environments where PFAS contamination exceeds standards often do not know how to protect themselves from the health risks of exposure. Many have been exposed to PFAS for decades and may continue to be exposed in their homes or workplaces. Some members of communities with documented exposure report feeling violated and concerned about the health and well-being of their families, friends, and loved ones (Raponi et al., 2021; Rizzuto, 2021). Many in these exposed communities who have discovered that their exposure exceeds health advisory levels are calling for a medical program to prevent, lead to early detection of, or treat any diseases related to the health risks they may face (Raponi et al., 2021; Rizzuto, 2021). Developing such a program is challenging, however, because of the uncertainties about the health effects of PFAS and potential harms from additional medical treatments; moreover, many of these diseases are not preventable or even treatable once exposures have occurred (Wones et al., 2009). Accordingly, clinicians generally do not know how to respond to patients' concerns about PFAS.

ENVIRONMENTAL JUSTICE

Compounding the challenge of responding clinically to PFAS contamination are issues of environmental justice and systemic racism in medical care. It is well established that environmental risks are not distributed uniformly across populations. Race, ethnicity, poverty, age, life stage, and other social factors can place people at disproportionately high risk for diseases with environmental causes as a result of hazardous exposures at increased levels compared to the general population (Gochfeld and Burger, 2011). While environmental justice research specific to PFAS contaminants has been limited, place-based factors that may put individuals at greater risk of exposure (siting of chemical companies, refineries, and industrial sites), coupled with insufficient access to environmental screening, information, and adequate health care, have disproportionate impacts on Black, Hispanic, and Indigenous communities, as well as low-income populations. A special report from *Scientific American* called this a "triple whammy of race, poverty, and environment converging nationwide to create communities near pollution sources where nobody else wants to live" (Kay and Katz, 2012, para. 12).

Copyright National Academy of Sciences. All rights reserved.

According to a 2014 paper by the Environmental Justice Health Alliance for Chemical Policy Reform, more than 134 million Americans live within the "vulnerability zones" of industrial facilities that store or use highly hazardous chemicals (Orum et al., 2014). The companies themselves define these vulnerability zones, determined by guidance from the EPA,[7] as areas that could be affected by the release of toxic chemicals. The scope of the research on which this paper was based was broad, but included industries with known PFAS contamination, such as waste management and chemical manufacturing. The authors found that, relative to the U.S. average, communities within the vulnerability zones are disproportionately African American or Latinx; are more likely to live in poverty; and have lower housing values, incomes, and education levels. As the extent of contamination becomes known, housing values have been shown to decrease, and those with the means to move are more likely to do so, leaving behind those with the fewest resources and options (Harclerode et al., 2021).

When considering environmental justice, it is important to think beyond exposure disparities (Mohai et al., 2009); core environmental justice issues relevant to PFAS also include rural health, industrial siting, and access to environmental exposure reduction (Bullard, 1996) and clinical care. A framework is needed that allows consideration of structural factors beyond race, ethnicity, and socioeconomic status and accounts for how individuals and communities are impacted by decisions made at the local, state, and policy levels by government, industry, and health care professionals. Pellow's Environmental Justice Framework accounts for the complexity of relationships and decisions that impact PFAS exposure and associated health outcomes (Pellow, 2004) (see Figure 1-4). Sze and London (2008) advance this argument by incorporating negotiation at the stakeholder level, as well as problem identification at the level of sociohistorical and structural factors, and then solution-oriented approaches reflecting considerations of sustainability and safety.

FIGURE 1-4 Pellow's Environmental Justice Framework.

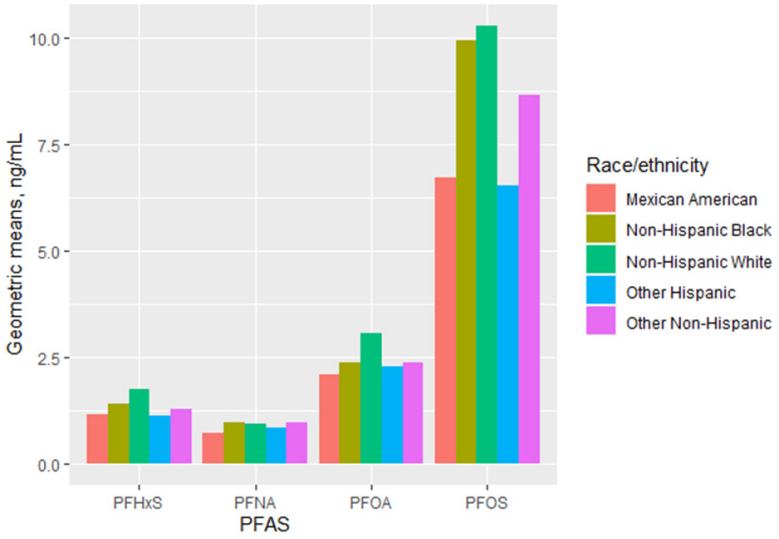
Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

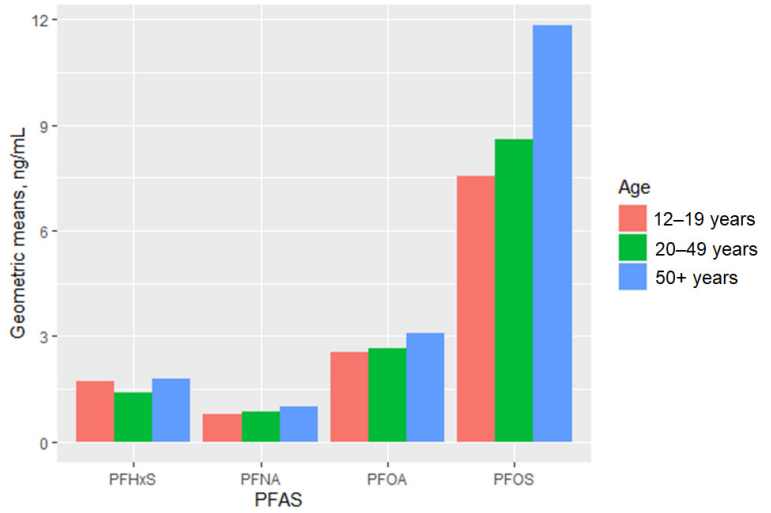
A first consideration in addressing environmental justice with respect to PFAS is understanding the sociohistorical context rather than a particular discrete event that has contributed to the presence of PFAS in certain communities. For example, PFAS contamination did not just randomly occur in rural communities serviced by well water that happened to be near industrial sites. Rather, the locating of certain industrial sites and decisions to dispose of PFAS with limited regard for the surrounding community's access to safe water are rooted in the relationship and history of these industries and communities. The disposal of these chemicals did not occur as single events lacking context, but reflected a pattern of decisions made over time. Understanding the historical and social context influencing how and where PFAS are distributed is an essential part of identifying effective mitigation strategies.

Second, Pellow's Environmental Justice Framework emphasizes the complex roles of the stakeholders involved. In the case of PFAS, environmental inequality can affect many different stakeholders, ranging from industry, to workers, to community members and organizations, to government entities such as local departments of public health. The complexity of these roles means there can exist synergistic and contradictory allegiances that impact what is valued, how resources are accessed and distributed, who has power, and what is considered profitable. With PFAS, industry's power and profit motive may trump a community's access to information and ability to test for and reduce exposure. Likewise, key health information for clinicians is governed by boards that decide about the content of medical education and training. Clinicians' lack of knowledge about environmental exposures such as PFAS, particularly in highly contaminated communities, can be particularly deleterious for the least-advantaged stakeholder groups.



A third consideration is the effects of social inequalities on exposure to PFAS, as relevant social stratification that affects exposure is not always clear or easy to study. Rural and urban disparities, for example, can be analyzed using National Health and Nutrition Examination Study (NHANES) data (with appropriate clearance), and living in a rural versus an urban area can definitely affect PFAS exposure, often through exposure to well water that is common in rural areas. Other, less obviously measurable influences can also drive exposures, however. Food insecurity, for example, even if only temporary, increases subsistence fishing (Quimby et al., 2020), which may cause people to fish for food in contaminated lakes or rivers. These structural and social factors put people at risk of exposure and can contribute to inequality. In short, even though relatively affluent areas can be heavily contaminated with PFAS, and non-Hispanic Whites are exposed to some of the highest PFAS concentrations (see below), solving the larger problem of PFAS contamination will still require attention to persistent social inequities. Otherwise, action to mitigate PFAS exposure could aggravate existing (or create new) environmental health disparities.

Fourth is the need to consider the role of agency—specifically, the power a community has to advocate for itself in conflicts. PFAS provide a unique example. PFAS contamination rose to national prominence partly because of exposures among well-educated, high-income, and mainly White communities. With PFAS, as with many social problems, power matters. At the same time, PFAS exposure varies regionally. In some parts of the country, the highest exposures are borne by less advantaged communities, making their relative ability to advocate for testing and responsive health care or to demand effective mitigation from their government somewhat tenuous.



While research on disparities in PFAS exposure is limited, several studies suggest that no differences exist by race, ethnicity, or socioeconomic status (Buekers et al., 2018; Nguyen et al., 2020; Sagiv et al., 2015). If one looks at time-aggregated estimates of PFAS exposure for the U.S. population, non-Hispanic Whites, older adults, and people of higher socioeconomic status have higher concentrations of these chemicals (see Figure 1-5). However, time-aggregated exposures present an incomplete picture. Looking at PFAS exposure by year stratified by race orethnicity suggests that in 2000, before the voluntary phase-out of PFOS andrelated chemicals, those in the racial group other non-Hispanic had the highest exposure to PFOS and PFHxS (see Figure 1-6). The implication of this finding is that widespread policy changes—such as the phase out of certain types of PFAS—greatly reduced exposure disparities. Because there are no national estimates of biomonitoring data for replacement PFAS, however, it is unknown whether the disparities observed with PFOS, PFHxS, and PFNA exist today for other PFAS.

PFAS CONTAMINATION AND ROUTES OF EXPOSURE

PFAS contamination is global. PFAS have been detected in regions with little human activity, including the atmosphere of remote locations (Shoeib et al., 2010), the Arctic and Antarctic seas (Armitage et al., 2006), and remote soils of every continent (Rankin et al., 2016). Environmental contamination with PFAS occurs in countless ways. Fluorochemical manufacturing sites release PFAS into water as well as into the air, from which they can settle into both soil and water. At military sites and commercial airports PFAS-containing foams are used in training exercises for firefighting. PFAS also can leak from landfills where PFAS-containing wastes are disposed, and can be released into the environment by PFAS-containing wastewater from wastewater treatment plants (Evich et al., 2022; Gomez et al., 2021; Sunderland et al., 2019) (see Figure 1-7). PFAS-treated consumer products have been implicated as sources of exposure in indoor settings (Harrad et al., 2010), and fluorotelomer products used to treat a wide range of consumer household and occupational products have been shown to degrade to form PFAS (Washington and Jenkins, 2015).

PFAS in the environment can contaminate drinking water when the chemicals reach public drinking water systems and private wells (Hu et al., 2016). PFAS can bioaccumulate in fish, shellfish, livestock, dairy, and game animals that contact them through contaminated food or water (De Silva et al., 2021; Death et al., 2021; Domingo and Nadal, 2017). Produce also can be contaminated if it is grown with contaminated drinking water or PFAS-contaminated compost or biosolids (Blaine et al., 2013; Scher et al., 2018).

Certain occupations may lead to increased PFAS exposures. They include, for example, jobs in facilities used to manufacture fluorochemicals or to produce PFAS-containing products, such as textiles or food contact materials. Other jobs with a known increased risk of exposure to PFAS include electroplating, painting, carpet installation and treatment, and jobs that require prolonged work with ski wax; increased exposures also occur among military and civilian firefighters who use PFAS-containing foams in training exercises and wear PFAS-impregnated gear (ATSDR, 2021). In addition, food workers and others in the hospitality industry may have elevated exposure if they handle PFAS-containing food packaging as part of their job (Carnero et al., 2021; Curtzwiler et al., 2021; Schaider et al., 2017).

Copyright National Academy of Sciences. All rights reserved.

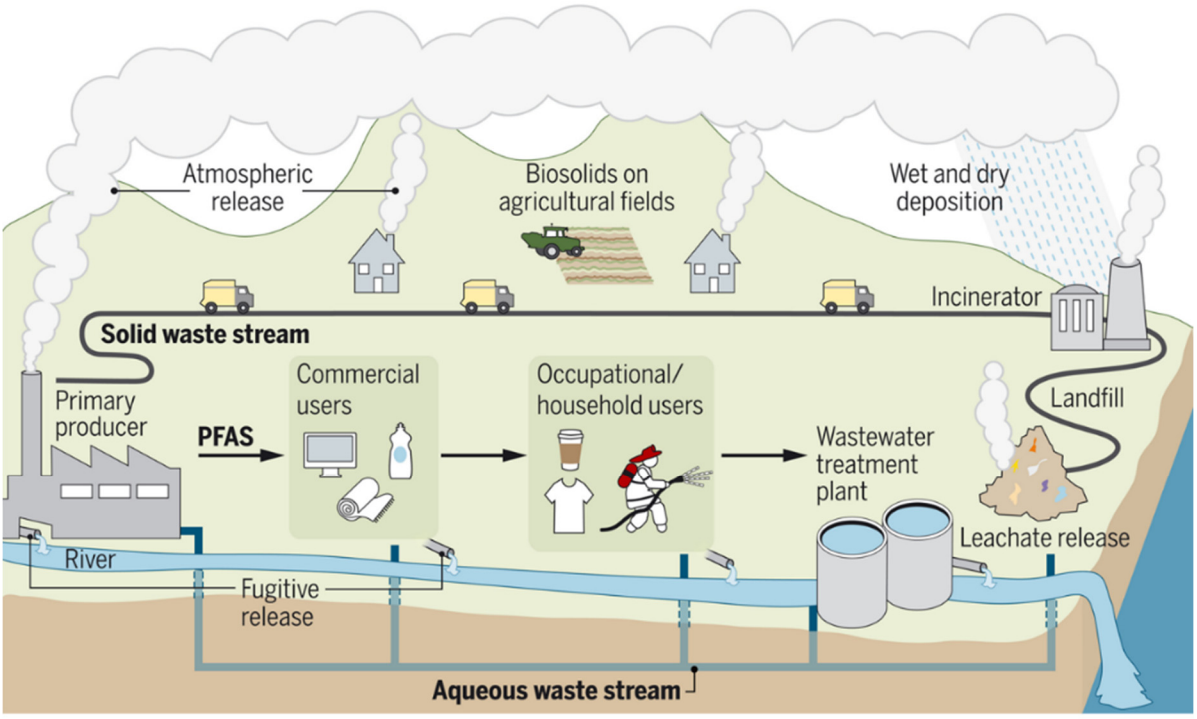

FIGURE 1-7 Examples of how PFAS enter the environment.
SOURCE: Evich et al., 2022.

Ingestion is the most well-studied route of exposure to PFAS in nonoccupational settings (Trudel et al., 2008). PFAS can be ingested by drinking contaminated water or by eating contaminated seafood or other contaminated foods, such as vegetables, game, or dairy products (Bao et al., 2019, 2020; Death et al., 2021; Domingo and Nadal, 2017; Herzke et al., 2013; Li et al., 2019). PFAS are often used in cookware and food contact materials, such as microwave popcorn bags and packaging of fast foods and processed foods (Carnero et al., 2021; Curtzwiler et al., 2021; Schaider et al., 2017). Exposure can also occur through accidental ingestion of PFAS-containing dusts (ATSDR, 2021[8]). PFAS cross the placenta, and PFAS from the mother's body burden can be passed on to her developing fetus (Gao et al., 2019; Manzano-Salgado et al., 2015); PFAS can also pass from mother to child through breast milk (Serrano et al., 2021; Zheng et al., 2021).

Inhalation and transdermal absorption are less well studied. Inhalation is well documented in occupational settings that use aerosolized PFAS (Gilliland, 1992). Volatile PFAS have been detected indoors (Fromme et al., 2015; Morales-McDevitt et al., 2021) and have been associated with persistent PFAS in serum (Fraser et al., 2013). Inhalation near factory emissions and incinerators contributes to exposures in nearby communities (ATSDR, 2021[9]). Inhalation from showering in contaminated water is an active area of research, but there are as yet no data formally evaluating this route.

PFAS are used in thousands of products (e.g., water- and stain-resistant clothing) and personal care products (e.g., sunscreen, makeup, dental floss). They also are used in such products as paint, textiles, firefighting foam, electroplating materials, ammunition, climbing ropes, guitar strings, artificial turf, and soil remediation substances (Glüge et al., 2020). The extent to which the use of such products contributes to human exposures remains unclear, however, because the relative contribution of PFAS exposures from sources other than food or water is not well characterized (DeLuca et al., 2021).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

POLICIES THAT COULD REDUCE EXPOSURE TO PFAS

The EPA's major policy levers for reducing harmful exposures to PFAS are the Toxic Substances Control Act (TSCA), which limits chemicals in commerce; the Safe Drinking Water Act; and the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA, commonly known as the "Superfund"), which designates hazardous sites for cleanup.

In 2000, the 3M Company (Maplewood, Minnesota), the primary U.S. manufacturer of PFOS, began a voluntary phase-out of perfluorooctanyl chemicals and related precursors, including PFOS, PFHxS, and PFOA[8] (ITRC, 2017). Between 2002 and 2013, the EPA issued four Significant New Use Rules under the TSCA that prevented others from manufacturing the chemicals 3M had voluntarily phased out (Richter et al., 2021) and required notifying the agency prior to any manufacture, use, or import of 271 other PFAS.[9] In 2006, the EPA encouraged eight leading PFAS manufacturers to join a global stewardship program focused on phasing out and ending the production of PFOA. At the same time, the TSCA allows some industries (including photographic imaging, semiconductors, etching, metal plating, and aviation) to continue using banned PFAS at low levels, and these industries are exempted from the provision requiring that the EPA be notified of any new use of banned PFAS (ITRC, 2017). Furthermore, these bans apply only to a handful of chemicals, most of which could easily be substituted for by other PFAS. And other PFAS not yet banned remain in use by industry while undergoing further biologic profiling and toxicity evaluation (Houck et al., 2021).

If PFAS were designated as hazardous substances, CERCLA could be used to lower exposures from contaminated sites, giving the EPA more authority to investigate and remediate those waste sites. The agency has not yet designated PFOS or PFAS as hazardous, however. And the Safe Drinking Water Act would be more protective if the standards were enforceable.[10]

Policy changes that could reduce PFAS exposures may be forthcoming. Recently, the EPA established an EPA Council on PFAS charged with building on the agency's ongoing work to understand better and ultimately reduce the potential risks posed by these chemicals. A PFAS Strategic Roadmap also was released, committing the agency to action. In addition, the EPA released for review by a science advisory board draft documents that will inform an enforceable National Primary Drinking Water Regulation for PFOA and PFOS.[11]

The EPA is not alone in its lack of action. The U.S. Food and Drug Administration (FDA) has delayed limiting PFAS in bottled water,[12] but has revoked regulations that allowed for long-chain PFAS (such as PFOA and PFOS) in food packaging in 2016,[13] and reached an agreement to phase out PFAS substances containing 6:2 fluorotelomer alcohol (Hahn, 2020). The Occupational Safety and Health Administration (OSHA) has set no occupational exposure limits.

The lack of federal standards has left states and communities responsible for creating policies to reduce exposures to these chemicals in the interest of protecting public health (Brennan et al., 2021). There is no consistency in these policies, and not all states have the authority to set standards more protective than those of the federal government (ECOS, 2020). Furthermore, leaving policy making to

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

state governments encourages a confusing patchwork of rules and advice. Health inequities thrive in such chaotic circumstances.

PROVIDING CLINICAL ADVICE IN COMMUNITIES EXPOSED TO PFAS

To help clinicians[14] respond to patient concerns about PFAS exposure, the Agency for Toxic Substances and Disease Registry (ATSDR) published *PFAS: An Overview of the Science and Guidance for Clinicians on Per- and Polyfluoroalkyl Substances.*[15] This guidance summarizes general information about PFAS and PFAS health studies and suggests answers to example patient questions. However, the ATSDR guidance does not provide specific recommendations on when to test for PFAS, how to order the tests, how to interpret the results, or what clinical follow-up based on PFAS exposure might look like. Interpretation of PFAS blood or urine results is challenging because the specific level of exposure at which harms may occur is unknown, and the science on the potential health effects of exposure to PFAS is advancing quickly, making it difficult to advise clinicians about what follow-up tests might be helpful.

ATSDR has the legal authority to issue guidance to clinicians in its "Criteria for Determining the Appropriateness of a Medical Monitoring Program under Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA),"[16] promulgated in 1995 (42 USC 9604[i][9]). Under the criteria, the purpose of medical monitoring is to detect individuals with exposures to hazardous substances and refer them to medical care for further evaluation and treatment. The criteria recommends actions that clinicians can take, such as early detection, treatment, or other interventions that interrupt "the progress to symptomatic disease, improve the prognosis of disease, improve the quality of life of the affected individual, or address diseases that are amenable to primary prevention" (42 USC 9604[i][14], p. 38842). Medical monitoring under the criteria is not a research mechanism, and suggests that other epidemiologic studies be carried out to further investigate the cause–effect relationship between exposures and health outcomes. ATSDR's authority to issue guidance to clinicians comes from a different section in the same law (42 USC 9604[i][14]), which grants the agency the authority to develop education materials on medical surveillance, screening, and methods of diagnosing and treating injury or disease related to exposure to hazardous substances.

The first well-documented case of community water contamination with PFAS resulted in recommendations for medical monitoring (see Box 1-2). Releases of PFOA-contaminated drinking water from the DuPont Washington Works facility near Parkersburg, West Virginia, were detected in the local area and a few nearby communities across the Ohio River. A class action lawsuit was filed—*Jack W. Leach et al. v. E.I. du Pont de Nemours & Company* (no. 01-C-608 W.Va., Wood County Circuit Court, filed April 10, 2002). The lawsuit resulted in a medical monitoring program that included suggested screenings for high cholesterol, thyroid disease, ulcerative colitis, testicular cancer, kidney cancer, pregnancy-induced hypertension, and blood testing for PFOA (Frisbee et al., 2009). The medical monitoring guidance generated by this high-profile case has led some community members to believe that the ATSDR guidance should provide recommendations for clinical follow-up, and advocates in many PFAS-exposed communities are working to establish medical monitoring programs (Rizzuto, 2021).

The absence of recommendations on testing and follow-up in ATSDR's PFAS clinical guidance is aligned with standard medical practice, as clinicians are expected to order tests only when how to interpret and act on the results is known. In addition, reporting of levels of PFAS in blood and urine to patients raises ethical questions, such as whether to report results in the absence of established health guidelines.

[14] The committee uses "clinician" throughout this report to refer to "a healthcare professional qualified in the clinical practice of medicine. Clinicians may be physicians, nurses, pharmacists, or other allied health professionals" as defined by the Centers for Medicare & Medicaid Services (https://www.cms.gov/Medicare/Quality-Initiatives-Patient-Assessment-Instruments/MMS/QMY-Clinicians [accessed June 16, 2022], para 2).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

BOX 1-2
The C-8 Science Panel and the C-8 Medical Panel

Background: In the early 2000s, contamination of drinking water with PFOA (also known as C-8 for the eight carbons in its chemical structure) was discovered in six water districts in two states near the DuPont Washington Works facility near Parkersburg, West Virginia. As a result, a class action lawsuit, *Jack W. Leach et al. v. E.I. du Pont de Nemours & Company* (no. 01-C-608 W.Va., Wood County Circuit Court, filed April 10, 2002), was filed. The lawsuit resulted in the formation of the C-8 Science Panel to determine "probable link conditions" associated with PFOA-contaminated drinking water. The settlement agreement defined "probable link" to mean that, based on the weight of the available scientific evidence, it is more likely than not that there is a link between exposure to PFOA and a particular human disease (Frisbee et al., 2009). The settlement also called for the formation of a separate medical panel "to develop general guidelines for medical monitoring related to the human diseases for which the science panel delivered a probable link finding and is different from what would otherwise be prescribed" if exposure to PFOA were absent.

Science Panel Findings: The science panel identified pregnancy-induced hypertension (including preeclampsia), kidney cancer, testicular cancer, thyroid disease, ulcerative colitis, and high cholesterol (hypercholesterolemia) as probable linked conditions (C-8 Medical Panel, 2013).

Medical Panel Findings: The medical panel recommended screenings for high cholesterol, thyroid disease, ulcerative colitis, testicular cancer, kidney cancer, pregnancy-induced hypertension, and blood testing for PFOA (C-8 Medical Panel, 2013).

At a workshop on PFAS exposure that occurred more than 1 year before the present study began, however, Andrea Amico, a member of a PFAS-impacted community in Pease, New Hampshire, traveled to Washington, DC, to represent her community's views on PFAS testing. She said that people in her community

> were exposed … without their consent, and now they have to fight tooth and nail to get a blood test result to know how much exposure they had? It just seems incredibly wrong…. We don't have all the answers yet, but not testing them is not the right answer.

Amico also argued for more access to testing despite the knowledge gaps regarding the interpretation of test results. She believes PFAS exposure testing would allow people to compare their levels with those of others in highly exposed communities, which could help them understand their potential health risks (NASEM, 2020). As it stands now, clinicians in communities with known PFAS contamination are left to make their own decisions about whether to test patients for PFAS exposure, which PFAS to test for, how to interpret the results, what health effects are associated with PFAS, and how to determine appropriate follow-up care for exposed patients. Pressed for time in clinic visits, clinicians may dismiss interest in PFAS testing or avoid recommending specific medical follow-up, and they may not even be clear on when or how to order a test.

COMMITTEE'S TASK AND APPROACH

Prompted by the tension between people in PFAS-exposed communities wanting preventive care for their exposure and clinicians not knowing what care should be provided, ATSDR and the National Institute of Environmental Health Sciences (NIEHS) asked the National Academies of Sciences, Engineering, and Medicine to form an ad hoc committee to provide advice on clinical care for patients exposed to PFAS. The committee included experts in epidemiology, toxicology, preventive medicine, pediatrics, nursing, public health, environmental medicine, philosophy, ethics, exposure science, and risk communication (see Appendix A for biographical information on the committee members). The committee's Statement of Task is provided in Box 1-3.

Copyright National Academy of Sciences. All rights reserved.

BOX 1-3
Statement of Task

An ad hoc committee appointed by the National Academies of Sciences, Engineering, and Medicine (the National Academies) will consider current evidence regarding human health effects of the most widely studied per- and polyfluoroalkyl substances (PFAS). The National Academies will provide the Centers for Disease Control and Prevention and the Agency for Toxic Substances and Disease Registry (CDC/ATSDR) and the National Institute of Environmental Health Sciences (NIEHS) an objective and authoritative review of current evidence regarding human health effects of those PFAS being monitored in the CDC's National Report on Human Exposure to Environmental Chemicals. The National Academies will also provide recommendations regarding potential changes to CDC/ATSDR PFAS clinical guidance including:

- Options and considerations to guide decision making for PFAS testing in a patient's blood or urine.
- PFAS concentrations that could inform clinical care of exposed patients.
- Appropriate patient follow-up and care specific to PFAS-associated health endpoints for those patients known or suspected to be exposed to PFAS.

This information will be used to inform how communities and individuals exposed to PFAS could be best served by clinicians. Specifically, the committee will undertake the following tasks:

1. Assess the strength of evidence for the spectrum of putative health effects suggested by human studies (including immune response, lipid metabolism, kidney function, thyroid disease, liver disease, glycemic parameters and diabetes, cancer, and fetal and child development) to establish a basis for prioritized clinical surveillance or monitoring of PFAS health effects. This assessment should characterize the likelihood of those health effects occurring (qualitative probability) given real world human exposures and identify the human populations at most risk (consider life stage, health status, exposure level). Data/evidence gaps that contribute to uncertainty about health effects of most concern should be annotated.
2. Develop general principles for clinical evaluation or biological testing given substantial scientific uncertainty about health effects or the value of such measures in informing care. These principles should address reasons for testing (e.g., opportunities to reduce morbidity and mortality), when to test, who to test, how to test, what to test for, risks of testing, and the related social and ethical implications of testing.
3. Review current knowledge about the contribution of PFAS exposure sources (i.e., drinking water, diet, the indoor environment, etc.) to human exposure and develop principles clinicians can use to advise patients on exposure reduction.
4. Advise whether changes to current CDC/ATSDR clinical guidance/recommendations on PFAS blood or urine testing are needed given the committee's general principles and assessment of the associations between PFAS exposure and clinically relevant health outcomes. Ultimately, the goal is to provide guidance on how clinicians can advise patients on PFAS testing and health outcomes that may be associated with PFAS as well as what to advise patients regarding standard medical or preventive care and exposure reduction.
5. Outline a process by which the CDC/ATSDR PFAS clinical guidance can be effectively reviewed and revised over the next decade.

Figure 1-8 provides an overview of the steps in the committee's approach to its charge: problem formulation and engagement with communities, development of principles for decision making under substantial scientific uncertainty, determination of strategies for reducing exposure to PFAS, development of advice for PFAS testing and levels of PFAS in blood or urine that could inform clinical care of exposed patients, determination of the health effects of PFAS, appropriate follow-up care of exposed patients, and advice on whether changes are needed with respect to ATSDR's PFAS clinical guidance.

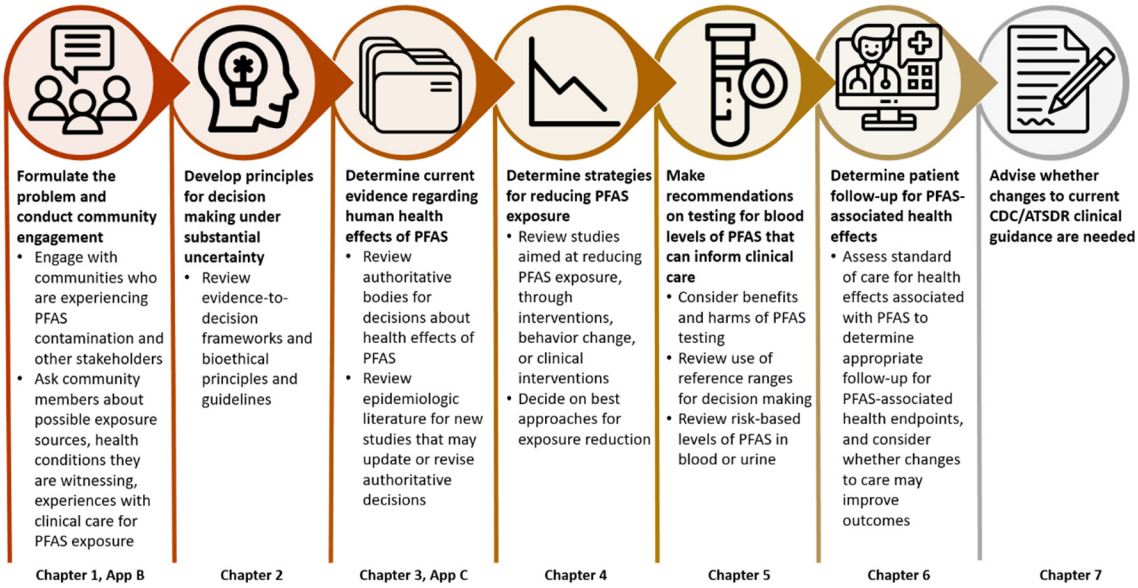

FIGURE 1-8 The committee's approach to the Statement of Task and the chapters and appendixes where the topics are discussed.
NOTE: ATSDR = Agency of Toxic Substances and Disease Registry; CDC = Centers for Disease Control and Prevention; PFAS = per- and polyfluoroalkyl substances.

Problem Formulation and Community Engagement

The committee held six public meetings between February 4 and August 12, 2021 (see Appendix C for the agendas of these public meetings). Leading up to its first meeting, the committee began to receive public input on the study. The testimony provided at the first public meeting revealed that many members of the public feel ignored or dismissed by clinicians and the medical community, and have assumed the role of community scientists, becoming experts in their communities' illnesses and experiences. People who live with potentially harmful exposures can have knowledge that is inaccessible to scientists as their experiential learning provides essential context for scientific findings (Brown, 1992). To incorporate this knowledge into the study, the committee, National Academies staff, and the study sponsors developed a community engagement plan. To aid in this process, the committee considered the Jemez Principles for Democratic Organizing, a set of recommendations developed to serve as a foundation on which diverse coalitions can together make justice-based decisions specifically weighing on inclusivity, as well as letting people speak for themselves (Solís and SPWU, 1997). Ultimately, the committee's community engagement plan consisted of several key elements (see Figure 1-9):

- a panel of community liaisons;
- three 2021 town halls (April 7, Eastern Town Hall; May 6, Middle Town Hall; May 25, Western Town Hall);
- community speakers from PFAS-impacted communities at every public meeting;
- open sign-up for public testimony to the committee at every public meeting; and
- encouragement for providing written testimony to the committee throughout the data-collection phase of the study.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

FIGURE 1-9 The committee's approach to community engagement.

The community liaisons were solicited through a nomination process similar to that used for National Academies committees. The community liaisons were intended to be an inclusive group; all nominees who appeared to be genuinely interested or had experience working with PFAS or similar environmental contamination issues were asked to join the group. National Academies staff held several meetings with the liaisons throughout the study process. The first call with the liaisons clearly described the mission of the National Academies, the goals of the study, what the study would not address, and the study timeline.

The role of the community liaisons was to provide input to the committee on behalf of PFAS-impacted communities. The liaisons aided the study process by suggesting speakers, topics, and discussion questions for the public meetings, and by answering questions to inform the report or the committee's work. They also prepared letters to the committee providing consensus opinions related to the Statement of Task and suggested reviewers for the report for consideration by National Academies staff.

Health Effects Associated with PFAS Exposure

The committee carefully considered the purpose of the literature review of putative health effects prescribed in its Statement of Task: to *establish a basis for prioritized clinical surveillance or monitoring of PFAS health effects.* Accordingly, the committee's review was focused on determining a set of health effects that may be associated with PFAS, which could then be used for preventive medicine recommendations and decisions. The Statement of Task limited the review to those PFAS included in the Centers for Disease Control and Prevention's (CDC's) *National Report on Human Exposure to Environmental Chemicals* (see Table 1-1).

Although the committee believes that studies on health effects in humans will most likely be limited to those PFAS in Table 1-1 because they are the most commonly studied in humans, other PFAS may cause harm because of similarities in biological persistence and toxicities (Kwiatkowski et al., 2020). Moreover, while different PFAS have distinct physical, chemical, and toxicological properties, people are exposed to more than a single PFAS. As a result, exposures are often to mixtures of PFAS such that specific effects are difficult to disentangle. Considering these issues and recognizing that some PFAS are less frequently measured than others, the committee ultimately decided to provide one strength-of-evidence determination for all PFAS for each health effect. Further description of the methods used for the committee's review is provided in Appendix D.

TABLE 1-1 PFAS Species Currently Included in the Centers for Disease Control and Prevention's *National Report on Human Exposure to Environmental Chemicals*

Abbreviated Name	Full Name	CAS Registry No.
MeFOSAA	Methylperfluorooctane sulfonamidoacetic acid	2355-31-9
PFHxS	Perfluorohexanesulfonic acid perfluorohexane sulfonic acid	355-46-4
n-PFOA (linear isomer), Sb-PFOA (branched isomers)	Perfluorooctanoic acid	335-67-1*
PFDA	Perfluorodecanoic acid	335-76-2
PFUnDA	Perfluoroundecanoic acid	2058-94-8
n-PFOS (linear isomer), Sm-PFOS (branched isomers)	Perfluorooctanesulfonic acid	1763-23-1*
PFNA	Perfluorononanoic acid	375-95-1

NOTES: CAS = Chemical Abstracts Service. * = CAS number refers to linear isomer only. Previous survey years have also included perfluorobutane sulfonic acid (PFBS), perfluoropentanoic acid (PFpA), perfluorododecanoic acid (PFDoDA), perfluorooctane sulfonamide (FOSA), and 2-(N-ethyl-perfluorooctane sulfonamido)acetate (EtFOSAA), according to Patrick N. Breysse's presentation to the committee on February 4, 2021.

Reducing Exposure to PFAS

This report does not review EPA policy actions, which are beyond the scope of the committee's task. A review of individual-level exposure reduction strategies is presented in Appendix E. Chapter 4 provides an overview of that literature and medical interventions to reduce PFAS body burden. The report reviews these individual-level strategies because the task calls for them; however, the committee does not believe that people should be responsible for protecting themselves from harmful chemicals. Well-established exposure prevention frameworks, such as the hierarchy of controls and the health impact pyramid, dictate that individuals should not be responsible for making such decisions (Frieden, 2010). Systems approaches to exposure reduction, such as setting an enforceable water standard, regulating PFAS from nonessential uses, and cleaning up hazardous waste sites, will be far more effective at reducing population-level exposures (see Figure 1-10).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Advice on PFAS Testing and Levels That Could Inform Clinical Care

The committee's approach to providing advice on PFAS testing and clinical care included a review of the harms and benefits of testing. To determine the levels of PFAS exposure that could inform clinical care of exposed patients, the committee did not complete dose-response modeling to determine a tolerable risk level. Instead, the committee reviewed various strategies for interpreting PFAS concentrations, such as use of reference ranges for comparison, and levels of risk determined by other agencies.

Follow-Up Care for Patients Known or Suspected to Be Exposed to PFAS

The committee considered relevant for patient follow-up recommendations for each condition that its review found had suggestive or limited suggestive evidence of an association with PFAS exposure. The committee believed that while it was important to categorize the strength of the evidence, all conditions with an association should be considered for patient follow-up since acknowledging the potential risk may make clinicians and patients more likely to prioritize screenings.

ORGANIZATION OF THE REPORT

This report is organized into eight chapters and five appendixes. Chapter 2 presents the committee's general principles for decision making under substantial scientific uncertainty. Chapter 3 presents the committee's assessment of the health effects of PFAS. Chapter 4 reviews strategies for reducing exposure to PFAS. Chapter 5 provides recommendations for PFAS testing and concentrations in blood or urine that could inform clinical care. Chapter 6 presents the committee's specific recommendations for patient follow-up. Chapter 7 addresses suggested changes to the ATSDR PFAS clinical guidance. Finally, Chapter 8 considers the implementation of the committee's recommendations. Appendix A provides biographical information on the committee members, National Academies staff, and the community liaisons; Appendix B provides a summary of the town halls; Appendix C contains the agendas of the committee's public meetings; Appendix D is a summary of the methods used in the committee's literature review; and Appendix E is a white paper describing a review of the PFAS personal intervention literature.

Principles for Decision Making Under Uncertainty

Given that there is some degree of uncertainty in all science, science-based decision making also involves uncertainty (Fischhoff and Davis, 2014). This uncertainty can arise from many different factors, including lack of available evidence, statistical variability, model uncertainty, and "deep" uncertainty about the fundamental scientific processes relevant to a decision (IOM, 2013). Yet, despite this uncertainty, when evidence exists, it helps predict what may happen when a decision is made (Fischhoff and Davis, 2014). Values also influence how scientific evidence is gathered and interpreted, thereby influencing how uncertainty is characterized and what decisions are made on the basis of that particular interpretation of the evidence (Douglas, 2009; Elliott, 2017; IOM et al., 1995). Thus, it is important to consider uncertainty in the broader context of the decision to be made and the values underlying the decision-making process (IOM, 2013).

In response to uncertainty, some public health professionals may wish to avoid acting as soon as science determines the risks of an exposure for fear that the association is not a true one and that acting too quickly could lead to inappropriate and costly public health measures (Boffetta et al., 2008). On the other hand, some may fear that if society waits for more certain evidence, meaningful action will be delayed (Blair et al., 2009). As a group of scientists with different backgrounds and perspectives, the committee grappled with both of these potential outcomes of its decisions. The committee established the principles in this chapter to help accomplish its charge, but also believes they may be useful to support the Agency for Toxic Substances and Disease Registry (ATSDR) in making decisions about medical follow-up and advice to communities exposed to per- and polyfluoroalkyl substances (PFAS) or other chemicals with uncertain effects.

DEVELOPMENT OF THE COMMITTEE'S PRINCIPLES

In its effort to identify principles for decision making under uncertainty, the committee solicited input from members of PFAS-impacted communities through its virtual town halls (see Chapter 1). The committee also reviewed decision-making frameworks, including a review paper (Norris et al., 2021), the criteria used by the U.S. Preventive Services Task Force (USPSTF) (Krist et al., 2018; Sawaya et al., 2007), GRADE (Grading of Recommendations Assessment, Development and Evaluation) (Moberg et al., 2018), a National Academies evidence framework for decisions regarding genetic testing (NASEM, 2017), the Evidence and Value: Impact on DEcision-Making (EVIDEM) framework (Goetghebeur et al., 2008), the principles used by the C-8 Medical Panel (C-8 Medical Panel, 2013), the ethical principles from the Belmont Report (HHS, 1979), and principles for precautionary reasoning (Resnik, 2021). A brief overview of these sources is included below.

The existing principles and frameworks the committee reviewed were not entirely satisfactory for the purposes of this study. Most of the existing frameworks were not designed to address situations characterized by limited evidence and substantial scientific uncertainty—the contexts the committee was charged to address. The committee understood that when evidence is incomplete, dangers can be associated both with taking action and with failing to act (Douglas, 2009; Elliott and Richards, 2017). Therefore, the committee adapted the principles and frameworks it reviewed to develop a set of principles appropriate for decision making under substantial scientific uncertainty.

KD2351

PRINCIPLES PUT FORWARD BY THE COMMITTEE

The committee decided to use the ethical principles proposed in the Belmont Report (HHS, 1979) and developed by Beauchamp and Childress (2001) as a foundation for its approach. Although these principles (nonmaleficence, beneficence, autonomy, and justice) were not initially proposed for decision making under uncertainty, they provide an ethical starting point for addressing such situations. In addition, they encompass many of the criteria and concepts included in other frameworks, such as considerations of benefits, harms, health equity, and human rights. The committee combined the principles of nonmaleficence and beneficence into a principle of proportionality—drawing on the Resnik (2021) framework for precautionary reasoning in response to uncertainty. The committee also added two other principles included in other decision-making frameworks but not captured by the principles from the Belmont Report. One is the principle of feasibility, found in several of the frameworks reviewed by Norris and colleagues (2021), including GRADE. It captures the importance of considering the capabilities of the current medical system and the ways it might need to develop to respond to decision needs. The other is the principle of adaptability, which builds on the call for review and revision in the National Academies framework for genetic testing and the emphasis in the USPSTF framework on revising recommendations in response to emerging scientific information. Box 2-1 briefly describes the committee's resulting five principles for exposure biomonitoring and patient follow-up under substantial scientific uncertainty about the health effects of PFAS exposure. Each of these principles is discussed in turn below.

Proportionality

The committee's first principle, proportionality, is adapted from Resnik's recommendations for precautionary decision making under uncertainty (Resnik, 2021, p. 81):

> **Proportionality:** Decisions should balance plausible harms and benefits proportionally, meaning that the harms and benefits are considered together and weighed based on a qualitative assessment of their potential likelihoods and magnitudes.

BOX 2-1
Principles for Decision Making Under Uncertainty Used in This Report

Proportionality: Decisions should balance plausible harms and benefits proportionally, meaning that the harms and benefits are considered together and weighed based on a qualitative assessment of their potential likelihoods and magnitudes.

Justice: Decisions should be informed by an emphasis on promoting justice, including by balancing benefits and harms fairly across the population of at-risk individuals, advancing health equity, and respecting human rights. In addition, justice requires consideration of sociohistorical context, stakeholders, existing structural inequalities, and issues of agency (the power a community has to advocate for itself in conflicts).

Autonomy: Decisions should be based on informed decision making by individuals and reflect respect for their values.

Feasibility: Decisions should take into account resource availability, including follow-up services.

Adaptability: Decisions should respond to new information about harms, benefits, and other relevant considerations (e.g., health equity and feasibility).

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

This principle draws on a common theme that cuts across most frameworks the committee considered: balancing harms and benefits. For example, the USPSTF states that in determining the benefits of a preventive services framework, one should consider evidence about the accuracy of screening, harms of early-intervention treatment and not treating, and the treatment benefits and harms of a particular preventive service. The USPSTF framework also considers the accuracy of a screening test and its relationship to the clinical health effect, and the harms associated with the screening for the health condition and treatment of the condition.

The principle of proportionality addresses harms and benefits in situations of substantial scientific uncertainty. To balance harms and benefits proportionally is to consider them together such that, all else being equal, policies with fewer or less severe harms (assessed in terms of their likelihood and magnitude) can be justified based on lesser benefits relative to policies with increased harms. This principle is particularly relevant for decision making under uncertainty because it can justify taking actions to realize potentially significant benefits even when the evidence for those benefits is limited, as long as the potential harms associated with the actions are minimal.

Proportionality provides an alternative to probability-based decision principles that require numerical ranking of the probabilities or utilities associated with effects. Although applying the principle of proportionality calls for considering the likelihood and magnitude of benefits and harms in some form, it does not require assigning numerical rankings to their likelihoods or magnitudes. Because of the qualitative nature of this principle, reasonable decision makers can potentially disagree about how to apply it in specific situations because judgments are required to weigh harms and benefits. Especially when the benefits associated with two policies are similar, and the likelihood and the magnitude of their harms cannot be estimated precisely, the principle of proportionality may not offer decisive guidance. Instead, this principle provides a general way of reasoning compatible with a range of more specific strategies for balancing harms and benefits under different forms of uncertainty (Douglas, 2009; Workman et al., 2020). It affirms that both harms and benefits need to be considered and that they need to be weighed against one another when making decisions (Resnik, 2021).

For this report, the harms of a decision could include physical effects, psychological effects, and opportunity costs (Harris et al., 2014). The committee does not consider the financial costs of paying for tests or treatment a harm. Costs could be considered under the principle of feasibility, but the committee excluded costs from feasibility as well. The reason for excluding costs is that, although a certain test or treatment may be expensive today, costs typically decrease over time if demand for the test or treatment increases. Many other organizations, such as the USPSTF, do not consider financial costs when formulating recommendations based on assessment of health benefits and harms, and the committee followed this approach. The committee did consider as potential harm the loss of income or financial damage incurred as a result of decisions (e.g., decreased property values caused by a community's learning about chemical contamination).

The principle of proportionality calls for considering benefits and harms that are plausible. The concept of plausibility provides a minimal threshold for determining which benefits and harms should even be considered. Resnik (2021, pp. 80–81) defines a scientific statement as plausible "if it is consistent with well-established scientific facts, hypotheses, laws, models, or theories"—a lower standard of evidence than is typically required for even weak scientific confirmation. Instead, this definition is designed to rule out "armchair speculation" about potential harms and benefits. If a harm or benefit is judged to be plausible, it can be considered in the overall assessment of proportionality. Nevertheless, harms and benefits deemed to have a reasonably low level of evidential support might still be given relatively little weight in proportionality assessment unless their potential magnitudes were estimated to be exceptionally high.

In situations of substantial scientific uncertainty, it is generally unrealistic to expect more than a qualitative assessment of the likelihoods and magnitudes of harms and benefits. This assessment may be informed by evidence, including epidemiological studies, toxicological studies (both animal models and mechanistic studies), modeling, and support from analogy. It should be guided by norms for the responsible acquisition and utilization of evidence, knowledge, and expertise. Still, the appropriate

KD2353

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

standards of evidence for drawing tentative conclusions about potential likelihoods and magnitudes may be much lower than would apply in other scientific contexts (Douglas, 2009; Elliott and Richards, 2017; Ginsberg et al., 2019).

Justice

Justice is the second principle for decision making in situations of substantial scientific uncertainty:

> **Justice:** Decisions should be informed by an emphasis on promoting justice, including by balancing benefits and harms fairly across the population of at-risk individuals, advancing health equity, and respecting human rights. In addition, justice requires consideration of sociohistorical context, stakeholders, existing structural inequalities, and issues of agency (the power a community has to advocate for itself in conflicts).

Justice is central to the Belmont Report and Beauchamp and Childress's framework for biomedical ethics (Beauchamp and Childress, 2001; HHS, 1979), and elements of justice are included in many of the frameworks discussed in the review by Norris and colleagues (2021). Beauchamp and Childress (2001, p. 226) describe justice as "fair, equitable, and appropriate treatment in light of what is due or owed to persons." Thus, an injustice involves "a wrongful act or omission that denies people benefits to which they have a right or distributes burdens unfairly."

In this report, the focus is on three elements of justice: fairness, equity, and human rights. Resnik (2001) emphasizes that decisions under uncertainty should be handled in a manner that is procedurally and distributively fair: the *process* for making decisions should be fair in the sense of incorporating all relevant stakeholders and employing transparent and accountable procedures, and the *endpoints* of the decisions should also be fair.

In the health care setting, the second element of justice—equity—calls for promoting health equity. Health equity is "the state in which everyone has the opportunity to attain full health potential, and no one is disadvantaged from achieving this potential because of social position or any other socially defined circumstance" (NASEM, 2017, p. 32). Promoting health equity is not the same as achieving similar health outcomes for everyone. Instead, promoting health equity in the context of this report means designing approaches that enable people to lead full, healthy lives regardless of their social circumstances, such as race, socioeconomic status, and geographic location. Health equity is a particularly important element of justice because it establishes the positive responsibility to provide the conditions necessary for people to lead healthy lives regardless of their social circumstances; without this positive responsibility, some ethicists have argued that the principle of justice does not provide significant guidance beyond what is already found in other bioethical principles, such as proportionality or autonomy (London, 2022).

Finally, justice involves respect for human rights. The committee's conception of human rights is drawn from the World Health Organization (WHO)-Integrate evidence-to-decision framework (Rehfuess et al., 2019), which emphasizes rights related to the availability and accessibility of health care and such general rights as nondiscrimination.

In cases of environmental pollution such as PFAS contamination, it is crucial to incorporate the concept of environmental justice into efforts to promote fairness, health equity, and human rights. According to the U.S. Environmental Protection Agency (EPA), "Environmental justice is the fair treatment and meaningful involvement of all people regardless of race, color, national origin, or income, concerning the development, implementation, and enforcement of environmental laws, regulations, and policies. This goal will be achieved when everyone enjoys:

- The same degree of protection from environmental and health hazards, and
- Equal access to the decision-making process to have a healthy environment."[1]

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

The environmental justice movement in the United States arose in recent decades out of the realization that communities of color, which already faced other social disadvantages, were also exposed to disproportionately high levels of environmental pollution (Bullard, 2018; Shrader-Frechette, 2002). Many places where PFAS contamination has been identified are rural and served by private well water, and they face other environmental and social challenges, such as co-occurrences of other contaminants; occupational exposures; and health inequities, such as less access to health care and a lack of economic resources with which to mitigate exposures. These less-advantaged rural communities may also have structural and agency-related factors that can impact their ability to minimize their exposure, as well as to seek and access adequate health care linked to exposures. Promoting environmental justice requires addressing these inequities, such as by taking steps to eliminate disproportionate lack of access to health care, exposure biomonitoring, patient follow-up for PFAS-associated health effects, and environmental remediation and mitigation. Required as well is addressing the needs of vulnerable populations, such as pregnant and nursing women, young children, and those who are immunocompromised.

Autonomy

The committee's third principle is autonomy:

> **Autonomy:** Decisions should be based on informed decision making by individuals and reflect respect for their values.

The Belmont Report emphasizes the importance of respecting individuals' autonomy and ability to make judgments; it also warns against withholding information that would enable them to judge. Beauchamp and Childress (2001) likewise emphasize that respect for autonomy requires eliminating constraints on individuals' decision making and fostering their self-determination. In practice, this principle has often been operationalized by focusing on obtaining individuals' informed consent to medical treatments or research experiments, but its implications are much broader. In the context of this report, the principle of autonomy calls for health care services to provide individuals with information and collaborate with them to facilitate decisions that accord with their values. This approach is fundamental in situations of substantial scientific uncertainty, when difficult decisions need to be made about how to weigh harms and benefits given limited information about their likelihoods and magnitudes. Different individuals can reasonably approach such situations in different ways. Therefore, the principle of autonomy affirms that patients should play a role in making these decisions.

In addition to fostering decisions that accord with patient values, the principle of autonomy supports other steps to empower patients and their communities. To facilitate patients' self-determination, health care providers and researchers should take steps to report information back to patients in ways that facilitate their future informed decision making. When patients are tested for exposure to potentially toxic substances, it is essential to provide them with (Brody et al., 2014; Morello-Frosch et al., 2009)

- information about their exposure level;
- a description of the potential health impacts, as well as the related signs and symptoms;
- how their exposure level compares with those of others in their area and across the country;
- the potential significance of their exposure level; and
- how they can reduce future risk, either of the exposure itself or its potential health impact(s).

The PFAS Research, Education, and Action for Community Health (PFAS-REACH) project is an example of an effort to provide accessible information to community members about how to interpret exposure biomonitoring results and what follow-up activities could be warranted to address PFAS-associated health effects (Boronow et al., 2017). It is also essential to respect the decision of some

KD2355

Copyright National Academy of Sciences. All rights reserved.

individuals not to be tested. Some individuals may not want to have information that increases their uncertainty or could lead to future medical monitoring that might not improve their health outcomes.

The principle of autonomy can also guide actions taken at the community level to help foster decision making by individuals. For example, there is growing recognition that community organizations and advocacy groups can generate important information about public health threats and develop actionable solutions (Corburn, 2005; Elliott, 2017; Wandersman, 2003). Thus, health care providers and public health institutions can foster individuals' autonomy by collaborating with these organizations that can help facilitate informed patient decision making.

Feasibility

The committee's fourth principle for making decisions under substantial scientific uncertainty is feasibility:

> **Feasibility:** Decisions should into take account resource availability, including follow-up services.

Feasibility, included in many evidence-to-decision frameworks reviewed by Norris and colleagues (2021), denotes the ability to conduct testing, clinical evaluation, and follow-up activities. An assessment of feasibility encompasses the infrastructure and resources currently available and whether they are sufficient to achieve the goals of a decision. In the context of PFAS exposure biomonitoring, for example, feasibility could include such considerations as the time and knowledge providers have available to facilitate environmental exposure assessments or their access to environmental occupational health physicians. Feasibility assessments may also include consideration of whether an action or policy is sustainable over time and it entails important legal, ethical, or bureaucratic barriers (Moberg et al., 2018). At the same time, however, it is crucial to recognize that feasibility assessments are relative to a particular point in time, and inputs and outputs can change. In some cases, a particular policy may not be feasible immediately because of a lack of resources or other institutional barriers, but those barriers may reflect past or present injustices that need to be remedied. Thus, for example, a feasibility assessment can guide policy makers to allocate additional resources when exposure biomonitoring or follow-up services are likely to have benefits or are needed to promote a just health care system. Therefore, the principle of feasibility needs to be considered alongside the principle of justice so it can guide future investments and institutional changes instead of detracting from efforts to address inequities and promote just outcomes. Unfortunately, the lack of a coordinated health system in the United States complicates any assessment of feasibility that goes beyond the requirements imposed on public health agencies. Individuals must rely on insurance or self-pay for many follow-up services, and access to high-quality primary care and specialty care services can be fraught with challenges.

Adaptability

The fifth and final principle is adaptability:

> **Adaptability:** Decisions should respond to new information about harms, benefits, and other relevant considerations (e.g., health equity and feasibility).

The National Academies evidence framework for decisions regarding genetic testing (NASEM, 2017) emphasizes that adaptability is important in decision contexts in which scientific information changes rapidly, as is the case with genetic testing. The USPSTF also emphasizes that its evaluation of the benefits and harms of preventive services is a process that needs to be revisited in light of new advances in research, testing, and treatment capabilities (Sawaya et al., 2007). This responsiveness to new information is especially important in situations of substantial scientific uncertainty, such as the decision

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

context surrounding PFAS. In such situations, it is often necessary to develop plans for acting even without decisive information about what course of action is best, and the harms associated with failing to act when warranted can often be more severe than the harms associated with taking actions that ultimately turn out to be unwarranted. When actions are taken without compelling information, however, it is crucial to reexamine regularly the state of the evidence and the consequences of the actions taken to reassess the best course of action. The adaptive management movement in environmental policy exemplifies this commitment to an ongoing process of learning and reevaluation. According to a National Research Council report on managing water resources, "Adaptive management promotes flexible decision-making that can be adjusted in the face of uncertainties as endpoints from management actions and other events become better understood" (NRC, 2004, pp. 1–2).

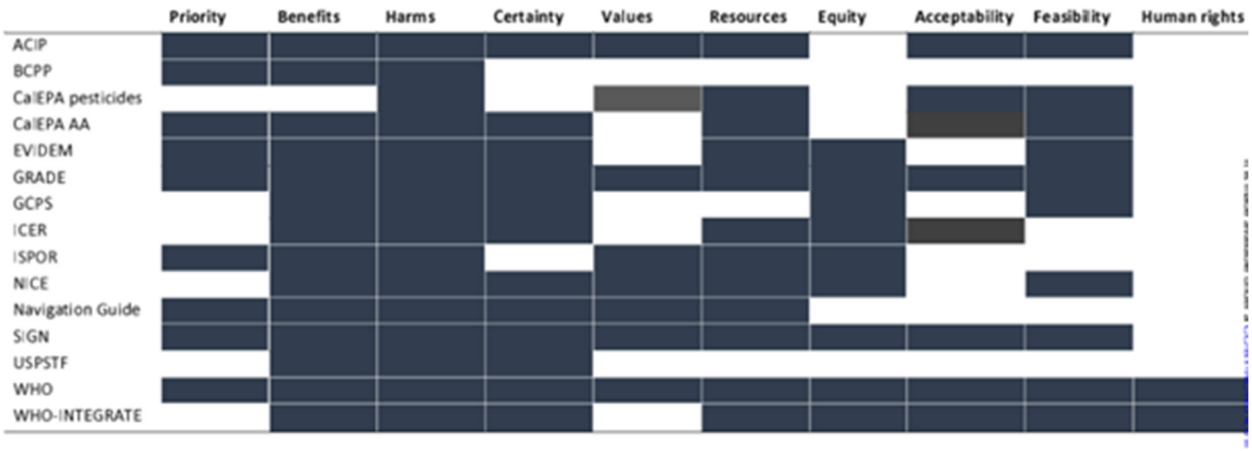
COMMITTEE'S CONSIDERATIONS IN DEVELOPING ITS PRINCIPLES

Among the committee's considerations in developing its principles for decision making under substantial scientific uncertainty were input from contaminated communities and a number of previously published evidence-to-decision frameworks.

Community Input from Town Halls

During its three town halls, the committee obtained perspectives from people living in or working with communities with PFAS contamination during its three Town Halls (see Appendix B). The committee recognizes that the views expressed at the town halls do not necessarily represent the views of all affected communities or all individuals within those communities; nonetheless, they provided input for the committee to consider. Important themes relevant to the development of principles for decision making under substantial scientific uncertainty included the following:

- Community members shared that they had to educate their clinicians about the exposures in their communities and the potential health effects that could result. They stated further that clinicians do not know how to provide advice on patient follow-up following PFAS exposure, whether PFAS exposure biomonitoring should be provided, or how to interpret PFAS exposure biomonitoring results if shared by the patient.
- Community members expressed the view that PFAS exposure biomonitoring should be available through traditional clinical care to all individuals. In addition, given that PFAS are ubiquitous in the environment and that many of the contamination sites have not been identified, exposure biomonitoring should be more widely available.
- Significant harms were not associated with exposure biomonitoring for PFAS. Community members understand that PFAS exposure biomonitoring may not directly inform their health, but they wish to have knowledge of their exposure levels as a first step.
- Speakers stated that PFAS exposure information could inform health care decisions and patient follow-up related to potential adverse health effects associated with PFAS exposure.



Evidence-to-Decision Frameworks Considered by the Committee

Norris and colleagues recently conducted a review of evidence-to-decision frameworks to inform the development of a new framework for recommending interventions to prevent or mitigate the harmful effects of adverse environmental exposures (Norris et al., 2021). The authors reviewed 18 frameworks and compared the criteria they used to justify decisions. Those criteria included the priority of the problem and several considerations related to benefits and harms, including desirable effects, undesirable effects, the certainty of evidence regarding desirable and undesirable effects, and the balance of effects. Other criteria included values, resources, equity, acceptability, feasibility, and human rights. Briefly, the frameworks reviewed by Norris and colleagues are summarized in Table 2-1.

GRADE (Grading of Recommendations Assessment, Development, and Evaluations)

GRADE has become the dominant evidence-to-decision framework over the past 15 years, including for clinical decision making and public health (Guyatt et al., 2008; Moberg et al., 2018; Norris et al., 2021). It includes evidence frameworks for several different decision contexts including clinical recommendations, individual perspective; clinical recommendations, population perspective; coverage decisions; and health system and public health recommendations or decisions. According to Norris and colleagues (2021), all applications of GRADE include roughly the same considerations:

- Is the problem a priority?
- How substantial are the desirable anticipated effects?
- How substantial are the undesirable anticipated effects?
- What is the overall certainty of the evidence of effects?
- Does the balance between desirable and undesirable effects favor the intervention or the comparison?
- Is there important uncertainty about, or variability in, how much people value the main outcomes?
- How large are the resource requirements (costs)?
- What is the certainty of the evidence of resource requirements (costs)?
- Does the cost-effectiveness of the intervention (the out-of-pocket cost relative to the net desirable effect) favor the intervention or the comparison?

It is important to recognize that GRADE emphasizes financial considerations, equity, acceptability, and feasibility more for health systems and public health decisions than for individual decisions (Norris et al., 2021).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

U.S. Preventive Services Task Force

The USPSTF is an independent panel of primary care, prevention, and evidence-based medicine experts. It uses an analytic framework (see Figure 2-1) to evaluate systematically the benefits and harms of a particular preventive service. In evaluating evidence concerning the benefits and harms of widespread implementation, both the evidence's certainty and the magnitude of the benefits and harms are assessed. As shown in Table 2-2, the USPSTF assigns a letter grade to each preventive service signifying its recommendation about the service's provision (Sawaya et al., 2007). It is important to note that the USPSTF does not consider cost when determining a letter grade.[2] If evidence is not available, the USPSTF considers the "chain of indirect evidence, including evidence about the accuracy of screening tests, the efficiency and harms of early treatment, and the association between changes in intermediate endpoints due to treatment and changes in health endpoints" (Mabry-Hernandez et al., 2018). As Table 2-2 indicates, when the certainty, based on the evidence, for the net benefit of screening is rated low, the USPSTF considers the evidence insufficient to make a recommendation. The USPSTF views its evaluation of the benefits and harms of a preventive service as a process, and continually revisits and reevaluates based on new advances in research, testing, and treatment capabilities (Sawaya et al., 2007).

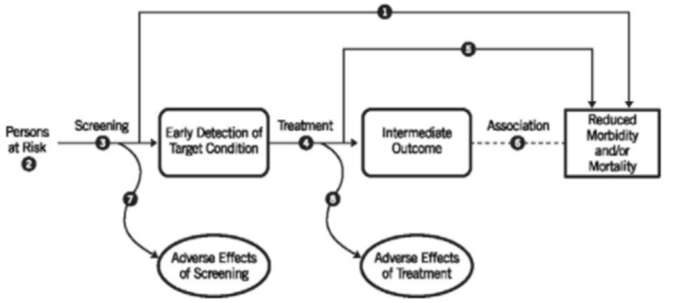

Figure 1. Generic analytic framework for a screening preventive service.

Note: Numbers correspond to the following key questions:

1. Is there evidence that randomizing a cohort of persons to screening or not screening results in greater reduced morbidity and mortality than the observed harms from screening and treatment?
2. Who are the persons at risk for the condition?
3. What are the performance characteristics of the screening test for the condition?
4. Does treatment of the screen detected condition result in improved intermediate outcomes?
5. Does treatment of the screen detected condition result in reduced morbidity and mortality?
6. Does an improvement in intermediate outcomes lead to improved health outcomes?
7. What are the harms associated with screening and diagnostic testing for the condition?
8. What are the harms associated with treatment of the condition?

Evidence and Value: Impact on DEcision-Making (EVIDEM) Framework

Goetghebeur and colleagues (2008) developed this framework to facilitate health care decision making. They conducted an extensive review and analysis of the literature and determined that a framework for addressing the value judgments related to assessing health care interventions should be able to do the following: "1) disentangle intrinsic and extrinsic value components; 2) develop a simple and rigorous system that applies multiple criteria decision analysis (MCDA) from a pragmatic standpoint based on actual thought processes; 3) provide practical access to the evidence on which value judgments are based; and 4) provide a practical method for decision-makers to provide feedback to data producers and all other stakeholders" (Goetghebeur et al., 2008, p. 273). Based on these needs, the authors built the EVIDEM framework, tailored to provide a "comprehensive, transparent structure grounded in global standards and local needs" (Goetghebeur et al., 2008, p. 283). The framework aims to consider all perspectives, values, and rationales related to the decision at hand.

National Academies Evidence Framework for Genetic Testing

In 2017, a National Academies committee developed an evidence framework for genetic testing that calls for a clear definition of the genetic scenario being considered and a triage process for evaluating whether the purpose of a test is worthwhile and an expedited provisional decision can be made (see Figure 2-2). In addition, given the rapidly advancing nature of the field of genetic testing, the framework includes the opportunity for review and revisions (NASEM, 2017).

C-8 Medical Panel

In February 2005, the West Virginia Circuit Court approved a class action settlement agreement in a lawsuit resulting from contamination of drinking water with perfluorooctanoic acid (PFOA, also known as C-8) from DuPont's Washington Works facility in Wood County, West Virginia (see Box 1-2 in Chapter 1). The agreement included establishing a science panel that conducted epidemiologic evaluations to determine probable link conditions associated with exposure to PFOA, and a separate medical panel that defined medical monitoring for members of the class (C-8 Medical Panel, 2013). The settlement agreement stated that the medical panel needed to consider the following factors in developing the medical monitoring protocol:

1. Increased risk … that the Class Member has a significantly increased risk of contracting the particular diseases relative to the risk in the absence of exposure;
2. Necessity of Diagnostic Testing … that the Class Member should undergo specific periodic diagnostic testing that would not be required in the absence of exposure to

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

C-8. The Settlement further specified that the desires of Class Members for reassurance that they did not have a probable link condition was a sufficient rationale for testing, and factors such as financial cost and the frequency of testing need not be given significant weight in assessing the need for testing; and

3. Existence of Monitoring Procedures … that testing procedures must exist that it is not necessary to show that detection and treatment in a pre-symptomatic state reduces the burden of the probable link condition. (C-8 Medical Panel, 2013, p. 1)

Belmont Report

The Belmont Report (HHS, 1979) was developed as a set of guidelines for protecting research participants. This seminal report on ethics and health care research outlines basic ethical principles and guidelines meant to assist in resolving ethical problems surrounding the conduct of research with human subjects. The three main principles are respect for persons, beneficence, and justice.

- *Respect for persons* requires that people be considered autonomous. Autonomous individuals can consider their personal goals and make their own decisions. To respect persons is to give weight to their opinions and choices while refraining from obstructing their actions or choices unless detrimental to others. Conversely, a lack of respect for persons or autonomous agents is to refuse to accept or validate their judgments, deny them the freedom to act on their judgments, or withhold information necessary to make a judgment.

KD2361

Copyright National Academy of Sciences. All rights reserved.

- *Beneficence* is an obligation to respect individuals and their decisions and protect them from harm. Two general rules guide the committee's understanding of beneficence: (1) do no harm, and (2) maximize possible benefits and minimize harms. The Hippocratic Oath requires physicians to make medical recommendations and decisions that benefit their patients "according to their best judgment." The committee recognizes that zero harm or risk may not be possible, but medical decisions need to consider when the benefits outweigh the risks.
- *Justice* refers to "fairness in distribution." In the present context, it means that PFAS research should have a fair distribution such that a certain group of people is not selected for the research to the exclusion of others. An injustice occurs when some individuals benefit from the research or intervention or are denied that benefit without good, ethical reason.

Beauchamp and Childress (2001) have developed these principles further in the established textbook *Principles of Biomedical Ethics* to guide biomedical decision making beyond the context of research ethics. For example, these authors refer to respect for autonomy instead of respect for persons and divide the principle of beneficence into nonmaleficence (avoiding harm) and beneficence (providing benefits).

Precautionary Reasoning

An extensive body of scholarship in medical and environmental decision making is devoted to precautionary reasoning and the precautionary principle. This work can inform decision making under substantial scientific uncertainty. Resnik (2021) proposes four criteria for assessing the reasonableness of precautionary measures, as shown in Table 2-3.

CONCLUSION

Building on the work of other experts and evidence-to-decision frameworks, the committee developed five principles to guide decision making under uncertainty for use throughout this report: proportionality, justice, autonomy, feasibility, and adaptability. The principles of proportionality, justice, and autonomy build on the ethical principles outlined in the Belmont Report (HHS, 1979) and developed further by Beauchamp and Childress (2001). These principles affirm that decision making in response to PFAS should weigh plausible benefits and harms proportionally while treating all individuals fairly, promoting health equity, respecting human rights, and supporting informed decision making by individuals in accordance with their values. The principles of feasibility and adaptability affirm that decisions should be responsive to emerging information about harms, benefits, and other considerations.

TABLE 2-3 Criteria for Reasonableness of Precautionary Measures

Proportionality	Reasonable measures balance plausible risks and possible benefits proportionally
Fairness	Reasonable measures are based on a fair balancing of risks and benefits; fairness includes distributive and procedural fairness
Epistemic Responsibility	Reasonable measures comply with norms for the responsible acquisition and utilization of evidence, knowledge, and expertise
Consistency	Reasonable measures are based on a consistent rationale for decision making

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

In the clinical setting, the committee's five principles converge under the principle of autonomy and shared decision making[3] between patient and clinician. For this reason, shared decision making is likely to be the practical way a clinician can incorporate the principles into the clinical encounter.

The committee's principles may provide a framework that ATSDR can use when writing clinical guidance for environmental exposures. Despite findings of associations between adverse health effects and chemical exposures, substantial scientific uncertainty exists about the causal role of environmental chemicals in many health outcomes. Regulatory agencies, public health agencies, and clinicians need to make thoughtful decisions about how to act in response to this uncertainty. The principles of proportionality, justice (particularly environmental justice), autonomy, feasibility, and adaptability can play a central role in these decisions.

Potential Health Effects of PFAS

This chapter summarizes results of the committee's review of the potential health effects of per- and polyfluoroalkyl substances (PFAS) in response to the following element of the committee's Statement of Task: "to establish a basis for prioritized clinical surveillance or monitoring of PFAS health effects." The aim of this review was to identify a set of health effects that may be associated with PFAS to support preventive medicine recommendations and decisions. Based on the review, the committee developed strength-of-evidence conclusions for the various health effects associated with PFAS.

The committee's Statement of Task limited this review to those PFAS included in the Center for Disease Control and Prevention's (CDC's) *National Report on Human Exposure to Environmental Chemicals* (see Table 3-1). The PFAS in Table 3-1 are those most commonly studied in epidemiological research, although other PFAS may also cause harm given some similarities with those in Table 3-1 with respect to biological persistence and toxicities (Kwiatkowski et al., 2020). It is important to note as well that while different PFAS have distinct physical, chemical, and toxicological properties, people are exposed to more than a single PFAS. As a result, exposures are often to mixtures of PFAS such that specific effects are difficult to disentangle. Considering these issues, and recognizing that some PFAS are less frequently measured, the committee ultimately decided to provide one strength-of-evidence determination for all PFAS for each health effect.

The Statement of Task did not limit the health effects included in the committee's review. Speakers at the committee's town halls described a variety of health effects of concern that they had observed in their communities and that may be associated with PFAS exposure. Cancers, endocrine effects, immune function, and fertility were the most frequently mentioned health effects (see Table 3-2). The committee considered this input to be valuable and paid special attention to the health effects of concern observed in communities when describing the evidence.

TABLE 3-1 PFAS Species Currently Included in the Centers for Disease Control and Prevention's (CDC's) *National Report on Human Exposure to Environmental Chemicals*

Abbreviated Name	Full Name	CAS Registry No.
MeFOSAA	Methylperfluorooctane sulfonamidoacetic acid	2355-31-9
PFHxS	Perfluorohexanesulfonic acid perfluorohexane sulfonic acid	355-46-4
n-PFOA (linear isomer), Sb-PFOA (branched isomers)	Perfluorooctanoic acid	335-67-1*
PFDA	Perfluorodecanoic acid	335-76-2
PFUnDA	Perfluoroundecanoic acid	2058-94-8
n-PFOS (linear isomer), Sm-PFOS (branched isomers)	Perfluorooctanesulfonic acid	1763-23-1*
PFNA	Perfluorononanoic acid	375-95-1

NOTES: CAS = Chemical Abstracts Service. * = CAS number refers to linear isomer only. Previous survey years have also included perfluorobutane sulfonic acid (PFBS), perfluoropentanoic acid (PFpA), perfluorododecanoic acid (PFDoDA), perfluorooctane sulfonamide (FOSA), and 2-(N-ethyl-perfluorooctane sulfonamido)acetate (EtFOSAA), according to Patrick N. Breysse's presentation to the committee on February 4, 2021.

TABLE 3-2 Categories of Health Effects Mentioned by Speakers at the Committee's Town Halls

Health Effect Category	No. of Speakers Mentioned
Cancers, including bladder, urinary tract, liver, breast, testicular, thyroid, bone, kidney, pancreatic, and ovarian, as well as melanoma, leukemia, multiple myeloma, and lymphoma	16
Disruption of the endocrine system, including impaired thyroid and disease	10
Impaired immune function	9
Fertility and reproductive issues, including menstruation and lactation concerns	9
Diabetes, other metabolic concerns, and obesity	8
Liver disease and impairment, including nonalcoholic fatty liver disease	7
Disease and impairment of the digestive system, including ulcerative colitis, gallbladder dysfunction, irritable bowel syndrome, and other colon impairment	6
High cholesterol	6
Autoimmune disease	5
Birth defects	5
Developmental and neurological impacts, including learning disorders and autism	5
High blood pressure, gestational hypertension, and preeclampsia	5
Asthma, pulmonary disease, and cardiovascular disease	5
Premature and underweight births	4
Skin rashes, hair loss, and other skin concerns	3
Chronic inflammation and allergic reactions	3
Arthritis, osteoporosis, and other impacts to the skeletal system	2
Multiple sclerosis	1

OVERVIEW OF EVIDENCE REVIEW APPROACH

Appendix D provides full details of the methods used for the committee's review. Briefly, the committee aimed to build upon existing decisions from other authoritative bodies. The focus was on more recent studies, both high-quality systematic reviews and published epidemiologic research articles, which could inform updates to authoritative conclusions regarding PFAS exposure and any human health effects. The review approach improved efficiency while minimizing the risk of excluding scientific findings that could inform the committee's recommendations.

Consideration of Authoritative Reviews

The committee focused on authoritative reviews produced by government agencies or other bodies that publish strength-of-evidence determinations through a process that includes peer review. As detailed in Appendix D, the committee focused on the findings from the following organizations, presented in chronological order by year the literature search was completed:

- C-8 Science Panel reports (last report published 2012)
- European Food Safety Authority (EFSA) (search complete: 2013)
- Organisation for Economic Co-operation and Development (OECD) (published 2013)

KD2367

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- International Agency for Research on Cancer (IARC) (search complete: 2014)
- U.S. Environmental Protection Agency (EPA) (search complete: 2015)
- National Toxicology Program (NTP) (search complete: 2016)
- Agency for Toxic Substances and Disease Registry (ATSDR) (search complete: 2018)

Among the authoritative reviews, ATSDR's *Toxicological Profile for Perfluoroalkyls* included the greatest number of PFAS that were included in the committee's Statement of Task (Methylperfluorooctane sulfonamidoacetic acid [MeFOSAA] was not included), was the most recent (literature search completed in September 2018), and was not limited in terms of health effects covered (ATSDR, 2021). Therefore, the committee used this source as the primary basis for the next stages of the review process.

The committee did not formally critique the quality of the any authoritative reviews, as each authoritative body has its own procedures for public comment and peer review to ensure that biases are limited in its reviews. Nonetheless, the committee noted several areas in which ATSDR's *Toxicological Profile for Perfluoroalkyls* could be strengthened. First, the toxicological profile does not provide a detailed description of the evidence identification methods or document its reasons for excluding specific studies. Second, the study quality assessment does not appear to follow a standard approach, and in some cases, it is difficult to identify the study designs that were included in the review. Third, the process for assessing the strength of the evidence is not well described. Despite these limitations, however, the committee concluded that the ATSDR review provided a basis for assessing evidence of association between PFAS and health effects.

Review of Systematic Reviews

As detailed in Appendix D, the committee's review of systematic reviews consisted of the following steps: a literature search, screening of abstracts, a full-text review of studies identified in the abstract screening, and evaluation of a final set of relevant studies. The literature search identified 639 potentially relevant articles, of which 26 systematic reviews met the committee's inclusion criteria and were evaluated using AMSTAR-2 (A MeaSurement Tool to Assess systematic Reviews) (Shea et al., 2017). The committee conducted a critical appraisal of the systematic reviews because such reviews can be subject to a range of biases. All high-quality systematic reviews included studies that were also reviewed in ATSDR's *Toxicological Profile for Perfluoroalkyls*. Thus, the systematic reviews were used as sources for reference in the committee's assessment, but they were not formally included as part of the final strength-of-evidence determination.

Review of Recent Epidemiologic Studies

As detailed in Appendix D, the committee's review of original literature consisted of the following steps: a literature search, screening of abstracts, a full-text review of studies identified in the abstract screening, evaluation of a final set of studies identified as relevant after the full-text review, data abstraction, and an evidence synthesis step.

The literature search identified 5,172 potentially relevant studies. After removal of duplicates (112 articles), 5,060 articles were subject to title and abstract screening by two independent reviewers. After 4,434 articles had been excluded because the titles and abstracts did not meet the committee's inclusion criteria, 626 articles were subjected to full-text review, during which additional articles were excluded if they had been published before 2018 or were listed among the references in ATSDR's *Toxicological Profile for Perfluoroalkyls* (n = 320); were cross-sectional in design (n = 160); were not published in English (n = 1); did not provide risk estimates associated with PFAS exposure (n = 3); or documented studies not conducted in humans (n = 3). Cross-sectional studies were excluded largely because this study design measures exposure and disease at the same time, and so cannot determine cause

KD2368

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

and effect. The remaining 139 articles were categorized according to the human health outcomes studied, as shown in Figure 3-1.

The committee's review of the recent literature focused mainly on those health effect categories for which additional evidence might have changed the committee's understanding of the association between PFAS exposure and health outcomes. The committee formally evaluated the individual studies for internal validity or "risk of bias," using a tool adapted from the Navigation Guide of Woodruff and Sutton (2014), assigning to each an overall assessment of its risk of bias (low, probably low, probably high, or high risk of bias). Effect estimates from the individual studies included in the review were extracted into a database and uploaded to a public website (Tableau Public) to allow for visualizations such as evidence maps and forest plots.[1] The effect estimates in the Tableau represent those from the model most adjusted for confounders. Appendix D provides the critical domains used by the committee to assess risk of bias, as well as the data abstraction procedure.

Evidence Synthesis

To assess the strength of evidence regarding the potential for PFAS to cause a particular health effect, the committee integrated the evidence reviewed in ATSDR's *Toxicological Profile for Perfluoroalkyls* with the evidence from its review of the original epidemiologic studies. A framework based on the Hill considerations, which help determine whether associations are causal, guided the synthesis of available evidence (Fedak et al., 2015; Hill, 1965; NASEM, 2018a). The committee considered the animal studies discussed in ATSDR's *Toxicological Profile for Perfluoroalkyls* and in the systematic reviews examined by the committee in making its determinations, as an aid to interpretation of the human studies. Toxicologic evidence, whether it supports or conflicts with evidence from epidemiologic studies, provides insights about biologic processes and informs how an observed association might be interpreted (NASEM, 2018a).

The committee's strength-of-evidence conclusions reflect one of the four categories described below (see Figure 3-2).

Sufficient Evidence of an Association

For effects in this category, a positive association between PFAS and the outcome must be observed in studies in which chance, bias, and confounding can be ruled out with reasonable confidence. For example, the committee might regard as sufficient evidence of an association evidence from several small studies that is unlikely to be due to confounding or to otherwise be biased and that shows an association that is consistent in magnitude and direction. Experimental data supporting biologic plausibility strengthen the evidence of an association but are not a prerequisite, nor are they sufficient to establish an association without corresponding epidemiologic findings.

Limited or Suggestive Evidence of an Association

In this category, the evidence must suggest an association between exposure to PFAS and the outcome in studies of humans, but the evidence can be limited by an inability to rule out chance, bias, or confounding with confidence. One high-quality study may indicate a positive association, but the results of other studies of lower quality may be inconsistent.

[1] The committee's public Tableau can be accessed at the following link: https://public.tableau.com/app/profile/nationalacademies/viz/NASEMPFASEvidenceMaps/PFASEvidenceMap. The information may be viewed as an evidence map or as a forest plot. Within forest plots, filters can be accessed using the "toggle filters" function in order to restrict the view to data on specific health effect categories and other factors (reference, chemical, study design, study population, etc.).

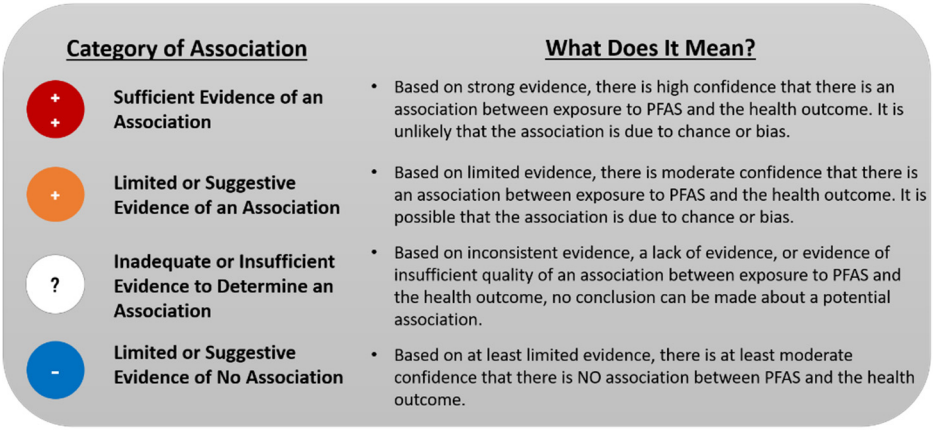

FIGURE 3-2 Categories of association used in this report.
NOTES: The categories of association only describe how strong the evidence is between PFAS and the health outcome. The risk of developing an outcome from exposure to PFAS for things in the same category can vastly differ and are dependent on whether an individual has other risk factors for developing the outcome.

Inadequate or Insufficient Evidence to Determine an Association

If there was not enough reliable scientific data to categorize the potential association with a health effect as "sufficient evidence of an association," "limited or suggestive evidence of an association," or on the other end of the spectrum, "limited or suggestive evidence of no association," the health outcome was placed in the category of "inadequate or insufficient evidence to determine an association" by default. In this category, the available human studies may have inconsistent findings or be of insufficient quality, validity, consistency, or statistical power to support a conclusion regarding the presence of an association. Such studies may have failed to control for confounding factors or may have had inadequate assessment of exposure.

Limited or Suggestive Evidence of No Association

A conclusion of "no association" is inevitably limited to the conditions, exposures, and observation periods covered by the available studies, and the possibility of a small increase in risk related to the magnitude of exposure studied can never be excluded. However, a change in classification from inadequate or insufficient evidence of an association to limited or suggestive evidence of *no* association would require new studies that corrected for the methodologic problems of previous studies and that had samples large enough to limit the possible study results attributable to chance.

COMMITTEE'S CONCLUSIONS

Annex Table 3-1 at the end of the chapter summarizes the health outcomes considered by the committee, the relevant conclusions from authoritative reviews, and the committee's overall conclusions for endpoints relevant to each outcome. The committee's conclusions reflect its integration of evidence reviewed in ATSDR's *Toxicological Profile for Perfluoroalkyls* and other authoritative reviews with the evidence garnered from the review of recent epidemiologic studies.

The committee found *sufficient* evidence of an association for the following diseases and health outcomes:

- decreased antibody response (in adults and children),
- dyslipidemia (in adults and children),

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- decreased infant and fetal growth, and
- increased risk of kidney cancer (in adults).

The committee found *limited* or *suggestive* evidence of an association for the following diseases and health outcomes:

- increased risk of breast cancer (in adults),
- liver enzyme alterations (in adults and children),
- increased risk of pregnancy-induced hypertension (gestational hypertension and preeclampsia),
- increased risk of testicular cancer (in adults),
- increased risk of thyroid disease and dysfunction (in adults), and
- increased risk of ulcerative colitis (in adults).

For a range of other health effects, the evidence was *inadequate* or *insufficient*. These include type 1 and gestational diabetes; cardiovascular disease; metabolic syndrome; obesity; infertility; male and female reproductive effects; reproductive hormone levels; and cancers other than kidney, breast, and testicular.

The committee's rationale for these conclusions is provided in the sections that follow, organized by human health outcomes. For effects with *limited* or *sufficient* evidence, the range of effect size estimates considered by the committee is indicated. Additional information, including an evidence map of recent studies, information about the quality of individual studies, and forest plots showing effect size estimates in a searchable format, can also be accessed from the committee's public Tableau.

With one exception (decreased infant and fetal growth), the committee provided forest plots for all outcomes with *sufficient* evidence of an association to display effect estimates from the studies with low or probably low risk of bias. Specifically, forest plots based on the data in the Tableau are displayed in this chapter for the following outcomes: changes in antibody response (a measure of immune function), total cholesterol (a marker of dyslipidemia), and hypertensive disorders of pregnancy. For these outcomes, the committee chose to display the effect estimate that was the most common across studies if more than one was available in the Tableau. For cancer, forest plots were created based on studies included in ATSDR's *Toxicological Profile and Polyfluoroalkyls* and the more recent epidemiologic studies. The committee handled cancer in this way because it was upgrading the previously observed association between PFAS and kidney cancer and drawing a new conclusion on breast cancer. Each cancer figure displays the PFAS with the strongest effect. For birthweight, there were many studies with probably or definitely low risk of bias, and those with definitely low risk of bias are displayed in a table rather than a forest plot. In addition to the outcomes with *sufficient* evidence of an association, one outcome with *limited* or *suggestive* evidence, hypertensive disorders of pregnancy, is displayed in a forest plot. This was an important outcome category to speakers at the committee's town halls.

SUMMARY AND RATIONALE FOR THE COMMITTEE'S CONCLUSIONS BY HUMAN HEALTH OUTCOMES

Immune System Effects

The committee's evaluation of the impact of PFAS on immune function considered evidence relevant to the three basic functions of the immune system: response to infection, response to foreign substances (allergy), and response to self (autoimmunity). The committee found *sufficient* evidence for an association of PFAS exposure with decreased antibody response to vaccination or infection, and *limited* or *suggestive* evidence of an association with ulcerative colitis (relevant to autoimmunity). There was *inadequate* evidence for other immune system endpoints, including infectious disease (response to infection) and response to allergens.

KD2372

Copyright National Academy of Sciences. All rights reserved.

Response to Infection

ATSDR concluded that there is suggestive evidence for an association between serum levels of perfluorooctanoic acid (PFOA), perfluorooctanesulfonic acid (PFOS), perfluorohexanesulfonic acid (PFHxS), and perfluorodecanoic acid (PFDA) and decreased antibody response to vaccines, and limited evidence of an association for perfluorononanoic acid (PFNA), perfluoroundecanoic acid (PFUnDA), and perfluorododecanoic acid (PFDoDA). Other authoritative reviews (including those of EFSA, EPA, NTP, and OECD) also found associations between PFAS and decreased antibody response to vaccines. Three more recent papers focus on antibody response early in life. Huang and colleagues (2020) conducted a study, with probably low risk of bias, which found that immunoglobulin G (IgG) levels were slightly lower among children with higher PFAS serum levels. The regression coefficient per 1-log10 nanograms per milliliter (ng /mL) increase in PFAS ranged from −0.04 (95% confidence interval [CI]: −0.11–0.04) for PFHxS to 0.00 for PFUnDA (95% CI: −0.06–0.05) (see Figure 3-3). In another study with probably low risk of bias, Timmermann and colleagues (2020) evaluated measles antibodies at three time points: before first vaccination (measuring antibodies passed from the mother) and after first and second vaccination; for most PFAS, no strong associations with antibody levels were found. For PFOS, there was an inverse association between PFAS levels in blood and antibody levels before first vaccination in boys (see Figure 3-4). In a study of bias of antibodies to hand, foot, and mouth disease (CA 16 and EV71 antibody), with probably high risk of bias, Zeng and colleagues (2019) observed that 3-month-old infants with higher PFAS cord blood levels were two to four times more likely to have levels of antibodies to hand, foot, and mouth disease that were below the clinically protective level (see Figure 3-5). This finding suggests that higher PFAS blood levels may contribute to lower antibody levels over time. Taken together, these three recent studies add support for the conclusion of *sufficient* evidence of an association between PFAS exposure and decreased antibody response.

The committee reviewed four papers focused on specific infectious diseases (chicken pox, common cold, otitis media, pneumonia, and respiratory tract infection) in children (Ait Bamai et al., 2020; Huang et al., 2020; Kvalem et al., 2020; Manzano-Salgado et al., 2019). All four studies were rated as having a probably low risk of bias; however, three of the studies used parental reports of infection to ascertain outcomes, which could result in information bias, leading in turn to null findings. The fourth study, by Huang and colleagues (2020), collected data on infections from medical records. These four studies did not provide strong evidence of an association of PFAS with these common illnesses, although there was some suggestion that for children without siblings, PFAS may be associated with respiratory syncytial virus (Ait Bamai et al., 2020). There was no evidence for fever among children with higher PFAS blood levels (Timmermann et al., 2020). The committee concluded there is *inadequate* or *insufficient* evidence of an association between PFAS exposure and risk of infection, although this is an area worthy of future research, including the relationship of PFAS to novel infections such as SARS-CoV-2 (see Box 3-1).

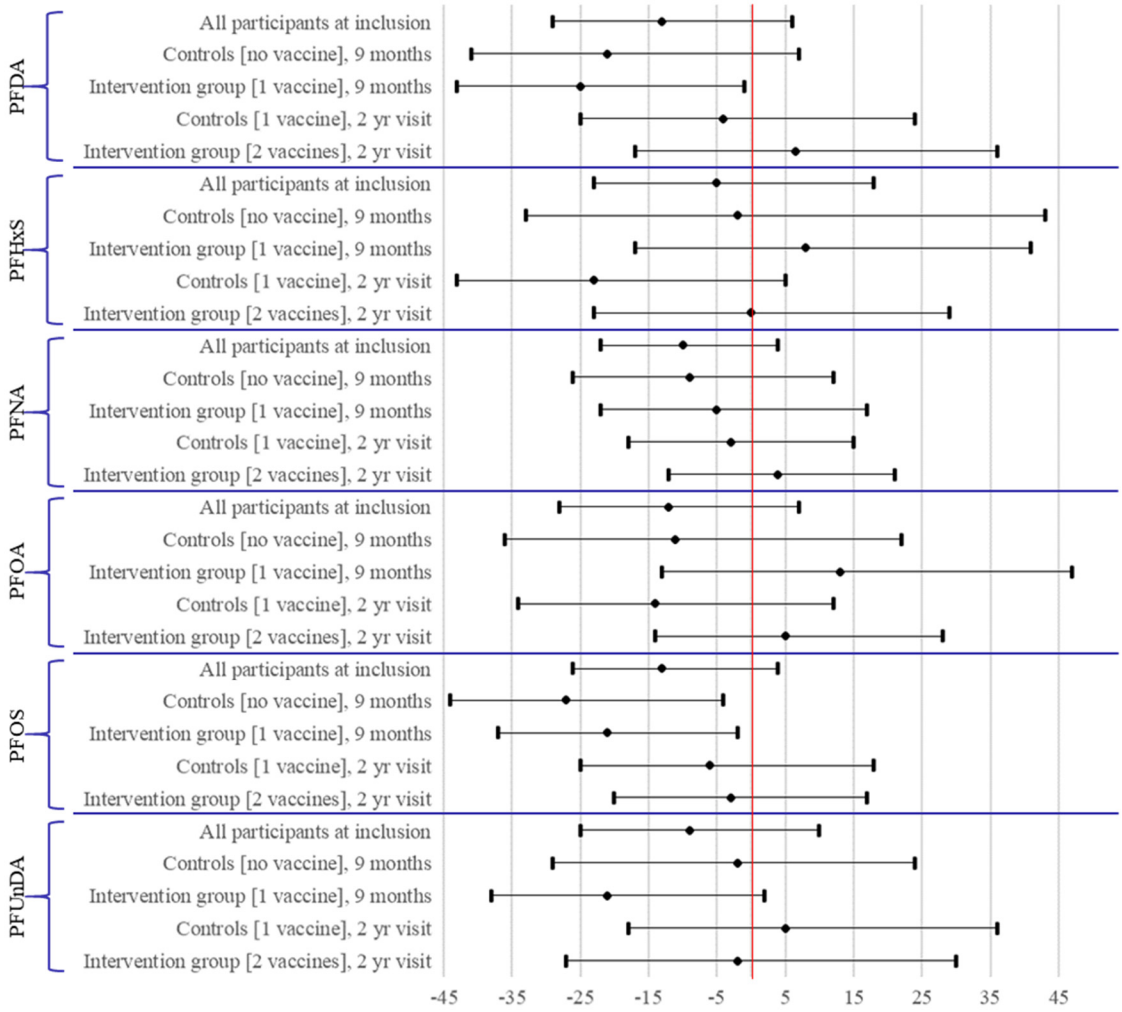

FIGURE 3-4 Regression coefficients for percent difference in measles antibody response per doubling of log10 nanograms per milliliter (ng /mL) serum PFOS.
DATA SOURCE: Timmerman et al., 2020.

Response to Foreign Substances (Allergy)

The committee reviewed several studies evaluating the impact of PFAS exposure on allergic symptoms and disease, all with a probably low risk of bias. The specific outcomes studied included allergies to food and inhaled substances, atopic dermatitis, dermatitis, changes in serum immunoglobulin E (IgE) levels, rhinitis, rhinoconjunctivitis, and results of skin prick tests. Six studies (Ait Bamai et al., 2020; Chen et al., 2018; Huang et al., 2020; Impinen et al., 2019; Kvalem et al., 2020; Wen et al., 2019) evaluated some aspect of allergic response, with most not providing strong evidence of an association with PFAS. The one exception is the study by Wen and colleagues (2019), which showed increased atopic dermatitis among those in the highest tertile of PFOA levels, but not for other PFAS. One study included in ATSDR's *Toxicological Profile for Perfluoroalkyls* found that PFAS exposure was associated with increased odds of asthma diagnosis among children at ages 5 and 13, but only those children who had not received measles, mumps, and rubella vaccination (Timmerman et al., 2020). Overall, the evidence for an association between PFAS and allergy response is *inadequate* or *insufficient*, a finding consistent with the authoritative review by EFSA.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

BOX 3-1
PFAS Exposure and Risk of SARS-CoV-2 Infection

SARS-CoV-2 is a novel virus with low immunity worldwide prior to the pandemic, which provides an opportunity to evaluate the impact of PFAS exposure on response to infection.

What types of studies have been conducted? Available studies evaluate SARS-CoV-2 infection, severity, and mortality.

What have the results shown?

- *Studies on SARS-CoV-2 infection*. The results of two studies show a slightly increased risk of SARS-CoV-2 infection associated with PFAS exposure, but the designs of both preclude drawing causal conclusions. One study, conducted in China, used a case-control format to compare PFAS levels in urine in cases of SARS-CoV-2 infection versus noninfected controls. PFOS, PFOA, and total PFAS levels in urine were higher in those with infection than those without. The observed odds ratios, adjusted for age, sex, body mass index (BMI), comorbidities, and urine albumin-to-creatinine ratio, were 1.94 (95% confidence interval [CI]: 1.39–2.96) for PFOS, 2.73 (95% CI: 1.71–4.55) for PFOA, and 2.82 (95% CI: 1.97–3.51) for the sum of 12 PFAS (Ji et al., 2021). Another study, of ecologic design, calculated sex- and age-standardized incidence ratios (SIRs) for SARS-CoV-2 infection among adults in the Ronneby, Sweden, area, where drinking water was highly contaminated with PFAS, and in a neighboring reference town with similar demographic characteristics but background levels of PFAS exposure (Nielsen and Jöud, 2021). The authors found a slight, but significant, elevated risk of SARS-CoV-2 infection in the former group (SIR = 1.19; 95% CI: 1.12–1.27).
- *SARS-CoV-2 severity*. The results of one study indicate that PFAS may influence the severity of COVID-19 disease, but the study design does not allow for causal determinations. Researchers in Denmark analyzed plasma samples from 323 people with COVID-19 (Grandjean et al., 2021). The authors observed that perfluorobutanoic acid (PFBA) showed an unadjusted odds ratio of 2.19 (95% CI; 1.39–3.46) for increasing the severity of the disease.
- *Studies on SARS-CoV-2 mortality*. One study showed a slight but not statistically significant increased risk of mortality following SARS-CoV-2 infection among individuals exposed to high levels of PFAS contamination; however, its design does not allow for causal determinations. Investigators compared SARS-CoV-2 infection in a community in Venetto, Italy, where drinking water was highly contaminated with PFAS, and in a similar Italian community without contaminated water, using a Bayesian ecological regression model adjusted for education level and baseline all-cause mortality. They found that the rate ratio for COVID-19 mortality for the area of high exposure versus the area of low exposure was 1.60 (90% CI: 0.94–2.51) (Catelan et al., 2021).

Conclusion: Taken as a whole, the extant research does not allow conclusions to be drawn on whether PFAS exposures may influence COVID-19 infection, severity, and mortality. Given that most of the available studies have been ecological, more evidence is necessary to address this question.

Response to Self (Autoimmunity)

As noted in authoritative reviews by the EPA and OECD, the C-8 Science Panel identified an association between PFAS and ulcerative colitis, a rare autoimmune condition of the gastrointestinal (GI) tract. In a follow-up to that study, Steenland and colleagues (2018) further evaluated the exposure–response relationship between PFAS and ulcerative colitis, examining Crohn's disease as well. They found that ulcerative colitis was positively associated with PFOA but not with other PFAS. The odds ratio for ulcerative colitis per 1 unit of log PFOA was 1.60 (95% CI: 1.14–2.24), but the trend by quintiles was not monotonic (1, 0.84, 40.98, 33.36, 2.86) (Steenland et al., 2018). The only other analysis of the association of PFAS with ulcerative colitis is a 2022 case-control study from the Nurses' Health Study using blood specimens collected between 1989 and 1999 (Lochead et al., 2022), identified after the committee had completed its review. This study did not find an association between ulcerative

KD2376

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

colitis and any PFAS measured; the median concentration of PFOA among the 80 cases was 3.97 ng/mL, higher than the median value of 2.93 ng/mL for the 114 ulcerative colitis cases in the Steenland study. Given the low incidence of ulcerative colitis, it will be difficult to replicate the findings from either of these studies in other populations. The Nurses' Health Study also observed a statistically significant decreased risk of Crohn's disease with PFAS; the Steenland study found no association with Crohn's disease. To assess the relationship between PFAS and inflammatory bowel disease, Xu and colleagues (2020b) measured two proteins (calprotectin and Zonulin) in feces and saw no association with PFAS.

Given the difficulty of evaluating these diseases, future studies are needed to characterize the impact of PFAS on autoimmunity. Although there is more recent inconsistent evidence, it is not strong enough to override the previous conclusion from the C-8 study. Overall, the committee concluded that there is *limited* or *suggestive* evidence of an association of PFAS with ulcerative colitis. The committee did not review studies that considered other autoimmune endpoints.

Cardiometabolic Outcomes

The committee's evaluation of the impact of PFAS on cardiometabolic outcomes considered evidence relevant to four disorders of the three basic functions of the cardiometabolic system: dyslipidemia, high blood pressure or hypertension, metabolic syndrome, and elevated body mass index (BMI) or obesity. The committee did not identify any studies that evaluated the association between PFAS and cardiovascular disease, a group of disorders involving the heart and blood vessels (coronary [ischemic] heart disease, cerebrovascular disease [stroke], peripheral arterial disease, rheumatic heart disease, congenital heart disease, and deep vein thrombosis and pulmonary embolism).[2] The committee concluded that there is *sufficient* evidence of an association of PFAS exposure with dyslipidemia in adults and children. This conclusion builds on those of the authoritative reviews considered by the committee, all of which (including those of ATSDR, EFSA, EPA, OECD, and the C-8 Science Panel) found associations between PFAS and dyslipidemia. The committee concluded that the evidence is *insufficient* for other findings related to cardiovascular risk factors and nonpregnancy clinical cardiovascular diseases. This conclusion is consistent with those of the authoritative reviews, which concluded that there was mixed to limited evidence supporting associations between PFAS and cardiovascular risk factors and diseases other than the four discussed above because of inconsistencies in measurement, differences in study designs and populations, and differences in adjustment for potential confounding factors.

Dyslipidemia

The studies identified by the committee that evaluated dyslipidemia used several types of study designs, including cohort and nested case-control approaches, and the studies encompassed both children and adults. Some of the major challenges to interpretation of their findings were that outcome definitions were inconsistent across studies (total triglycerides, total cholesterol, and low-density lipoprotein [LDL], and high-density lipoprotein [HDL], sometimes measured in a variety of different units). In addition, the study populations included were very broad with respect to age range, sex, and race or ethnicity representation, making it difficult to interpret and generalize the results across studies. In addition, the timing of exposure to PFAS was often unclear, particularly in the studies of adults, in which confounding could be an issue. The study designs and sample sizes varied; there were six cohort studies and one nested case-control study, most of which were rated as having probably low risk of bias. Figures 3-6 and 3-7 display effect estimates from those studies of low or probably low risk of bias that evaluated the impact of PFAS exposure on total cholesterol (the most consistent effect measured across

[2] See https://www.heart.org/en/health-topics/consumer-healthcare/what-is-cardiovascular-disease (accessed June 28, 2022).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

studies) in adults (Donat-Vargas et al., 2019b; Lin et al., 2019; Tian et al., 2021) and children (Mora et al., 2018). The effects documented across studies were heterogenous, possibly because of the timing of the exposures and outcome measurements. Overall, the committee concluded that there is *sufficient* evidence of an association between PFAS and dyslipidemia, as the recent epidemiologic literature provides additional confidence in the conclusions of authoritative reviews regarding this association.

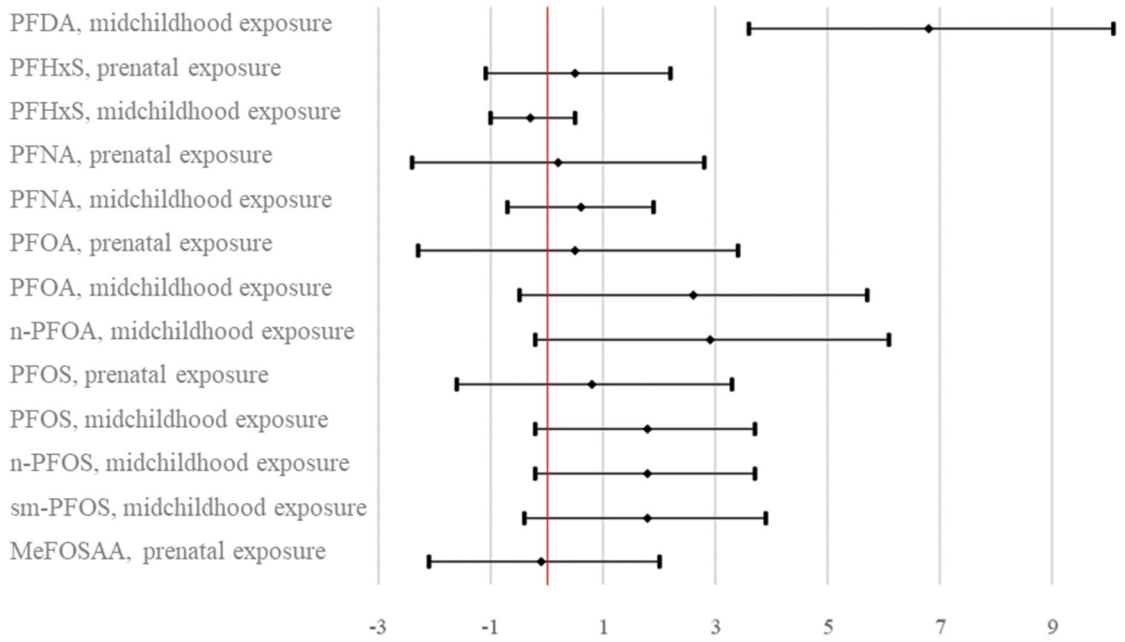

FIGURE 3-7 Regression coefficients for total cholesterol per interquartile range (IQR) increase in PFAS exposure in children.
DATA SOURCE: Mora et al., 2018.

High Blood Pressure or Hypertension

The authoritative reviews do not identify an association between PFAS and high blood pressure or hypertension. The committee identified four studies rated as having probably low or definitely low risk of bias that evaluated the impact of PFAS exposure on hypertension, blood pressure, systolic blood pressure, and diastolic blood pressure (Donat-Vargas et al., 2019b; Lin et al., 2020b; Mitro et al., 2020a). The populations and designs varied greatly across these studies: Donat-Vargus and colleagues (2019b) was a nested case-control study of middle-aged women and men; Lin and colleagues (2020b) was a randomized, controlled clinical trial conducted at 27 clinical centers around the United States from 1996 to 2001; and Mitro and colleagues (2020a) was a cohort study among postpartum females. Donat-Vargus and colleagues (2019b observed that the effect estimates for the impact of exposure to PFAS and hypertension were inconsistent. Lin and colleagues (2020b) observed modest and mostly null associations of plasma PFAS concentrations with high blood pressure and hypertension. Mitro and colleagues (2020a) observed higher systolic blood pressure (e.g., 1.2 mm Hg [95% CI: 0.3, 2.2] per doubling of PFOS) at 3 years postpartum. Given the inconsistency of the evidence, the committee concluded that the evidence is *inadequate* or *insufficient* to determine an association between PFAS and high blood pressure or hypertension.

Metabolic Syndrome

The authoritative reviews do not identify an association between PFAS and metabolic syndrome. Metabolic syndrome is a group of risk factors that increases the risk of heart disease and stroke. Diagnosis requires that an individual have three of the following risk factors: (1) a large waist circumference (males: >102 cm, females: >88 cm); (2) high triglyceride levels (≥1.7 mmol/L); (3) low HDL cholesterol (males <1.04 mmol/L, females <1.30 mmol/L); (4) high blood pressure (≥130 over ≥85 mm Hg); and (5) high fasting glucose levels (≥6.1 mmol/L) (Beilby, 2004). The committee did not identify any new

Copyright National Academy of Sciences. All rights reserved.

epidemiologic studies reporting associations between exposure to PFAS and a diagnosis of metabolic syndrome. The committee concluded that the evidence is *inadequate* or *insufficient* to determine such an association, although the relationship is plausible given the association between PFAS and dyslipidemia.

Elevated Body Mass Index or Obesity

The authoritative reviews do not identify an association between PFAS and elevated BMI or obesity. Epidemiologic studies have assessed associations between exposure to PFAS and anthropometric outcomes because some PFAS may activate peroxisome proliferator-activated receptor (PPAR) gamma, which promotes adipogenesis (Liu et al., 2018; Takacs and Abbott, 2007). Sex differences in obesity, coupled with differences in exposures within certain subpopulations, may place certain groups at increased risk of overweight and obesity (Fenton et al., 2021; Mitro et al., 2020b; Starling et al., 2019). In addition, exposure during certain periods of growth and development may have short- and long-term consequences for overweight and obesity among children and adolescents, with later-life health consequences (Araújo and Ramos, 2017; Fenton et al., 2021; Gross et al., 2020; Hruby and Hu, 2015; Yeung et al., 2019). Co-exposures to psychosocial factors and other chemicals that also promote fat cell development may work synergistically with PFAS chemicals to impact fat growth and development, with impacts on body weight and growth measures (Araújo and Ramos, 2017; Braun et al., 2021; Chen et al., 2019; Fenton et al., 2021; Jensen et al., 2020a; Liu et al., 2018, 2020; Mitro et al., 2020b; Rahman et al., 2019; Romano et al., 2021; Shoaff et al., 2018; Starling et al., 2019, 2020).

The committee identified several studies that evaluated the impact of exposure to PFAS on obesity, four being rated as having a definitely low risk of bias (Braun et al., 2021; Chen et al., 2019; Mitro et al., 2020a,b; Shoaff et al., 2018). These four studies varied greatly in the ages of the populations assessed. Two of the studies used data from the Health Outcomes and Measures of the Environment (HOME) study cohort (Braun et al., 2021; Shoaff et al., 2018), and one was a study of children in Shanghai, China (Chen et al., 2019). The fourth investigated the impact of PFAS exposure on adiposity among postpartum women (Mitro et al., 2020b). The study by Braun and colleagues (2020) (which largely updates Shoaff et al., 2018)—assessed exposure to PFAS (PFOA, PFOS, and PFHxS) at 16 weeks' gestation and delivery, and measured weight and length or height and calculated child BMI at several time points across the life course (4 weeks to 12 years). The authors observed some suggestive evidence of an impact on BMI trajectory (age × PFOA interaction p value = 0.03) for PFOA, but not for PFOS and PFHxS. The study in Shanghai, China, was a prospective birth cohort study that measured 10 PFAS in cord blood plasma and assessed child adiposity measures at 5 years of age. The authors observed no association for the PFAS considered in this review, but did observe that, among girls, perfluorobutane sulfonic acid (PFBS) exposure had a significant positive association with waist circumference and waist-to-height ratio (p values <0.05). Mitro and colleagues (2020b) observed that PFOS and PFOA were associated with greater adiposity at 3 years' postpartum. The heterogeneity of the effects found across studies is the reason the committee concluded that the evidence for an association between PFAS exposure and elevated BMI or obesity is *inadequate* or *insufficient* in adults and children, although this is an area worthy of future study.

Developmental Outcomes

The committee's evaluation of the impact of PFAS on developmental outcomes considered evidence relevant to fetal growth, development of genitalia, and neurodevelopment. The committee concluded that there is *sufficient* evidence of an association between PFAS exposure and reductions in birthweight. This conclusion builds on those of the authoritative reviews (including ATSDR, EFSA, and OECD). ATSDR concluded that the evidence is suggestive of association between serum PFOA and PFOS and small decreases in birthweight. The committee concluded that there is *insufficient* evidence of an association between PFAS exposure and either development of the external genitalia or neurodevelopmental outcomes.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Birthweight

The committee identified numerous studies with low or probably low risk of bias that examined the relationship between exposure to PFAS and birthweight (Buck Louis et al., 2018; Chu et al., 2020; Gao et al., 2019; Kashino et al., 2020; Marks et al., 2019; Wikstrom et al., 2020; Workman et al., 2019). The magnitude and precision of the estimates of the impacts of PFAS exposure on birthweight varied across and within studies, but the direction of the effect was consistent. None of the studies found a statistically significant effect of PFAS exposure on an increase in birthweight. Table 3-3 presents the estimated impact of PFAS on birthweight from the two studies reviewed by the committee that were rated as having low risk of bias. Overall, these studies strengthened conclusions and supported the committee's assessment that there is *sufficient* evidence of an association of PFAS exposure with small reductions in birthweight.

TABLE 3-3 Effect Estimates Change in Birthweight Per Change in PFAS, from Studies Rated as Having Low Risk of Bias[3]

PFAS	Short Citation	Population	Estimated Change in Birthweight (g) (95% CI)	Units
PFOA	Buck Louis et al., 2018	infants	−5.9 (−28.75 to 16.94)[a]	standard deviation (SD) increase in log-PFOA
	Chu et al., 2020	infants	−73.64 (−126.39 to − 20.88)[b]	1 natural logarithm (ln) change in PFOA
		female infants	−56.04 (−129.32 to 17.24)[c]	1 ln change in PFOA
		male infants	−71.8 (−148.61 to 5)[c]	1 ln change in PFOA
PFOS	Chu et al., 2020	infants	−83.28 (−133.2 to − 33.36)[b]	1 ln change in PFOS
		female infants	−71.91 (−143.86 to 0.05)[c]	1 ln change in PFOS
		male infants	−71.52 (−142.44 to − 0.61)[c]	1 ln change in PFOS

[a] Adjusted for maternal age, education, prepregnant body mass index, serum cotinine, infant sex, and a chemical–maternal race/ethnicity interaction term.
[b] Adjusted for gestational age, maternal age, maternal occupation, maternal education, family income, parity, and infant sex.
[c] Adjusted for gestational age, maternal age, maternal occupation, maternal education, family income, and parity.

Development of Genitalia

Authoritative reviews have yet to associate PFAS exposure with the development of genitalia, a possible indicator of reproductive disorders (Bonde et al., 2016). The committee identified one study that evaluated PFAS exposure and hypospadias and cryptorchidism, potential manifestations of testicular dysgenesis syndrome at birth (Anand-Ivell et al., 2018). Two studies (Arbuckle et al., 2020; Tian et al., 2019) evaluated PFAS and measures of anogenital distance (distance from the anus to the penis or scrotum in males or to the clitoris in females).

Anand-Ivell and colleagues (2018) conducted a case-control study within a large national biobank of amniotic fluid samples, which was rated as having a probably high risk of bias due to the high potential for confounding. The study found no influence of PFOS on cryptorchid or hypospadias (comparison of mean PFOS in amniotic fluid: control versus cryptorchid versus hypospadias). Arbuckle and colleagues (2020) conducted a cohort study with probably low risk of bias and reported inconsistent findings regarding PFAS and anogenital distance. Although the authors observed an association between PFOA (measured in first-trimester maternal plasma) and increased anoscrotal distance (adjusted for active smoking status during pregnancy and gestational age), when they examined the data by quartiles, they found no consistent patterns of association, and the effect estimates were imprecise with wide confidence intervals. Tian and colleagues (2019) conducted a cohort study with probably low risk of

[3] This table was altered after release of the pre-publication version of the report to correct data entry errors.

bias to evaluate the impacts of a PFAS on anogenital distance measures. They observed that maternal plasma concentrations (ln-transformed) of PFOS, PFDA, and PFUnDA were inversely associated with anoscrotal distance and anopenile distance measures at birth. For anoscrotal distance, they found per ln unit increase in PFAS concentrations −0.65 (−1.27 to −0.02) mm for PFOS; −0.58 (−1.11 to −0.06) mm for PFDA; and −0.57 (−1.09 to −0.06) mm for PFUnDA. For anopenile distance, they found per ln unit increase in PFAS concentrations −0.63 (−1.24 to −0.01) mm for PFDA and −0.76 (−1.36 to −0.16) mm for PFUnDA. The committee determined that, taken together, the evidence is *inadequate* or *insufficient* to determine an association between PFAS exposure and the development of external genitalia, largely because effects were inconsistent across studies.

Neurodevelopmental Effects

The committee divided the literature on neurodevelopmental effects of PFAS into studies of learning and behavior and of autism spectrum disorder.

Learning and behavior The committee identified 12 studies with low or possibly low risk of bias that examined learning and behavior using psychometrically valid tools to evaluate the impact of PFAS on neurodevelopment in children. The ages of the children varied greatly across studies, as did the timing of the exposure measurement used in the analysis, making it difficult to generalize the findings. For example, Hoyer and colleagues (2018) observed weak effects on child behavior of prenatal exposure to some PFAS. In analysis that combined results from birth cohorts in Greenland and Ukraine, the odds ratio (OR) for hyperactivity was 1.8 (CI: 1.0–3.2) for one nanoliter-unit (nL-unit) increase in prenatal PFNA and 1.7 (CI: 1.0–3.1) for one nL-unit increase in prenatal PFDA exposure. Using the Ages and Stages Questionnaire, Niu and colleagues (2019) found that prenatal plasma concentrations of most PFAS, including PFHxS, PFOS, PFOA, PFNA, and PFDA tended to be associated with an increased risk of developmental problems in personal/social skills, and the associations for PFNA and PFDA were significant (per nL-unit increase). The committee concluded that the evidence is *inadequate* or *insufficient* to determine an association of PFAS exposure with neurodevelopmental effects, largely because of the heterogeneity of both the effects measured and the results observed.

Autism spectrum disorder The committee identified four studies with low or probably low risk of bias evaluating the impacts of PFAS exposure on autism spectrum disorder (Long et al., 2019; Lyall et al., 2018; Oh et al., 2021; Shin et al., 2020). Lyall and colleagues (2018) conducted a population-based, nested case-control study of children born from 2000 to 2003 in southern California and did not observe an association between exposure to PFAS and autism. Long and colleagues (2019) conducted a case-control study that compared exposure to PFAS in amniotic fluid between cases and controls, and observed a negative association between PFAS in amniotic fluid and autism spectrum disorder diagnosis (OR: 0.410; 95% CI: 0.174–0.967). Shin and colleagues (2020) conducted a case-control study of autism spectrum disorder and observed that PFHxS and PFOS were borderline associated with increased odds of child diagnosis of autism spectrum disorder (per ng/mL increase: OR = 1.46; 95% CI: 0.98–2.18 for PFHxS, OR = 1.03; 95% CI: 0.99–1.08 for PFOS). Oh and colleagues (2021) conducted an analysis of the impacts of PFAS exposure on the risk of developing autism spectrum disorder and found that increased PFOA exposures were associated with negative trend Early Learning Composite scores and all four subscales. When they compared trajectories of the scores between low- and high-scoring groups, PFOA was associated with having lower or decreasing Early Learning Composite scores (risk ratio [RR] = 1.49; 95% CI: 1.09–2.03). The committee determined that the evidence is *inadequate* or *insufficient* to determine an association between exposure to PFAS and neurodevelopment, largely because effects were inconsistent across studies.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Cancers

Authoritative reviews have considered the carcinogenic potential of PFAS, and IARC has classified PFOA as possibly carcinogenic to humans (Benbrahim-Tallaa et al., 2014). The committee concluded that there is *sufficient* evidence for an association between PFAS and kidney cancer. This conclusion builds on those of the authoritative reviews (C-8 Science Panel, EPA, ATSDR), which concluded that the evidence for an association between PFAS and cancer in humans is limited, and takes into account robust findings from more recent epidemiological studies. The committee concluded that there is *limited* or *suggestive* evidence for cancers of the testis and breast. The conclusion on testicular cancer is consistent with the authoritative reviews, and the finding on breast cancer is based on the more recent epidemiological studies considered by the committee. The committee found that the existing body of literature on other cancers constituted *inadequate* or *insufficient* evidence to determine an association with PFAS.

Kidney Cancer

The committee's assessment that there is *sufficient* evidence of an association between PFAS exposure and kidney cancer was motivated in large part by the study with low risk of bias conducted by Shearer and colleagues (2021). These investigators conducted a nested case-control study within the Prostate, Lung, Colorectal and Ovarian Cancer Screening Trial with a large sample size, appropriate controls, and validated endpoints (renal cell carcinoma diagnosis [C64.9 in the *International Classification of Diseases for Oncology*, Second Edition]). The statistical analyses conducted by the authors were robust and adjusted for relevant confounders, and sensitivity analysis was performed to assess whether effects were still observed regardless of kidney function. The study clearly showed that ORs for kidney cancer were significantly elevated among individuals in the highest PFOA exposure category, with a strong exposure-response trend. This study and earlier studies (Barry et al., 2013; Vieira et al., 2013) demonstrating a consistency in the direction and magnitude of this effect among those with the highest exposure form a body of literature that the committee concluded constitutes *sufficient* evidence of an association. Effect estimates for associations between PFOA exposure and kidney cancer are summarized by study in Figure 3-8.

Testicular Cancer

The committee's conclusion of *limited* or *suggestive* evidence of an association between PFAS exposure and testicular cancer is consistent with the conclusions of the authoritative reviews. ATSDR does not draw a clear conclusion with respect to PFAS and testicular cancer, but the C-8 Science Panel identified a probable link with incident testicular cancer based on evidence from studies by Barry and colleagues (2013) and Vieira and colleagues (2013). These two studies were also included in the EPA review (2016), which noted the positive associations they found with PFOA and their overlap in cases. IARC (2016) stated that the evidence for an association with testicular cancer was credible and unlikely to be explained by bias and confounding, but limited by small sample numbers. EFSA (2020) found that there was insufficient support for the carcinogenicity of PFOA and PFOS in humans. Given a lack of new studies on this association, the committee found the existing evidence to be supportive of a conclusion of *limited* or *suggestive* evidence of an association between PFAS exposure and testicular cancer (see Figure 3-9).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Breast Cancer

ATSDR did not draw a clear conclusion with respect to PFAS and breast cancer. Studies included in the ATSDR review found inconsistent associations, with Bonefeld-Jørgensen and colleagues (2014) finding an inverse association with PFHxS and null association for PFOS and PFNA, while Wielsøe and colleagues (2017) found positive associations with all these chemicals. Wielsøe and colleagues (2017) also found positive associations between PFDA, PFUnDA, and PFHpA (not statistically significant), and no association for PFDoDA. Bonefeld-Jorgensen and colleagues (2014) found a positive association with FOSA. IARC (2016) also reviewed the null study of Bonefeld-Jorgensen and colleagues (2014), as did EPA (2016), which stated that no associations were found in the general community. Recent studies, however, found more associations suggestive of a relationship between PFAS and breast cancer. A nested case-control study with low risk of bias found an association between estrogen receptor–positive breast cancer and PFOS (Mancini et al., 2020). An additional study with probably low risk of bias found no evidence of associations between PFAS and breast cancer (Cohn et al., 2020). Two additional recent studies had high risk of bias because the exposure was measured after the cancer diagnosis had been made (Hurley et al., 2018; Tsai et al., 2020). Hurley and colleagues (2018) found no evidence of associations between PFAS exposure and breast cancer, whereas Tsai and colleagues (2020) found evidence of associations among women aged ≤50. Those associations were stronger among women with estrogen receptor–positive tumors. Figure 3-10 summarizes the effect estimates for associations between PFOS exposure and breast cancer by study. The committee found that this body of literature constitutes *limited* or *suggestive* evidence of an association of PFAS exposure with breast cancer.

Reproductive Outcomes

In its review of reproductive outcomes, the committee considered evidence on hypertensive disorders of pregnancy, female reproductive effects, reproductive hormone levels, infertility and subfecundity, and gestational diabetes. The committee concluded that there is *limited* or *suggestive* evidence of an association between PFAS exposure and hypertensive disorders of pregnancy, preeclampsia, and gestational hypertension without preeclampsia. This conclusion is consistent with that of the C-8 Science Panel and subsequent authoritative reviews by ATSDR, EPA, and OECD. Consistent with ATSDR, the committee concluded that there is *insufficient* evidence of an association between PFAS exposure and other reproductive outcomes.

Hypertensive Disorders of Pregnancy (Gestational Hypertension and Preeclampsia)

The committee identified five recent studies examining PFAS exposure and preeclampsia, all having probably low risk of bias (see Figures 3-11–3-15). The four cohort studies (Birukov et al., 2021; Borghese et al., 2020; Huang et al., 2019; Wikstrom et al., 2019) supported the conclusions from the authoritative reviews. Wikstrom and colleagues (2019) observed modestly elevated risk for preeclampsia, but not necessarily a consistent exposure-response trend, and Borghese and colleagues (2020) observed no association with gestational hypertension without preeclampsia. Birukov and colleagues (2021) evaluated exposure to PFAS in early pregnancy and maternal blood pressure trajectories in pregnancy, gestational hypertension, and preeclampsia. No clear associations were observed with gestational hypertension (de novo blood pressure >140/90 mm Hg after 20 weeks' gestation on two or more episodes with at least 4 h in between or significant aggravation of preexisting hypertension) or preeclampsia (gestational hypertension with proteinuria [>0.3 g/24 h or at least +1 on sterile urine dipstick]). Birukov and colleagues (2021) did observe modest but not statistically significant increases in blood pressure for PFOS and PFOA. Another cohort study measuring PFAS in cord blood found an association with preeclampsia but not gestational hypertension (Huang et al., 2019).

KD2385

Copyright National Academy of Sciences. All rights reserved.

A case-control study of preeclampsia and PFAS measured in maternal serum categorized PFAS into quartiles; the women in the highest quartiles had no significant increased risks of developing preeclampsia compared with the women in the lowest quartile in adjusted analyses (Rylander et al., 2020). Given that the studies showed a tendency toward an association between PFAS and hypertensive disorders of pregnancy, the committee concluded that there is *limited* or *suggestive* evidence of an association.

Fertility and Fecundity

A conclusion in ATSDR's *Toxicological Profile for Perfluoroalkyls* is that "epidemiological studies provided mixed evidence of impaired fertility (increased risks of longer time to pregnancy and infertility) for PFOA, PFOS, PFHxS PFNA, PFHpA, and PFBS: the results are not consistent across studies or were only based on a single study. The small number of studies evaluating fertility for PFDA, PFUnDA, PFDoDA, and FOSA did not find associations and no study has evaluated reproductive outcomes and PFBA" (ATSDR, 2021, p. 359). The committee identified a few more recent studies to update that authoritative review.

Zhang and colleagues (2018) conducted a case-control study to evaluate the impact of PFAS on risks of premature ovarian insufficiency, and observed positive associations with PFOA, PFOS, and PFHxS (highest versus lowest tertile, PFOA: OR, 3.80; 95% CI: 1.92–7.49; PFOS: OR, 2.81; 95% CI: 1.46–5.41; PFHxS: OR, 6.63; 95% CI: 3.22–13.65). The study was rated as having high risk of bias for a potential for reverse causality (Zhang et al., 2018). Ma and colleagues (2021) conducted a small cohort study in a fertility clinic in Zhejiang, China, that evaluated the association between PFAS exposure and fertility measures (numbers of retrieved oocytes, mature oocytes, two-pronuclei (2 PN) zygotes, good-quality embryos, and semen parameters). The authors found that maternal plasma concentrations of PFOA were negatively associated with the numbers of retrieved oocytes (p-trend 0.023), mature oocytes

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

(p-trend 0.015), 2 PN zygotes (p-trend 0.014), and good-quality embryos (p-trend 0.012). Higher paternal plasma PFOA concentrations were found to be significantly associated with reduced numbers of 2 PN zygotes (p-trend 0.047), but no associations were found between maternal or paternal PFAS levels and the probability of implantation, clinical pregnancy, or live birth. Given the mixed evidence, the committee concluded that there is *insufficient* evidence of an association between PFAS exposure and fertility or fecundity.

Male Reproductive Effects

For its authoritative review, ATSDR looked at articles examining the relationship between PFAS and sperm quality and concluded that while some associations with serum perfluoroalkyl levels were observed for some markers of sperm quality, the markers measured were not consistent across studies. The committee identified only one new study evaluating the effect on PFAS on male reproduction (Ma et al., 2021). This study found no significant association between PFAS and sperm progressive motility rate, but did find associations of some PFAS with decreased sperm concentration. Given that this study has some potential for bias, the committee concluded that the evidence is *inadequate* or *insufficient* to determine an association.

Female Reproductive Effects

Female reproductive effects discussed here include menopause, age at menarche, and duration of breastfeeding. The authoritative reviews did not find associations for other female reproductive outcomes (polycystic ovary syndrome, endometriosis), and the committee identified no new studies of these effects.

In its *Toxicological Profile for Perfluoroalkyls*, ATSDR concludes that there is some suggestive evidence of an association between serum PFAS levels and an increased risk of early menopause; however, this finding may be due to reverse causation since an earlier onset of menopause would result in a decrease in the removal of perfluoroalkyls in menstrual blood. One more recent cohort study (Ding et al., 2020), with low risk of bias, found an association of PFAS with earlier onset of menopause. Mixed results were observed in a study of age at menarche (Ernst et al., 2019) and a study of cycle irregularity (Singer et al., 2018) (rated as probably having and having low risk of bias, respectively).

ATDSR's *Toxicological Profile* does not offer conclusions on the impact of PFAS exposure on duration of breastfeeding. The committee identified one more recent study, with probably low risk of bias, that observed mostly null associations but also a decreased hazard of breastfeeding cessation by 3 and 6 months with increasing maternal serum concentrations of PFNA, PFDA, and PFUnDA during pregnancy (Rosen et al., 2018). The committee concluded that there is *insufficient* human evidence of an association of PFAS with female reproductive effects, including breastfeeding duration.

Reproductive Hormone Levels

ATSDR's *Toxicology Profile* reviews the literature on associations between PFAS concentrations and reproductive hormones. The conclusion of this review is that while some studies examining reproductive hormone levels have observed associations with PFAS, the findings are inconsistent across studies, and there are too few studies to enable interpretation of the results.

The committee found several more recent studies evaluating the relationship between PFAS and reproductive hormone levels, but these studies varied in the populations they included and the hormones measured, among other factors, making it difficult to synthesize the evidence. For example, three studies evaluated the impact of PFAS on estradiol levels (Ma et al., 2021; Yao et al., 2019; Zhang et al., 2018). The study by Ma and colleagues (2021) was conducted among couples visiting a fertility clinic in China; the study by Zhang and colleagues (2018) was a case-control study of adult women in China; and Yao and colleagues (2019) analyzed PFAS and hormone levels in infant cord blood. The studies that measured testosterone were also distinct; two were analyses of data from birth cohorts (Jensen et al., 2020b; Nian et al., 2020); two were studies in pregnant women (Anand-Ivell et al., 2018; Yao et al., 2019); and two were studies in Chinese adults (Ma et al., 2021; Zhang et al., 2018). The committee concluded that the evidence is too heterogeneous to support drawing conclusions and therefore *inadequate* or *insufficient* to determine an association.

Gestational Diabetes

ATSDR's *Toxicology Profile* reviews the evidence for an association between PFAS and gestational diabetes and concludes that the results of the studies reviewed do not suggest an association. The committee identified four more recent studies evaluating the impact of PFAS on gestational diabetes. These studies had varying designs, including case-control, cohort, and nested case-control (Preston et al., 2020a; Rahman et al., 2019; Wang et al., 2018; Xu et al., 2020a) and had somewhat inconsistent results. Xu and colleagues (2020a) and Rahman and colleagues (2019) observed an effect on gestational diabetes, whereas Preston and colleagues (2020a) and Wang and colleagues (2018) observed an effect on glucose homeostasis. Given the inconsistent effects reported, the committee concluded the evidence is *inadequate* or *insufficient* to determine an association.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Endocrine Outcomes

The committee's evaluation of the impact of PFAS on endocrine outcomes considered evidence in the following subcategories: thyroid disease, hyper- and hypothyroidism and thyroid hormones, and diabetes. The committee found *limited* or *suggestive* evidence of an association with thyroid hormones and disease, and *inadequate* evidence for diabetes.

Thyroid Hormones and Disease

The authoritative review of the C-8 Science Panel and subsequent authoritative reviews completed by ATSDR, EPA, and OECD found associations between PFAS exposure and thyroid hormones and disease. Among the more recent cohort studies with probably low or low risk of bias, the majority observed weak to no association with thyroid hormone levels or subclinical hypothyroidism in children and adults (Blake et al., 2018; Itoh et al., 2019; Jansen et al., 2020; Kim et al., 2020; Lebeaux et al., 2020; Liang et al., 2020; Preston et al., 2020b; Reardon et al., 2019; Xiao et al., 2020). Timing of exposure, life stage, and dietary factors all are likely to modify the relationship between PFAS and thyroid hormones, which could account for the weak observations observed in recent studies. For example, in a cohort study with low risk of bias that measured maternal and cord sera for PFAS and thyroid hormones, Lebeaux and colleagues (2020) found that individual PFAS or mixtures of PFAS were generally not associated with any thyroid hormones, although they did observe a slight association between PFAS and cord serum thyroid-stimulating hormone, with PFOS being the major contributor of the mixture (Bayesian kernel machine regression model estimate per doubling of PFOS [$\beta = 0.09$; 95% credible interval: −0.08–0.27]). They also observed some indication of effect measure modification by maternal thyroid peroxidase antibody status for the associations of PFAS with cord free thyroxine. The committee concluded that there is *limited* or *suggestive* evidence of an association between PFAS and thyroid hormones and thyroid disease.

Diabetes

Authoritative reviews have not found evidence of an association between PFAS and diabetes. ATSDR concluded that, while one prospective cohort study (Sun et al., 2018) suggested an association of PFOA and PFOS with risk of diabetes, overall the epidemiological studies did not provide support for an association between serum PFAS levels and increased risk of diabetes or related outcomes (e.g., increases in blood glucose, glucose tolerance). The committee identified three more recent studies with a probably low risk of bias examining type 2 diabetes. Their results were mixed, with elevated associations observed by Charles and colleagues (2020), an inverse association by Donat-Vargas and colleagues (2019a), and weak or null associations observed by Cardenas and colleagues (2019). One study identified after the committee had completed its literature review (Valvi et al., 2021) observed a modest association with decreased insulin sensitivity and increased pancreatic beta cell function in a cohort study of young adults, but associations with type 2 diabetes were not examined. No new studies examined type 1 diabetes. Given the mixed effects observed, the committee concluded that evidence is *inadequate* or *insufficient* to determine an association between PFAS exposure and diabetes.

Hepatic Outcomes

Authoritative reviews, including those by ATSDR, EFSA, and EPA, have consistently found associations between PFAS and liver effects. ATSDR noted that decreases in serum bilirubin were observed in studies of PFOA, PFOS, and PFHxS, suggestive of liver alterations. The committee identified four more recent studies on PFAS and liver effects with probably low or definitely low risk of bias, including a prebirth cohort study in Boston, a cohort study in Sweden, a study of pooled data from longitudinal birth cohorts across Europe, and a study based on a liver registry in Atlanta (Jin et al., 2020;

KD2393

Copyright National Academy of Sciences. All rights reserved.

Mora et al., 2018; Salihovic et al., 2018; Stratakis et al., 2020). All studies observed some association between PFAS and the liver, but the effects observed were slightly heterogeneous. Mora and colleagues (2018) observed an inverse association between PFAS exposure and alanine transaminase in the prenatal period and in childhood. Salihovic and colleagues (2018) observed that changes in levels of many measured PFAS were positively associated with alanine transaminase and alkaline phosphatase levels and negatively associated with bilirubin. Stratakis and colleagues (2020) observed that higher prenatal exposure to a PFAS mixture was associated with increased risk of liver injury during childhood, as indicated by enzyme levels exceeding the 90th percentile for the study population. And Jin and colleagues (2020) observed that PFAS exposure was associated with more severe disease in children with nonalcoholic fatty liver disease. Taken together, the committee concludes that the available studies provide *limited* or *suggestive* evidence of an association between PFAS exposure and liver enzyme levels.

Respiratory Outcomes

Authoritative reviews, including those of ATSDR, EFSA, and EPA, have not yet drawn conclusions about PFAS exposure and respiratory effects. Respiratory outcomes considered by the committee include pulmonary function tests (objective measures of how well the respiratory system is working); respiratory diseases, including obstructive airway diseases, such as asthma and chronic obstructive pulmonary disease; restrictive diseases, such as pulmonary fibrosis; and respiratory symptoms, such as wheeze, cough, phlegm, and dyspnea (shortness of breath). The committee identified 10 recent studies evaluating the association between PFAS exposure and respiratory outcomes. Three studies with probably low risk of bias evaluated PFAS and pulmonary function in cohorts of children (Agier et al., 2019; Kung et al., 2021; Manzano-Salgado et al., 2019); results were mixed within each study. Several studies evaluated the impact of PFAS exposure on asthma and respiratory symptoms, such as cough and wheeze; results were mixed both between and within studies (Ait Bamai et al., 2020; Beck et al., 2019; Impinen et al., 2019; Kvalem et al., 2020; Manzano-Salgado et al., 2019; Timmermann et al., 2020; Zeng et al., 2019). Taken together, the committee concludes that the available studies provide *inadequate* or *insufficient* evidence of an association between PFAS exposure and liver enzyme levels.

Hematological Outcomes

ATSDR evaluated the impact of PFAS on hematological parameters and concluded that PFAS are associated with no consistent alteration in hematological parameters. The committee did not identify any more recent studies on hematological effects. Thus, the committee concludes that the evidence is *inadequate* or *insufficient* to determine an association between PFAS exposure and hematological effects.

Musculoskeletal Outcomes

The authoritative reviews identify several studies evaluating possible PFAS-associated risk of osteoarthritis, osteoporosis, and reduced bone mineral density (BMD). The committee identified two more recent studies evaluating the relationship between PFAS exposure and bone health (Banjabi et al., 2020; Hu et al., 2019). A case-control study with high risk of bias found that serum PFAS concentrations increased the odds of diagnosis of osteoporosis among adults in Saudi Arabia (Banjabi et al., 2020). A study with probably low risk of bias evaluated BMD within a weight-loss trial of U.S. adults aged 30–70 and found associations between higher plasma PFAS concentrations and lower BMD at baseline, as well as a faster decline in BMD (Hu et al., 2019). The study by Hu and colleagues (2019) provides longitudinal evidence. However, the study was designed to measure weight loss, and its conclusions may not be generalizable to the broader population. In addition, the study is at risk of

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

selection bias because only a small percentage of the study participants had both measures of BMD. There is also a risk of information bias from residual confounding because the analysis did not account for nutritional and menopausal status. Because of the small sample size, moreover, the authors did not adjust for multiple comparisons. Taken together with the evidence presented in ATSDR's *Toxicological Profile*, these findings are intriguing and merit further study. The committee concluded that the evidence is *inadequate* or *insufficient* to determine an association between PFAS and bone health. Nevertheless, the available evidence does raise concerns about the potential adverse effects of PFAS on bone health in both children and adults that warrant further investigation.

Renal Outcomes

ATSDR evaluated the impact of PFAS on kidney disease and biomarkers of renal function, but did not draw any conclusions because results were mixed across studies for most outcomes, and most studies were cross-sectional, so causal determinations could not be made. The committee identified three more recent studies evaluating impacts of PFAS on glomular filtration rate. A cohort study of participants in a medical surveillance program for residents near a former U.S. Department of Energy uranium-processing site assessed serum PFAS and measures of glomular filtration rate at repeated time points from 1990 to 2008 and found decreased glomular filtration rate to be associated with serum PFAS (Blake et al., 2018). The study had a probably high risk of bias because of a small potential for selection bias into the cohort and a slight risk of reverse causality. Two studies analyzing a diabetes prevention trial (Lin et al., 2021, which updates Cardenas et al., 2019) found that plasma PFAS concentrations during the diabetes prevention program were inversely associated with glomular filtration. Each quartile increase in baseline plasma measures of six PFAS was associated with 2.26 ml/min/1.73 m^2 lower glomular filtration (95% CI: −4.12, −0.39) at years 5 and 9. The study's strengths included tests of reverse causation and a lengthy follow-up period, although there is potential for residual confounding. The study's principal limitation is related to the generalizability of the findings to the general population given the inclusion criteria of overweight or obesity and prediabetes. Overall, the committee concluded that the evidence is *inadequate* or *insufficient* to draw a conclusion regarding an association between PFAS exposure and renal function. Nevertheless, the available evidence does raise concerns about the potential adverse effects of PFAS on renal function that warrant further investigation.

Neurological Outcomes

The authoritative reviews do not draw conclusions about the impact of PFAS on neurological outcomes, such as changes in motor function; behavioral changes; mood disorders; sensory disorders; cognitive disorders; and changes in neurochemistry, neurophysiology, or neuropathology. One recent case-control study nested within the diabetes prevention trial mentioned above found no association between any PFAS measured in serum and neuropathy in either the diabetes cases or the controls (Cardenas et al., 2019). The committee concluded that the evidence is *inadequate* or *insufficient* to draw a conclusion regarding an association between PFAS exposure and neurological outcomes.

EVIDENCE GAPS

The committee found several conditions to be associated with exposure to PFAS. The effects of PFAS span many different organ systems and disease states. The human populations most at risk of these health effects include those with a family history of or other risk factors for associated health effects and those who are in vulnerable life stages, including pregnancy, fetal development or early childhood, and the elderly. The committee did not complete a meta-analysis of the impact of each individual PFAS on each health outcome or provide an overall estimate of risk because the data from the studies are highly heterogeneous, limiting the applicability of meta-analytic techniques. The committee

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

also observed gaps in the evidence for many health effects, whereby the evidence was *inadequate* or *insufficient* to determine associations. These gaps include

- immune effects other than reduced antibody response, and ulcerative colitis;
- cardiovascular outcomes other than dyslipidemia;
- developmental outcomes other than small reductions in birthweight;
- cancers other than kidney, breast, and testicular;
- reproductive effects other than hypertensive disorders of pregnancy;
- endocrine disorders other than thyroid hormone levels;
- hepatic effects other than liver enzyme levels;
- respiratory effects;
- hematological effects;
- musculoskeletal effects, such as effects on bone mineral density;
- renal effects, such as renal disease; and
- neurological effects.

It is critical to recognize that an assessment of *inadequate* or *insufficient* evidence does not mean there is no significant and important association between PFAS exposure and the outcome under consideration. It is quite possible that further research into the association of PFAS exposure with these outcomes would provide the evidence necessary to change the assessment to the category of either *limited* or *suggestive* or *sufficient* evidence. The committee believes that ongoing research on and review of these associations will be important in updating its clinical recommendations. A gap also remains in determining which developmental effects are the most clinically meaningful. For some outcome categories, the available research spans many different tests, all of which assessed slightly different effects, making the evidence difficult to synthesize and support strong conclusions. An authoritative organization needs to determine which endpoints are the most critical to evaluate to support clinical follow-up recommendations.

Additionally, most studies reviewed by the committee were not conducted among people known to have high exposures to PFAS. As a result, there is a gap in understanding of the effects of PFAS among those highly exposed, and the evidence presented in this report may therefore underestimate the effects of PFAS.

Although the committee aimed to assess the available scientific evidence as carefully and systematically as possible, it was sensitive to the fact that value judgments are unavoidable when performing an assessment of this kind (Elliott, 2017; Elliott and Richards, 2017; Jasanoff, 1998). These judgments include decisions about what forms of evidence to include, how to weigh and categorize different pieces of evidence, and what standards of evidence to demand before drawing conclusions. Literature from the sociology of science and medicine emphasizes not only that different expert communities may disagree about how to make these decisions (Cetina, 1999) but also that lay communities may make these decisions in ways that differ from those of expert communities (Epstein, 1996; Ottinger, 2010; Suryanarayanan and Kleinman, 2016). For example, because lay communities are often particularly concerned about addressing urgent health issues or informing time-sensitive policy decisions, they may accept lower standards of evidence than experts typically do (Brown, 1992). These differing evidential approaches across different communities raise the potential for differing rates of positive and negative errors (Douglas, 2009; Elliott, 2017; Elliott and Richards, 2017). Different communities also have varying background disease risk, which may lead to differing associations with PFAS and differing needs for risk assessment as it relates to these associations.

With these observations in mind, the committee acknowledges that other expert and lay communities might draw different conclusions about PFAS health risks, either by including different lines of evidence or by making alternative judgments when assessing the available evidence. This is one of the reasons that the committee emphasizes the importance of patient autonomy and shared decision making in

KD2396

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

subsequent chapters. Although the committee's evaluation of the evidence can provide an important starting point for decision making by clinicians and their patients, some individuals and groups could employ different evidential standards. Therefore, the committee encourages ongoing efforts to make scientific information about PFAS publicly available and understandable so that patients and clinicians can make informed decisions that respect individual patient values.

ANNEX TABLE 3-1 Health Effects of PFAS by Category

Health Effect Category	Specific Health Effects Included	Authoritative Strength-of-Evidence Conclusion	Committee's Strength-of-Evidence Conclusion
Immunological	Response to infection Response to allergens Response to self: autoimmunity	ATSDR: Evidence is suggestive of an association between serum levels of PFOA, PFOS, PFHxS, and PFDA and decreased antibody responses to vaccines; there is also limited evidence of this effect for PFNA, PFUnDA, and PFDoDA. EFSA: PFOS and PFOA are associated with reduced antibody response to vaccination, observed in several studies. Some of the studies suggest that serum levels of PFOS and PFOA are associated with increased propensity for infection. Epidemiological studies provide insufficient evidence to draw conclusions on associations between exposure to PFASs and asthma and allergies. EPA: Human epidemiology data show associations between PFOA exposure and decreased vaccination response. Increased risk of ulcerative colitis was found in the PFOA high-exposure community study, as well as in a study limited to workers in that population. NTP: The evidence indicating that PFOA affects multiple aspects of the immune system supports the overall conclusion that PFOA alters immune function in humans. However, the mechanism(s) of PFOA-associated immunotoxicity is not clearly understood, and effects on diverse endpoints, such as suppression of the antibody response and increased hypersensitivity, may be unrelated. The NTP concludes that PFOS is presumed to be an immune hazard to humans based on a high level of evidence from animal studies that PFOS suppressed the antibody response and a moderate level of evidence from studies in humans. Although the mechanism(s) of PFOS-associated immunotoxicity is not clearly understood, potential mechanisms by which PFOS may reduce disease resistance include suppression of the antibody response and of NK cell function. OECD: A study with 656 children demonstrated that elevated exposures to PFOA and PFOS are associated with reduced humoral immune response to routine childhood immunizations in children aged 5 and 7. A large epidemiological study of 69,000 persons conducted by the C-8 Science Panel found probable links between elevated PFOA blood levels and ulcerative colitis.	Sufficient: decreased antibody response (in adults and children) Limited or suggestive: ulcerative colitis in adults Inadequate or insufficient: response to allergens, all other immune outcomes

Copyright National Academy of Sciences. All rights reserved.

Cardiometabolic	Cardiovascular disease, dyslipidemia, metabolic syndrome, obesity	ATSDR: The results of epidemiological studies of PFOA, PFOS, PFNA, and PFDA suggest an association between perfluoroalkyl exposure and increases in serum lipid levels, particularly total cholesterol and low-density lipoprotein (LDL) cholesterol. EFSA: Epidemiological studies provide clear evidence of an association between exposure to PFOS, PFOA, and PFNA and increased serum levels of cholesterol. There is insufficient evidence of associations with diabetes, obesity, and metabolic syndrome. EPA: Human epidemiological data show associations between PFOA exposure and high cholesterol. These epidemiological studies have generally found positive associations between serum PFOA concentration and total cholesterol in PFOA-exposed workers and high-exposure communities (i.e., increasing lipid level with increasing PFOA); similar patterns are seen with LDL cholesterol but not with high-density lipoprotein (HDL) cholesterol. OECD: The C-8 Science Panel's epidemiological study of 69,000 persons found probable links between elevated PFOA blood levels and high cholesterol (hypercholesterolemia). C-8 Science Panel: There is a probable link between exposure to C-8 and high cholesterol (hypercholesterolemia).	Sufficient: dyslipidemia in adults and children Inadequate or insufficient: other outcomes
Developmental	Infant and fetal growth, neurodevelopment, development of the reproductive system	ATSDR: Evidence is suggestive of an association between serum levels of PFOA and PFOS and small decreases in birthweight. EFSA: There may well be a causal association between PFOS and PFOA and birthweight. Maternal serum levels in studies reporting results on other PFASs were generally much lower, and those studies provide no evidence of an adverse association between other PFASs and birthweight. EPA: The epidemiological studies found no association of PFOA with neurodevelopmental effects or with preterm birth and other complications of pregnancy. OECD: High levels of PFOS and PFOA are toxic for reproduction and development of the fetus (such as reducing birthweight and lowering semen quality).	Sufficient: small reductions in birthweight Inadequate or insufficient: all other outcomes, such as development of the reproductive system, neurodevelopment
Cancer	Kidney cancer, testicular cancer, breast cancer	EPA: Under EPA's *Guidelines for Carcinogen Risk Assessment* (EPA, 2005), there is "suggestive evidence of carcinogenic potential" for PFOA. Epidemiology studies demonstrate an association of serum PFOA with kidney and testicular tumors among highly exposed members of the general population. There is suggestive evidence of carcinogenic potential for PFOS. Human epidemiology studies found no direct correlation between PFOS exposure and the incidence of carcinogenicity in worker-based populations. Although one worker cohort showed an increase in bladder cancer, smoking was a major confounding factor, and the standardized incidence ratios were not significantly different from those for the general population. Other worker and general population studies found no statistically significant trends for any cancer type.	Sufficient: kidney cancer in adults Limited or suggestive: testicular cancer, breast cancer in adults Inadequate or insufficient: all other cancers

continued

ANNEX TABLE 3-1 *continued*

Health Effect Category	Specific Health Effects Included	Authoritative Strength-of-Evidence Conclusion	Committee's Strength-of-Evidence Conclusion
		IARC: There is "limited" evidence in humans for the carcinogenicity of PFOA. A positive association was observed for cancers of the testes and kidney. Overall, PFOA is possibly carcinogenic to humans (Group 2B). OECD: High levels of PFOS and PFOA have been found to be potentially carcinogenic in animal tests. The C-8 Science Panel's epidemiological study of 69,000 persons found probable links between elevated PFOA blood levels and testicular and kidney cancer. C-8 Science Panel: There is a probable link between exposure to C-8 and kidney and testicular cancer.	
Reproductive	Infertility, male reproductive effects, female reproductive effects, hormone levels, hypertension during pregnancy, gestational diabetes	ATSDR: There is suggestive epidemiological evidence of an association between serum PFOA and PFOS and pregnancy-induced hypertension and/or preeclampsia. EPA: Human epidemiological data show associations between PFOA exposure and pregnancy-induced hypertension and preeclampsia. OECD: High levels of PFOS and PFOA are toxic for reproduction and development of the fetus (e.g., reducing birthweight and lowering semen quality). In addition, 8:2 fluorotelomer phosphate diesters (8:2 PAPs), 8:2 FTOH, and PFOA show endocrine effects in different in vitro and in vivo tests. The C-8 Science Panel's epidemiological study of 69,000 persons found probable links between elevated PFOA blood levels and preeclampsia and elevated blood pressure during pregnancy. C-8 Science Panel: There is a probable link between exposure to C-8 and pregnancy-induced hypertension (including preeclampsia).	Limited or suggestive: pregnancy-induced hypertension (gestational hypertension and preeclampsia) Inadequate or insufficient: all other effects, such as fecundity, infertility, male reproductive effects, female reproductive effects, reproductive hormone levels, gestational diabetes
Endocrine	Thyroid disease, hypothyroidism, hyperthyroidism, thyroid hormone levels, type 1 and 2 diabetes	EPA: Human epidemiology data show associations between PFOA exposure and thyroid disorders. The epidemiological studies found no associations between PFOA and diabetes. OECD: 8:2 fluorotelomer phosphate diesters (8:2 PAPs), 8:2 FTOH, and PFOA show endocrine effects in different in vitro and in vivo tests. The C-8 Science Panel's epidemiological study of 69,000 persons found probable links between elevated PFOA blood levels and thyroid disease. C-8 Science Panel: There is a probable link between exposure to C-8 and thyroid disease.	Limited or suggestive: thyroid disease or dysfunction in adults Inadequate or insufficient: all other outcomes, including type 1 and 2 diabetes

Copyright National Academy of Sciences. All rights reserved.

Hepatic	Liver disease, altered serum liver enzymes and bilirubin	ATSDR: Increases in serum enzymes and decreases in serum bilirubin, observed in studies of PFOA, PFOS, and PFHxS, are suggestive of liver alterations. EFSA: Epidemiological studies provide evidence for an association between exposure to PFAS and increased serum levels of the liver enzyme alanine transferase (ALT). The magnitude of the association was small, however, and few studies found an association with ALT outside the reference range. There were no associations with liver disease. EPA: Human epidemiology data show associations between PFOA exposure and increased liver enzymes.	Limited or suggestive: liver enzyme alterations in children and adults
Respiratory	Respiratory symptoms, pulmonary function, respiratory diseases	None	Insufficient
Hematological	Blood disorders or impacts on blood-forming organs	None	Insufficient
Musculoskeletal	Loss of muscle tone or strength, muscular rigidity, muscular atrophy, arthritis, altered bone density, arthralgia (joint pain)	None	Insufficient
Renal	Kidney disease and biomarkers of renal function	None	Insufficient
Neurological	Parkinson's disease, memory loss, neuropsychological function	None	Insufficient

PFAS Exposure Reduction

It is difficult to provide clear advice on how to reduce exposure to per- and polyfluoroalkyl substances (PFAS) because there are many potential exposure sources. Importantly, even if the source of a person's exposure is completely removed, it will take years for the internal body burden (levels in the body) of many PFAS to be fully eliminated. Biological half-lives (i.e., the time it takes for plasma concentration to decrease by 50 percent after exposure) vary depending on the PFAS; half-life estimates for the four most studied PFAS (perfluorooctanoic acid [PFOA], perfluorooctane sulfonic acid [PFOS], perfluorohexane sulfonate [PFHxS], and perfluorononanoic acid [PFNA]) range from around 2 to 8 years (Li et al., 2018; Olsen et al., 2007). These long biological half-lives are due to reabsorption in the kidney and enterohepatic recirculation, both processes greatly reducing the capacity to eliminate PFAS (Harada et al., 2007).

In developing this chapter, the committee first created a conceptual model for exposure reduction (see Figure 4-1). The premise of this model is that if any exposure pathway is interrupted, exposure should be reduced. For example, if PFAS were no longer used in industries, they would not be in consumer products or waste streams, so exposures would be reduced. Similarly, if PFAS in the environment are cleaned up, exposures will decrease.

Support for the committee's conceptual model is found in the changes in exposure at the population level due to industry-wide changes in PFAS production. For example, serum PFAS concentrations in the United States declined over time following the 3M company's (Maplewood, Minnesota) voluntary phase-out of perfluorooctanyl chemicals and related precursors, including PFOS and PFOA, in 2000 (ITRC, 2017) (see Figure 4-2). Therefore, there is evidence that removing these chemicals from products on a large scale can result in lower levels in a population.

SOURCES AND ROUTES OF EXPOSURE TO PFAS

The sources of and routes of exposure to PFAS are an active area of investigation. What is well known is that PFAS exposure is highly complex, with pathways that include occupational exposures, environmental contamination, consumer product use, and food exposures. Specific sources of exposure include, for example, jobs in fluorochemical manufacturing facilities or where PFAS-containing products, such as textiles or food contact materials, are made. Other jobs with a known increased risk of exposure to PFAS include electroplating; painting; carpet installation and treatment; serving as a military or civilian firefighter, which entails using PFAS-containing foams in training exercises and wearing PFAS-impregnated gear; and jobs that require prolonged work with ski wax (ATSDR, 2021). In addition, food workers and others in the hospitality industry may have elevated exposure since they handle PFAS-containing food packaging as part of their job duties (Carnero et al., 2021; Curtzwiler et al., 2021; Schaider et al., 2017).

Ingestion is the most well-studied route of exposure in nonoccupational settings (Trudel et al., 2008). Ingestion of PFAS can occur through drinking contaminated water; eating contaminated seafood; or consuming other contaminated foods, such as vegetables, game, or dairy products (Bao et al., 2019, 2020; Death et al., 2021; Domingo and Nadal, 2017; Herzke et al., 2013; Li et al., 2019). PFAS are often used in cookware and in materials that came in contact with food, such as microwave popcorn bags or packaging used for fast foods or processed foods (Carnero et al., 2021; Curtzwiler et al., 2021; Schaider et al., 2017). Exposure can also occur through accidental ingestion of PFAS-containing dusts (Fraser et al., 2013). PFAS cross the placenta, and PFAS from the mother's body burden can be passed on to her developing fetus (Gao et al., 2019; Manzano-Salgado et al., 2015). Maternal transfer of PFAS can also occur through breastfeeding (Serrano et al., 2021; Zheng et al., 2021).

Inhalation and transdermal exposures are less well studied. Inhalation of PFAS is well documented in occupational settings that use aerosolized PFAS (Gilliland, 1992). Volatile PFAS have been detected indoors (Fromme et al., 2015; Morales-McDevitt et al., 2021), and inhalation near factory emissions and incinerators contributes to exposures in nearby communities (Fenton et al., 2021). There

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

are as yet no data formally evaluating inhalation from showering in contaminated water, but this is an active area of research.

PFAS are used in thousands of products (e.g., products containing water; stain-resistant clothing; and personal care products, such as sunscreen, makeup, and dental floss). PFAS are also used in such products as paint, textiles, firefighting foam, electroplating material, ammunition, climbing ropes, guitar strings, artificial turf, and soil remediation products (Glüge et al., 2020). The extent to which use of products contributes to human exposures is unkown, however, because the relative contribution of PFAS exposures from sources other than food or water is not well characterized (DeLuca et al., 2021).

The presence of PFAS in everyday consumer products may be an important source of exposure for the general population, but this likely varies greatly by individual (Rodgers et al., 2022). Consumer products are often treated with fluoropolymers to impart water and stain resistance, and fluoropolymers can result in exposure to the nonpolymer PFAS discussed in this report in several ways. Nonpolymer PFAS can be present as impurities in fluoropolymer-containing products because these PFAS are used as processing aids in chemical production or are degradation products of the fluoropolymers (Rodgers et al., 2022; Schellenberger et al., 2019). Moreover, fluoropolymer PFAS can degrade (biodegradation) slowly when exposed to water and release fluorotelomer alcohols, which are precursors to nonpolymer PFAS. Once the precursor PFAS are in the human body, they can transform to such PFAS as PFOA, PFOS, and PFHxS (Washington and Jenkins, 2015).

APPROACH TO DETERMINING ADVICE ON PFAS EXPOSURE REDUCTION

To inform its recommendations on how clinicians can advise patients on PFAS exposure reduction, the committee looked at several sources of evidence. The committee contracted with a consultant to review the literature evaluating the effectiveness of behavioral interventions in reducing exposure to PFAS. The consultant also reviewed several studies that model estimates of PFAS intake, which could inform predicted changes in serum PFAS levels if exposure routes were modified (see Appendix E). The committee reviewed studies on PFAS exposure through breastfeeding since this route impacts a vulnerable population and is of particular interest to people in PFAS-impacted communities, as voiced by speakers at the committee's town halls (see Appendix B). The committee also evaluated studies of medical interventions for reducing internal levels of PFAS (e.g., phlebotomy or taking of prescription drugs). PFAS exposure pathways discussed in Chapter 1 were used to outline strategies clinicians can use to determine whether a patient may be at risk of PFAS exposure based on residential and work history. In addition, the committee reviewed advice from other entities on PFAS exposure reduction, such as that provided by nongovernmental organizations, state and local governments, and other countries.

CONTRIBUTION OF INDIVIDUAL EXPOSURE SOURCES TO HUMAN EXPOSURE

Behavioral Intervention Studies

Studies evaluating the impact of behavior change on reducing exposures would help determine the impact of behavior on human exposure. This section, based on a literature review conducted by LaKind Associates (see Appendix E), provides an overview of the literature available to inform what individuals can do to reduce their serum PFAS levels. The literature review used a three-step approach to identify relevant publications in PubMed, EMBASE, and Google Scholar (see Appendix E for keywords and the search strategy). Studies were selected that entailed interventions designed to reduce human exposure to PFAS, specifically interventions that could be carried out by individuals. Secondary references of retrieved articles were reviewed to identify publications not found through the electronic search. An additional literature search was then conducted to identify reviews containing estimates of human PFAS intakes. The final search date was March 5, 2021.

The reviewed intervention studies are presented here by exposure route, with the primary focus being on drinking water and diet. Literature on interventions for other exposure sources, such as dust and

KD2413

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

consumer products, is more limited. Lastly, breastfeeding is an important potential source of exposure for infants, and lactating could reduce parents' PFAS levels. After reviewing the relevant studies, this section concludes by assessing the effectiveness of behavior modifications based on the current literature.

Drinking water has been identified as a substantial source of PFAS exposure for many populations (Andrews and Naidenko, 2020; Domingo and Nadal, 2019). Studies of interventions focused on drinking water are consistent in demonstrating the effectiveness of water filtration at reducing levels of certain PFAS. Consumers have a variety of options for filtering PFAS from drinking water, including whole-house, under-sink, and filtering-pitcher devices. The committee identified seven publications and one agency report evaluating possible drinking water interventions. Of these, five (Ao et al., 2019; Herkert et al., 2020; Iwabuchi and Sato, 2021; MDH, 2008; Patterson et al., 2019) evaluate use of whole-house, under-sink, and filtering-pitcher devices, and three (Ao et al., 2019; Gellrich et al., 2013; Heo et al., 2014) evaluate differences in PFAS concentrations between tap water and bottled water.

In a study of real-world uses of water filtration options, Herkert and colleagues (2020) tested municipal, well, and filtered (n = 89) and unfiltered (n = 87) tap water in residences (N = 73) in North Carolina for 11 PFAS. The filters tested varied in both type and filtration method (reverse osmosis, granulated activated carbon, single-stage, dual-stage). Notably, reverse osmosis and dual-stage filters were found consistently to remove most measured compounds at an average of ≥90 percent efficiency; some short-chain replacement PFAS are difficult to remove with carbon filtration (Herkert et al., 2020). Use of bottled water can also be a way to reduce PFAS exposure from drinking water, although some bottled waters contain detectable levels of C-3–C-10 perfluorocarboxylic acids (PFCAs) and C-3–C-6 and C-8 perfluorosulfonic acids (PFSAs) (Chow et al., 2021). In Parkersburg, West Virginia, for example, the use of bottled water resulted in a dramatic reduction in serum PFOA levels among a contaminated community living near a Teflon-manufacturing plant (Emmett et al., 2006).

Changes in diet may potentially reduce PFAS exposure, given that PFAS can be present in a number of food products, including wild-caught fish and game, livestock, and produce, as well as prepared foods. Fish and seafood have been identified as sources of PFAS, but the levels of PFAS vary by fish type and water body (Sunderland et al., 2019). PFAS-contaminated drinking water can also impact home-grown vegetables (Brown et al., 2020; Emmett et al., 2006). The majority of ingestion-based intervention studies focused on seafood preparation, but there was no strong evidence that fish preparation methods influenced PFAS levels (Alves et al., 2017; Barbosa et al., 2018; Bhavsar et al., 2014; Del Gobbo et al., 2008; Hu et al., 2020; Kim et al., 2020; Luo et al., 2019; Taylor et al., 2019).

A study on PFAS exposure from indoor dust found significantly lower PFAS levels in vacuumed dust from rooms with PFAS-free furnishings relative to control rooms (78 percent reduction, 95% CI: 38–92). Results suggest that modifying personal behavior to be capable of identifying and purchasing PFAS-free furnishings can decrease exposure levels from indoor dust (Scher et al., 2019).

Literature on PFAS in consumer products is available only for nonstick pans and dental floss, and these studies have several weaknesses, including recall bias, small sample sizes, and lack of replication. Their results do not provide enough evidence to suggest that modifications in behavior relative to those products would decrease PFAS exposure, but in the absence of such evidence, consumers should be aware of which products contain PFAS (Scher et al., 2019; Young et al., 2021).

Another factor that complicates consumer choices aimed at avoiding PFAS is the lack of consistent labeling of products. A recent study (identified after Appendix E of this report had been completed) that screened 93 market items across three different product types (furnishings, apparel, and bedding) found that PFAS were present in many items that were labeled as green or nontoxic (Rodgers et al., 2022).

To summarize, the available literature is limited in presenting recommendations for effective behavior modifications to reduce internal levels of PFAS. In places with water contamination, individuals can reduce their exposure through use of water filtration. In places without PFAS water contamination or workplace exposure, diet is believed to be the primary exposure route, but there is limited information with which to recommend dietary interventions. No intervention study has examined exposure reduction and its impact on serum concentrations, likely in part because to fully show effectiveness for an

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

intervention, it would have to be conducted over a long enough time to account for the long half-lives of PFAS.

Modeled Estimates of PFAS Intakes

In the absence of studies demonstrating the impact of interventions on reducing PFAS exposure, exposure models may help inform predicted changes in serum PFAS levels if exposure routes are modified. Pharmacokinetic modeling is useful for estimating the body burden from different exposure routes, but such models are often limited by the many assumptions made about intake factors (e.g., food contamination). High-quality data on the distribution of PFAS in different food types and consumer products are sparse. Nonetheless, pharmacokinetic models can be used to estimate the variability possible in exposure reduction and the impact of changes with different parameters. Although imperfect, exposure modeling can provide, at a minimum, an estimate of the change in internal PFAS body burden if PFAS levels in diet or water were decreased.

Studies that have estimated intake of PFOS and PFOA have been used to determine the dominant routes of exposure in communities without contaminated drinking water (see Appendix E). Estimates of how much PFAS exposure comes from diet in adults vary widely, from 16–99 percent for PFOA to 66–100 percent for PFOS (Egeghy and Lorber, 2011; Haug et al., 2011; Lorber and Egeghy, 2011; Sunderland et al., 2019; Vestergren and Cousins, 2009); no estimates are available for individual food products. For dust, the estimates are 1–11 percent for PFOA and 1–15 percent for PFOS (Sunderland et al., 2019). For PFOA, the dominant routes are thought to be oral exposure resulting from consumption of fish and seafood, drinking water, and ingestion of dust. For PFOS, the dominant routes are thought to be ingestion of food and water, ingestion of dust, and hand-to-mouth transfer from treated carpets (Trudel et al., 2008). Residual PFOA in food packaging (used to greaseproof food-containing paper products) is another potential route of exposure (Trudel et al., 2008); polyfluoroalkyl phosphoric acids in food packaging can also be metabolized in the body to PFOA (Begley et al., 2005; Carnero et al., 2021; Curtzwiler et al., 2021; Schaider et al., 2017).

Interpretation of the estimated intake studies is challenged by several factors. First, while diet appears to be a major pathway of exposure, there is little information on PFAS in commercial foods commonly consumed in the United States. The U.S. Food and Drug Administration (FDA) has released PFAS data for certain foods that could be used to model source contributions to PFAS intake in future studies. However, the FDA data for produce, meat, dairy, and grain products are based on a small sample size, and the results "cannot be used to draw definitive conclusions about the levels of PFAS in the general food supply."[1]

The relative importance of different PFAS sources varies by study, population, and time period of exposure (Sunderland et al., 2019). The production and use of individual PFAS have changed over time and will continue to do so. Serum PFAS levels in the United States dropped following the phase-out of production of PFOS and PFOA; however, exposures to C9–C11 PFCAs have not followed the same trend. Thus, it is important to use recent environmental, consumer product, and dietary data to develop robust estimates of current dominant pathways of PFAS exposure. In a recent review evaluating nonoccupational intakes via background PFAS exposures, De Silva and colleagues (2021) observed that the inconsistency among studies in the relative importance of different exposure sources may be due to differing concentrations of PFAS in sources, as well as the assignment of differing values for exposure intake factors (e.g., exposure frequency and duration). The authors conclude, "Without rigorously conducted exposure studies it is challenging to rank order the most important human exposure pathways and without these data, our ability to design evidence-based exposure intervention strategies will be limited."

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Exposure to PFAS Through Breastfeeding

Breastfeeding is a route of exposure of great interest to people who spoke at the committee's town halls. Breast milk is the only food many infants receive in their first 6 months of life, and if the breast milk they receive is contaminated with PFAS, it may take years for their body burden to be reduced, given the long half-lives of some PFAS.

In her testimony at the committee's first town hall (April 7, 2021), Loreen Hackett (PFOA Project New York) stated that in her view, health care mantras such as "breast milk is best" need to be thoroughly reevaluated in exposed communities, noting that breastfeeding "may double or triple PFAS levels in an infant compared to the mothers thereby increasing risks to their developing systems." She stressed that families in exposed communities cannot make informed reproductive choices or other family decisions without improved information tailored to their situation, and she relayed concerns among community members expressing guilt for unknowingly poisoning their child over the course of pregnancy and breastfeeding.

Nonetheless, data on PFAS in breast milk are very limited. A few studies measuring PFAS in breast milk in North America (Kubwabo et al., 2013; Tao et al., 2008; Zheng et al., 2021) indicate transfer from the parent to the child during the first months of life. And although the concentrations in breast milk are generally much lower than the concentrations in maternal serum (Cariou et al., 2015; Kärrman et al., 2007; Kim et al., 2011; Liu et al., 2011), breastfeeding has been shown to contribute significantly to children's serum levels of some PFAS (Gyllenhammar et al., 2018, 2019; Koponen et al., 2018). In a cohort of 2- to 4-month-old infants in Sweden, for example, bottle-fed infants had mean serum concentrations twice as low as those of their exclusively breastfed counterparts, and serum levels of PFOA, PFNA, and PFHxS increased 8−11 percent per week of exclusive breastfeeding (Gyllenhammar et al., 2018). Where measured and estimated PFAS concentrations in breast milk in the United States have been compared with drinking water screening values of the Agency for Toxic Substances and Disease Registry (ATSDR), some exceedances have been observed, especially in communities impacted by PFAS contamination (LaKind et al., 2022) (see Figure 4-3).

Whether lactational exposure to PFAS can have adverse health effects in children has not been well studied to date. Formula feeding can also lead to PFAS exposure through either contaminated formula or formula reconstituted with contaminated drinking water. Given the increased exposures observed in breastfed versus formula-fed infants, it is not clear whether the benefits of breastfeeding outweigh the risks to the child among lactating persons with very high levels of PFAS exposure.

Guidance to breastfeed remains the best feeding advice for most infants given the many benefits of breastfeeding for both mothers and babies.[2] Even though PFAS exposures have been occurring for many years, research has consistently shown benefits of breastfeeding, providing confidence in the traditional guidance, although a more in-depth understanding of this exposure route is warranted to inform protection of such a vulnerable population.

MEDICAL INTERVENTIONS FOR POTENTIALLY REDUCING PFAS BODY BURDEN

There have been few studies overall and no clinical trials evaluating treatments to reduce PFAS body burden, even in cases of very high exposure. The few evaluations available have focused on the use of cholesterol-lowering medications and phlebotomy.

PFAS are secreted in the bile and have enterohepatic recirculation; therefore, researchers have been interested in medications that enhance bile sequestration as potential approaches for reducing PFAS body burden. Cholestyramine is a bile-sequestering agent that is used mainly to reduce low-density lipoprotein (LDL) cholesterol. In a cross-sectional study of C-8 Health Project participants, 36 of 56,175 adults were being treated with cholestyramine and were found to have lower levels of PFAS compared with those not taking this medication (Ducatman et al., 2021). Another medication, probenecid, was not

[2] See https://www.cdc.gov/breastfeeding/about-breastfeeding/why-it-matters.html (accessed May 23, 2022).

significantly associated with serum PFAS levels in this study. Cholestyramine has also been evaluated in a few small case studies of 1 to 20 individuals (Genius et al., 2010, 2013). Results of these studies suggest that cholestyramine may be an effective treatment to accelerate PFAS fecal excretion, but replication in studies with more participants is needed. No studies have assessed whether PFAS levels rebound when treatment with cholestyramine is discontinued.

Phlebotomy has been discussed as a way to reduce the body burden of PFAS. Genuis and colleagues (2014) asked six patients aged 16–53 years from a highly PFAS-exposed family to submit to routine blood draws (500 mL) for up to 5 years, resulting in a cumulative 2–12 L of blood drawn. The levels of PFOA, PFOS, and PFHxS decreased in these individuals over that time at a faster rate than expected according to first-order excretion kinetics. In a recent randomized controlled trial of 285 firefighters, serum PFOS and PFHxS concentrations were significantly reduced in subjects who regularly donated blood or plasma over 12 months compared with the control group; the decline was more pronounced in the plasma donation group (Gasiorowski et al., 2022). While these studies indicate that phlebotomy can be effective at reducing PFAS levels in blood, there are no established serum concentrations of PFAS at which the benefits of this intervention reasonably outweigh the harms, and the safety and utility of this approach are uncertain.

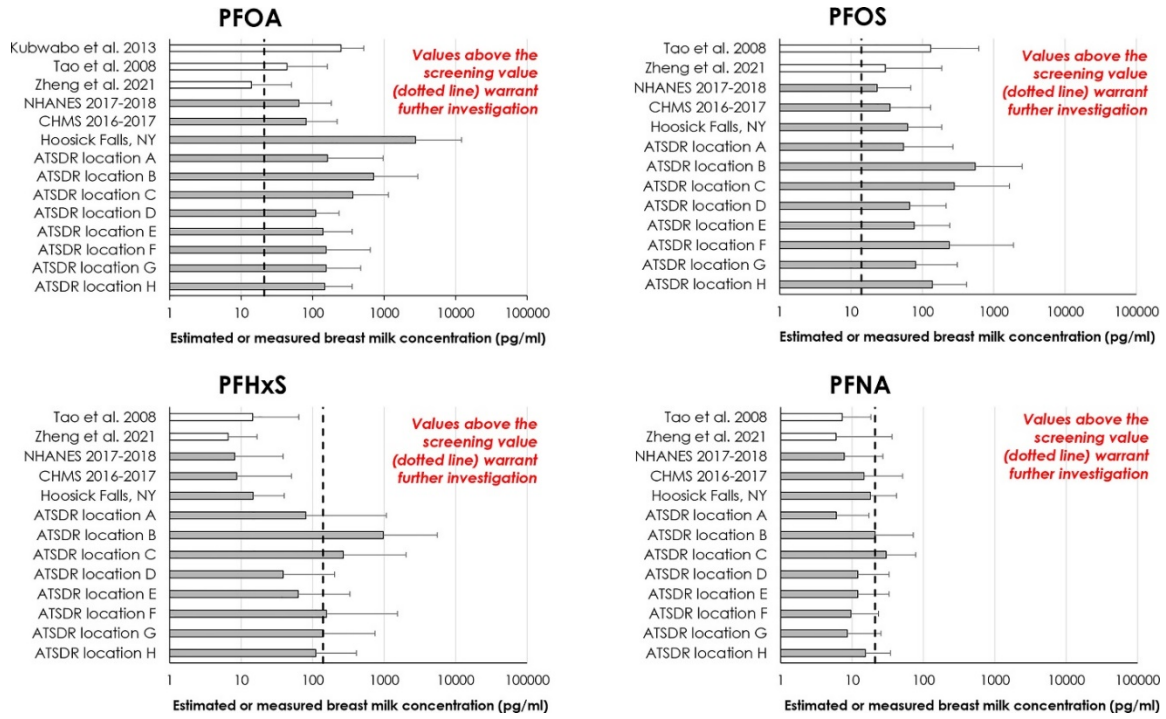

FIGURE 4-3 Measured (white bars) and estimated (gray bars) breast milk concentrations of per- and polyfluoroalkyl substances (PFAS) in the United States and Canada, in comparison with children's drinking water screening values (dotted line).
NOTES: Bars represent the mean measured breast milk levels for the data from Kubwabo and colleagues (2013) and Tao and colleagues (2008); the median measured breast milk levels from Zheng et al. (2021); and the geometric mean estimated breast milk levels for the National Health and Nutrition Examination Survey (NHANES), the Canadian Health Measures Survey (CHMS), and PFAS-contaminated communities. Error bars represent maximum measured concentrations in Kubwabo and colleagues (2013) and Tao and colleagues (2008), and 95th percentile estimated concentrations for NHANES, CHMS, and PFAS-contaminated sites. Of note, PFOS, PFHxS, and PFNA were not detected in breast milk samples from Kubwabo and colleagues (2013). The xx-axis is log-scale. Agency for Toxic Substances and Disease Registry children's drinking water screening values: PFOA (21 ppt), PFOS (14 ppt), PFHxS (140 ppt), and PFNA (21 ppt) (ATSDR, 2018).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

EXISTING ADVICE ON PFAS EXPOSURE REDUCTION

Several federally funded academic projects and nonprofit organizations provide information about PFAS, including how to identify potential community exposure and reduce personal exposure. Because concerned individuals look to online resources for data and information, a few of the resources are summarized here, with the caveat that they have not been tested empirically, and the data they present may be incomplete, or the sources on which the data are based may be missing. Furthermore, in discussing these online resources, the committee is not endorsing them, nor do their content and conclusions necessarily represent the committee's views. In addition to the sources discussed below, many state health departments have state-level resources on PFAS that may be trusted sources of information.

PFAS-REACH

PFAS-REACH (Research, Education, and Action for Community Health) is a project funded by the National Institute of Environmental Health Sciences to develop guidance materials and data interpretation tools for use by communities impacted by PFAS-contaminated drinking water. The project is led by Silent Spring, Northeastern University, and Michigan State University, with collaboration from community partner organizations that include Testing for Pease, Massachusetts Breast Cancer Coalition, and Community Action Works. The project's online resource center, PFAS Exchange, provides factsheets and interactive maps; a factsheet on how to reduce one's exposure is most relevant to the discussion in this chapter.[3] Figure 4-4 shows the PFAS Exchange recommendations.

FIGURE 4-4 Recommendations for reducing PFAS exposure available through the PFAS Exchange. SOURCE: PFAS-REACH project.

[3] See https://pfas-exchange.org/how-to-reduce-your-exposure-to-pfas (accessed June 17, 2022).

PFAS Project Lab

Northeastern University, one of the academic partners for the PFAS-REACH project, operates the PFAS Project Lab within its Social Science Environmental Health Research Institute (SSEHRI). Among the Lab's publicly available resources is the PFAS Sites and Community Resources Map.[4] The map interface provides the locations of known and suspected PFAS contamination sites (see Figure 4-5), as well as community resources and state action. The data were collected from government websites, news articles, and publicly available sources. The map began as a collaborative effort with the Environmental Working Group (EWG), an advocacy group (see below and Chapter 1, Figure 1-2). The SSEHRI map "aims to help affected residents and community groups to access information about data in their states and learn how to connect with other activists working on PFAS issues."[5]

Environmental Working Group

The EWG is included as a data source in the PFAS Project Lab. The EWG site also provides an interactive map that "serves to show the extent of PFAS water contamination as documented by states, the department of defense and EWG's testing," providing the locations of industrial and military sites with known PFAS contamination.[6] Additionally, the EWG provides a guide for avoiding exposure to PFAS chemicals. The EWG's recommendations are similar to those in the PFAS-REACH factsheet (see Figure 4-4) regarding consumer choices. The EWG has developed several consumer guides providing information on the chemicals (not just PFAS) present in a variety of commercial products, including sunscreen, cosmetics, personal care and beauty products, bug repellants, and household cleaners, among others.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

FINDINGS AND RECOMMENDATIONS

The committee found that few evidence-based recommendations can be made for reducing exposure to PFAS on an individual level.

Occupational exposures to PFAS may be much higher than community exposures. In accordance with the hierarchy of controls, methods for reducing workplace exposure can include replacing the chemical with a less hazardous one; engineering controls, such as ventilation to reduce inhalation of the chemical; administrative controls, such as rotating operations to reduce the amount of time an individual worker is around a chemical; or personal-level controls, such as personal protective equipment, including gloves and masks.

Ingestion is an important route of exposure to PFAS in the general population; thus it is important to reduce consumption of PFAS in drinking water and foods. Contamination of drinking water with PFAS is a widespread problem in the United States, and the extent of the contamination has not been completely characterized. Both municipal and private sources of drinking water (e.g., private wells) can be contaminated with PFAS as a result of fluorochemical manufacturing, use of firefighting foams, or discharge of landfill leachate to drinking water sources. If PFAS are in drinking water, switching to another source of water with lower PFAS concentrations will reduce exposure.

Consumption of game may also cause to exposure to PFAS. To date, 11 states have developed or are in the process of developing advisory guidelines for fish, wildlife, and other food products to protect human health from exposure to PFAS. These advisories offer guidance on limiting the quantity of consumption of these foods. These advisories are state-specific and range from do not eat (e.g., fish or deer in Michigan with PFOS concentrations over 300 parts per billion [ppb]) to no need to limit consumption (e.g., New Jersey fish with more than 0.56 nanograms per gram [ng/g] of PFOS). The Environmental Council of the States has compiled information from participating states on state PFAS standards, advisories, and guidance values (ECOS, 2020).

For clinicians, based on its review of the evidence on PFAS exposure reduction, the committee makes the following recommendations:

Recommendation 4-1[7]: Clinicians advising patients on PFAS exposure reduction should begin with a conversation aimed at first determining how they might be exposed to PFAS (sometimes called an environmental exposure assessment) and what exposures they are interested in reducing. This exposure assessment should include questions about current occupational exposures to PFAS (such as work with fluorochemicals or firefighting) and exposures to PFAS through the environment. Known environmental exposures to PFAS include living in a community with PFAS-contaminated drinking water, living near industries that use fluorochemicals, serving in the military, and consuming fish and game from areas with known or potential contamination.

Recommendation 4-2: If patients may be exposed occupationally, such as by working with fluorochemicals or as a firefighter, clinicians should consult with occupational health and safety professionals knowledgeable about the workplace practices to determine the most feasible ways to reduce that exposure.

Recommendation 4-3: Clinicians should advise patients with elevated PFAS in their drinking water that they can filter their water to reduce their exposure. Drinking water filters are rated by NSF International, an independent organization that develops public health standards for products. The NSF database can be searched online for PFOA to find

[7] The committee's recommendations are numbered according to the chapter of the main text in which they appear.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

filters that reduce the PFAS in drinking water included in the committee's charge. Individuals who cannot filter their water can use another source of water for drinking.

Recommendation 4-4: In areas with known PFAS contamination, clinicians should advise patients that PFAS can be present in fish, wildlife, meat, and dairy products and direct them to any local consumption advisories.

There are fewer evidence-based exposure-reduction recommendations for patients without known sources of exposure:

Recommendation 4-5: Clinicians should direct patients interested in learning more about PFAS to authoritative sources of information on how PFAS exposure occurs and what mitigating actions they can take. Authoritative sources include the Pediatric Environmental Health Specialty Units (PEHSUs), the Agency for Toxic Substances and Disease Registry (ATSDR), and the U.S. Environmental Protection Agency (EPA).

Recommendation 4-6: When clinicians are counseling parents of infants on PFAS exposure, they should discuss infant feeding and steps that can be taken to lower sources of PFAS exposure. The benefits of breastfeeding are well known; the American Academy of Pediatrics, the American Academy of Family Physicians, and the American College of Obstetricians and Gynecologists support and recommend breastfeeding for infants, with rare exceptions. Clinicians should explain that PFAS can pass through breast milk from a mother to her baby. PFAS may also be present in other foods, such as the water used to reconstitute formula and infant food, and potentially in packaged formula and baby food. It is not yet clear what types and levels of exposure to PFAS are of concern for child health and development.

Additionally, there is a critical need for more data to understand PFAS exposure among breastfed infants:

Recommendation 4-7: Federal environmental health agencies should conduct research to evaluate PFAS transfer to and concentrations in breast milk and formula to generate data that can help parents and clinicians make shared, informed decisions about breastfeeding.

At this time, it not possible to eliminate all sources of PFAS exposure. There are some sources people can try to limit if they desire and have the resources to do so. If patients are resource-limited, it is most important that if PFAS contamination of their water is known or suspected, they use water filtration or another source of water for drinking that is lower in PFAS. In keeping with the principle of adaptability, it is also important to direct patients to reliable sources of information on PFAS, such as ATSDR, the U.S. Environmental Protection Agency, and state and local departments of public health so they can obtain accurate and up-to-date information.

PFAS Testing and Concentrations to Inform Clinical Care of Exposed Patients

The Centers for Disease Control and Prevention (CDC) and various other health agencies routinely conduct biomonitoring, including measuring of exposure biomarkers in human tissues, as an important part of environmental public health surveillance (Latshaw et al., 2017). With the exception of a few environmental exposures, however, such as children's blood lead measurements, biomonitoring is rarely included in routine clinical care. Biomonitoring integrates all sources and routes of exposure into measurements of internal exposure. In this regard it is advantageous because it is more reflective of aggregate exposure than are measures of external exposure, but as a consequence, it does not identify the specific source of an exposure. Nonetheless, when properly interpreted, biomonitoring data can be used to monitor exposure levels and trends, evaluate potential health risks connected to specific sites or populations, and inform public health decisions (Latshaw et al., 2017).

Biomonitoring can be based on the direct measurement of environmental chemicals or their reaction or breakdown products (metabolites) in human tissues and fluids, such as blood (serum, plasma, and whole blood), urine, hair, nails, and breast milk (CDC, 2021; NRC, 1987). Traditionally, biomarkers have been classified as biomarkers of exposure, effect, or susceptibility (see Figure 5-1).

This chapter addresses options and considerations to guide decision making for per- and polyfluoroalkyl substances (PFAS) testing in a patient's biological samples, strategies for interpreting biomonitoring data, and PFAS concentrations that could inform clinical care of exposed patients.

OPTIONS AND CONSIDERATIONS TO GUIDE DECISION MAKING FOR PFAS TESTING

PFAS Laboratory Methods

There are no standard methods for PFAS exposure biomonitoring; some, but not all, laboratories use methods similar to those used by the CDC. Unlike most clinical laboratories, laboratories that offer PFAS testing are not subject to measurement standardization through external proficiency testing programs that evaluate laboratory performance against preestablished criteria. Laboratories that offer PFAS testing also need not comply with clinical certification, such as Clinical Laboratory Improvement Amendments (CLIA) certification, for reporting of results to patients. To support the quality and integrity of results, PFAS testing should be conducted in laboratories that meet the following criteria:

- have an extensive quality assurance/quality control (QA/QC) program (Kannan et al., 2021);
- report National Institute of Standards and Technology Standard Reference Material (NIST-SRM)–traceable data (Kannan et al., 2021); and
- employ laboratory methods with relative standard deviations of less than 15 percent and with limits of detection (LODs) in the picogram/mL region, consistent with the LODs of the CDC and academic laboratories (FDA, 2018; SWGTOX, 2013).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

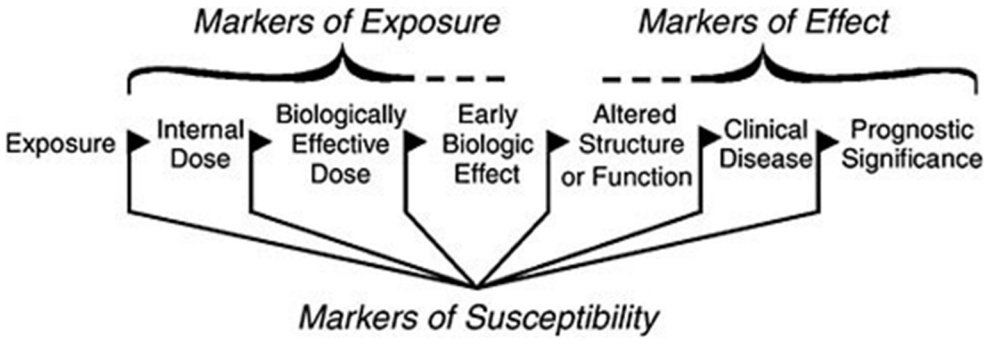

FIGURE 5-1 Simplified flow chart of classes of biomarkers.
SOURCE: NRC, 1987.

Which PFAS are most important to measure depends on the reasons for testing. A method comparable to that of the CDC that reports the linear and branched isomers of PFAS will allow comparison of individual results with those in the *National Report on Human Exposure to Environmental Chemicals* (CDC, 2015, 2021)—an informative method for individuals who wish to understand whether their exposure is high or low compared with background exposures in the U.S. population. For people with a past history of exposure to PFAS not included in the CDC panel, laboratory tests need to detect the compounds to which the person is suspected to have been exposed. However, adequate targeted exposure biomonitoring approaches may not currently exist for measuring many PFAS—especially those that are emerging or newly studied—that may be of concern in some communities. Most laboratories can test only for a limited number of PFAS; a typical PFAS panel will include fewer than 25 specific PFAS. SRMs exist for some but not all PFAS. NIST 1957 has reference values for 7 PFAS, and NIST 1958 includes 5 PFAS. The availability of SRMs for a broader range of PFAS would support higher-quality data for more PFAS.

Interpretation of PFAS biomonitoring data depends on the analytical methods being used, the matrix (blood, serum, plasma, urine, breast milk, etc.) in which the PFAS are measured, and the pharmacokinetics of the PFAS being measured.

Analytical Methods

Biological samples are generally analyzed using targeted analytical methods (i.e., for specific PFAS for which methods and standards are available), leaving a wide array of PFAS unaccounted for. Methods for measuring total extractable or adsorbable organofluorine can circumvent the limitations of targeted analytics, but these methods are also plagued by important challenges. Some non-PFAS are merged into the total organofluorine load. Moreover, clear health guidance values for total organofluorine have not been—and may very well never be—derived (see Box 5-1) because toxicological testing and risk assessments are typically conducted on a chemical-by-chemical basis so regulations can be derived for specific chemicals, although it is well known that single-chemical exposures are not reflective of how exposures occur in reality (NRC, 2009). Untargeted testing can also be used to assess exposure to PFAS, but is less standardized and precise than current targeted testing. Untargeted approaches, especially those that employ multiplexing techniques to account for high levels of endogenous chemicals, may provide a better overall picture of total PFAS exposure; as of now, however, those data would not be quantifiable and would provide only a qualitative (presence or absence) estimate of exposure (Guo et al., 2022).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

BOX 5-1
Total Organofluorine Testing

In communities that could be exposed to many different PFAS, total organofluorine testing could be considered. This method measures all the organic compounds containing fluorine in a sample. In so doing, it addresses the challenge of the lack of a standard reference for so many PFAS. In a study of blood samples from the Swedish population, for example, 70 percent of organofluorine compounds measured in samples from women aged 16–44 using extractable organofluorine measurements were not accounted for by the 63 PFAS measured in targeted analyses (Aro et al., 2021). However, these measures of total organic fluorine include compounds that have a fluorine atom but are not typically considered PFAS (e.g., pesticides such as trifluralin, fluometuron, and benefin; or drugs such as Prozac). With untargeted mass spectroscopy techniques, then, it may be possible to detect many more PFAS, but confirming their identity and quantifying them can be challenging if authentic standards are not available for them, which is often the case. At this point, moreover, methods for measuring total organofluorine are not standardized and are used primarily in academic and research laboratories (Aro et al., 2022), and there are no reference- or risk-based concentrations with which to compare measurements, making interpretation difficult. Still, the committee believes total organofluorine measurements hold promise for addressing the vast number of PFAS compounds as a class and notes that at least one commercial laboratory has started using this testing.

Biological Matrix

The specific PFAS to which a patient is at risk of exposure may also dictate the biological samples (e.g., blood, urine) that should be collected. Most studies measure PFAS in serum, which is likely the best matrix for measuring PFAS with long biological half-lives (Calafat et al., 2019). Other matrices, such as whole blood or urine, may be better suited to the detection of PFAS with short biological half-lives or those whose distribution in the body differs from that of the most commonly studied PFAS, such as perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic (PFOS) (Calafat et al., 2019; Poothong et al., 2017).

PFAS can be measured in multiple biological matrices, including but not limited to whole blood, serum, plasma, urine, breast milk, and hair (Alves et al., 2015). Overall, most studies have used either serum or plasma to evaluate PFAS exposure, and the measured concentrations in serum and plasma are comparable for PFOA, PFOS, and perfluorohexane sulfonate (PFHxS) (Ehresman et al., 2007). PFAS concentrations in other matrices can provide information on exposure during specific periods of life; for example, PFAS levels in segments of hair can help reconstruct historical exposures, and PFAS levels in breast milk make it possible to estimate infants' intake through breastfeeding (Zheng et al., 2021). On multiple occasions, this study's town hall participants indicated that they wanted to know not only their serum PFAS levels but also their breast milk levels, as these translate into early-life exposure for their children.

While urine, breast milk, and hair samples can be obtained relatively noninvasively, biomonitoring efforts in the United States have focused largely on serum, which is one of the most important biological compartments for the distribution of many PFAS in the body. Consequently, reference ranges and risk-based biomonitoring levels are limited or unavailable for other matrices. To date, the published literature provides measurements in breast milk for fewer than 200 people in the United States. If breast milk levels are measured, they can be interpreted by comparison with breast milk levels estimated using data from the National Health and Nutrition Examination Survey (NHANES), a series of surveys on the health status, health-related behaviors, and nutrition of the U.S. population (Lakind et al., 2022). Finally, much remains unknown about the distribution of the wide array of PFAS; for some of them, such traditional matrices as serum may not be optimal for estimating exposure to those PFAS whose distribution into these matrices is not significant.

Micro-samples are samples in which blood, usually from a pricked finger or heel stick, is collected into a small cuvette or spotted onto specially prepared filter paper and dried in open air under

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

ambient conditions. Micro-samples have several advantages: they are minimally invasive, do not have to be collected by a phlebotomist, reduce biohazard risks, and in some cases do not require refrigeration or freezing (Freeman et al., 2018). On the other hand, the blood collected from a pricked finger is capillary blood, which, unlike venous blood, contains interstitial fluid, and research is needed to determine whether capillary blood concentrations are comparable to serum measurements. Capillary blood also requires validation, particularly if collected as dried blood spots because volume is difficult to estimate as a result of hematocrit and chromatographic effects, although K+ standardization is showing promise (Barr et al., 2021). Newborn blood spots have, however, been used successfully in research studies to evaluate exposures to PFAS and assess changes in exposures over time (Gross et al., 2020; Ma et al., 2013; Yeung et al., 2019).

Pharmacokinetics

Some PFAS, including PFOA and PFOS, have a relatively long biological half-life, and measurement of these PFAS in serum may represent chemical exposures that occurred in past years. For some other PFAS, half-lives are on the order of days. For example, GenX is estimated to have a biological half-life of 81 hours (Clark and TCS, 2021); as a result, its measurement in serum or urine likely represents exposure that occurred much more recently, such as in the last few weeks. In such cases, samples taken at different times may be needed to derive an adequate representation of long-term exposure. Alternative measures for estimating long-term exposure include exposure reconstruction of drinking water levels. Also, some physiological events may influence biological levels of PFAS. Pregnancy and breastfeeding can increase PFAS excretion, for example, so levels in mothers may not be reflective of levels prior to pregnancy (Kato et al., 2014).

Sample Contamination

The concentrations of PFAS measured in most human tissues can be considered trace concentrations, making sample contamination an issue. Contamination occurring during sample collection, transport, storage, or preparation can impact the ability to interpret a laboratory result. For example, PFAS are commonly used in medical collection equipment, such as Teflon-capped blood test tubes. Teflon should therefore be avoided in sample collection equipment intended for PFAS measurement (NASEM, 2018a), and field blanks may need to be performed to ensure that contamination is negligible.

Commercially Available PFAS Testing Laboratories

A few laboratories currently offer PFAS testing. NMS labs (Horsham, Pennsylvania) offers PFAS testing through a clinician request for out-of-pocket payment (Test Code 39307, CPT Code[s] 82542; reported by town hall speakers to cost more than $600) or reimbursement from insurance. NMS can measure six PFAS in serum: perfluorobutanesulfonic acid (as the linear isomer) (PFBS), perfluoroheptanoic acid (as the linear isomer) (PFHpA), perfluorohexanesulfonic acid (as the linear isomer) (PFHxS), perfluorononanoic acid (as the linear isomer) (PFNA), perfluorooctanesulfonic acid (as the linear isomer) (PFOS), and perfluorooctanoic acid (as the linear isomer) (PFOA).[1] It is important to note that although the NMS panel does not completely overlap with the specific PFAS the committee was charged to evaluate, it does include PFOA, PFOS, and PFNA, three of the PFAS that are commonly reported as detected in NHANES and therefore typically contribute the most to exposure. The NMS panel would be more comparable to NHANES if it included the branched isomers of PFOS and PFOA, and PFHxS.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

EMPower DX (Framingham, Massachusetts), a subsidiary of Eurofins Scientific (Luxembourg City, Luxembourg), recently began offering direct-to-consumer testing for more than 40 PFAS via self-collected finger prick sample at a cost of $399.[2] The website for this lab reports that the test will "quantitatively determine PFAS concentrations … and positive or negative detections are reported with 99% confidence" (para. 4). In an email communication, company representatives reported that NIST reference standards are used, and that coefficients of variation are being developed for all PFAS in the panel.[3] As discussed above, method validation is needed for PFAS measurements from capillary blood to know how comparable they are to measurements from other PFAS tests.

Harms and Benefits of PFAS Testing

Based on the committee's principle of *proportionality* (see Chapter 2), it is necessary to consider the plausible harms and benefits associated with PFAS testing, although the weight of each will depend on the individual. Harms of PFAS testing include fear induced by blood draw, a small risk of injury or infection at the draw site, difficulties in interpreting results, and psychological stress that may occur when people who are tested learn that they or their family members have high levels of PFAS exposure. On the other hand, biomonitoring for PFAS blood levels may also alleviate fears associated with not knowing one's PFAS levels. Another potential benefit is increasing awareness of exposure so that exposures can be reduced. If sources of exposure are identified, actions taken to reduce these exposures, such as using a water filter, may also benefit family members in addition to the person who was tested. Community-level benefits may be associated with PFAS testing as well, such as empowering communities to respond to contamination and providing a baseline with which to evaluate the impact of community-level interventions to reduce exposure. Additionally, biomonitoring for PFAS in the context of epidemiologic studies could provide more information about PFAS-associated health effects.

To evaluate these potential harms and benefits associated with biomonitoring, the committee considered research studies evaluating the harms and benefits of reporting biomonitoring results to study participants (report-back). Report-back has been an active area of research by multidisciplinary teams, focused on whether and how to report study results to participants. These studies have varied in design, but methods used generally include interviews with study participants, investigators, and/or institutional review boards. They may also include focus groups; advisory councils; stakeholder workshops; observations at community meetings; one-on-one user testing of reports; and digital analytics, such as page views or time spent interacting with digital results pages. Investigators in these studies have identified harms associated with reporting of biomonitoring results, such as stress or concerns about the health effects associated with exposures, but the levels of stress reported have not been high enough to be considered extreme worry or panic (Emmett et al., 2009; Ohayon et al., 2017; Ramirez-Andreotta et al., 2016). Report-back studies have found further that when biomonitoring results are returned with information about how study participants could be exposed to the chemicals, what health effects are potentially associated with exposure, and what strategies could reduce exposure, participants express appreciation for receiving the results and feel empowered by the information (Adams et al., 2011; Altman et al., 2008; Brody et al., 2014; Giannini et al., 2018; Hernick et al., 2011; Perovich et al., 2018; Ramirez-Andreotta et al., 2016; Tomsho et al., 2019). Moreover, research studies have found that participants appreciate receiving test results even when the health implications of those results are unclear (Adams et al., 2011; Hernick et al., 2011; NASEM, 2018b). One study that compared the benefits of receiving individual versus aggregate biomonitoring results found that the former motivated participants to access information about environmental sources of chemical exposure and their health effects. The study also found that personal report-back increased engagement with exposure reports among Black participants.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Report-back was associated with a small increase in psychological stress, but the authors suggest that this stress could motivate appropriate behavior change to reduce exposure (Brody et al., 2021).

In many cases, community members who provided testimony at the committee's town halls were strongly in favor of PFAS testing and described being frustrated with the numerous difficulties encountered in accessing the testing (see Appendix B). Kristen Mello of Westfield Residents Advocating for Themselves (WRAFT) said to the committee:

> You don't have a problem getting an insurance assessor when your car is hit, you don't have a problem getting an insurance assessor when you have a tornado, but this slow motion unfolding environmental and public health disaster … is intentionally keeping the information from us so that we cannot take action.

Furthermore, Emily Donovan of Clean Cape Fear, said:

> Sadly it feels like guinea pigs are treated better, because at least their exposures are thoroughly studied for the betterment of humanity.

And Cathy Wusterbarth of Need Our Water said:

> We've tested the fish; we've tested the deer; we've tested the groundwater, the waterways, and the foam. When are we going to test the people?… The only risk [of testing] is to the polluters who do not want us to link them to our exposure.

Community members stated that they want access to PFAS testing so that they can understand their personal level of exposure and, as suggested by Ayesha Khan of Nantucket PFAS Action Group, "help those who are exposed to be proactive in reducing exposure and managing risk." An example of the how PFAS testing can help people manage health risks was presented by Sandy Wynn-Stelt, who learned that the drinking water in her home was contaminated with PFAS at a level more than 1,000 times the current U.S. Environmental Protection Agency (EPA) health advisory and paid out of pocket for PFAS testing. She shared her results with her clinician, and they decided to conduct clinical follow-up for any of the conditions associated with PFAS, including impacts on thyroid hormone levels. The results of her thyroid tests led to other follow-up and ultimately to her diagnosis of thyroid cancer. Wynn-Stelt believes her PFAS testing led to an earlier diagnosis and better outcomes for her cancer.

Social and Ethical Implications of PFAS Testing

Many town hall speakers voiced frustration about not having access to testing for PFAS. Speakers mentioned the injustices related to having been exposed to PFAS without their consent or knowledge and their frustration with being unable to access testing. They shared that PFAS testing, when available, is expensive. Town hall speakers also suggested that discussion of PFAS testing should be conducted in a culturally sensitive manner, be available in a variety of languages, and be at a reading level that the average American can understand (e.g., 4th-grade level).

Another important social consideration is that people who are tested for PFAS may experience social and economic conflicts related to their testing. If a PFAS blood test identifies community contamination, business revenue and property values may be adversely affected (Harclerode et al., 2021). People who draw attention to the contamination may experience anger and social isolation from other community members. Indeed, one town hall speaker asked that their name be removed from the town hall agendas and the committee's website because they were worried about angering neighbors by talking about their contaminated well.

Art Schaap, a dairy farmer in New Mexico, discovered that his farm was unknowingly subjected to severe PFAS contamination due to use of military aqueous film-forming foam (AFFF). After learning

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

of the contamination, Schaap voluntarily tested his herd for PFAS and discovered that his cows were highly exposed. The PFAS contamination on Schaap's farm devastated his livelihood because he had limited options available for getting rid of the contaminated animals in any profitable way. The dairy, beef, and rendering industries do not want PFAS-contaminated animals or products. The result for Schaap was the stranding of at least 4,000 cows, the death of 1,200, and the dumping of 1,500 loads of milk (see Appendix B for Schaap's complete testimony).

PFAS Testing: Findings and Recommendations

Applying the principle of *proportionality*, the committee believes that the benefits of PFAS testing for those who request it typically outweigh the harms (see Box 5-2). The harms reported in studies of report-back of biomonitoring results are worry about the harms of exposure, decreased property values, and potential social isolation or ostracism. In many cases, people who request testing are already worried about their exposure, which is why they are requesting the testing, and they may already be at risk of decreased property values associated with contamination. People in exposed communities have been "contaminated without consent" and "poisoned without permission."[4]

BOX 5-2
Potential Harms and Benefits of PFAS Testing

Potential Harms

- Fear of blood draw
- Small risk of injury or infection at draw site
- Difficulties in interpreting results
- Stress or concern about the health effects from exposure
- Decreased property values
- Social isolation
- Clinical consequences from medical follow-up as a result of exposure

Potential Benefits

- Increased awareness of exposure so that exposure can be reduced
- Empowerment of communities to respond to contamination
- Relief from the stress of not knowing one's exposure level
- Identification of the potential risk for health conditions associated with PFAS exposure to inform subsequent preventive care
- Help in monitoring whether efforts to reduce exposure are working through the conduct of baseline and follow-up tests.

An important element of the principle of *justice* is making PFAS testing easily accessible and readily available to all regardless of ability to pay, race, ethnicity, age, occupation, or location. Some populations are at increased risk of PFAS exposure and therefore may be at increased risk for a wide range of health conditions. These factors favor making exposure biomonitoring available to all who desire it. The principle of *autonomy* (i.e., respect for the ability of people to make their own health decisions) also favors allowing people who are likely to have a history of elevated exposure to PFAS and want PFAS testing to receive it and those who do not, to refuse it. These decisions require *shared decision making*[5] between patient and clinician and should include clarifying that exposure biomonitoring results

[4] Quotes from Andrea Amico, speaker at the committee's meeting on July 13, 2021.

[5] Barry and colleagues (2012) build on concepts in Charles (1997) and the Institute of Medicine's (2001) *Crossing the Quality Chasm: A New Health System for the 21st Century*, describing shared decision making as the

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

do not predict future health conditions and can only indicate the potential for an increased risk for certain conditions associated with exposures. Allowing people the opportunity to discuss with their clinicians whether they should undergo PFAS testing shows respect for patient values and is particularly important for people who have experienced environmental injustice as a result of PFAS contamination in their community.

The committee acknowledges that important factors need to be addressed. There are deficiencies in the current cost payment model, and the availability of PFAS testing may need to be addressed. Clinicians and health care facilities will also need to be made aware of reimbursement policies and laboratory codes (e.g., CPT; Reference Lab Order Code). New Hampshire recently required that health insurance cover PFAS blood testing.[6] PFAS testing can currently be ordered online without a provider, and the committee believes the testing and interpretation of its results are most beneficial if done with the guidance of a clinician.

The committee makes the following recommendations:

Recommendation 5-1: As communities with PFAS exposure are identified, government entities (e.g., Centers for Disease Control and Prevention [CDC]/Agency for Toxic Substances and Disease Registry [ATSDR], public health departments) should support clinicians with educational materials about PFAS testing so they can discuss testing with their patients. These educational materials should include the following information:

- **How people can be exposed to PFAS: Exposure routes include occupational exposures and work with fluorochemicals or as a firefighter; consumption of contaminated drinking water in communities that obtain their water from sources near commercial airports, military bases, fluorochemical manufacturing plants, wastewater treatment plants, landfills, or incinerators where PFAS-containing waste may have been disposed of or farms where sewage sludge may have been used; and consumption of contaminated fish or game if fishing or hunting occurs in contaminated areas. Individuals living near fluorochemical plants may also be exposed via inhalation of air emissions.**
- **Potential health effects of PFAS exposure and strategies for reducing exposure.**
- **Limitations of PFAS blood testing: PFAS blood testing does not identify the sources of exposure or predict future health outcomes; it only assesses body burden at the time of sample collection. For example, a person with low blood levels today may have had higher levels in the past.**
- **The benefits and harms of PFAS testing.**

Recommendation 5-2: Clinicians should offer PFAS testing to patients likely to have a history of elevated exposure. In all discussions of PFAS testing, clinicians should describe the potential benefits and harms of the testing and the potential clinical consequences (such as additional follow-up), related social implications, and limitations of the testing so that patient and clinician can make a shared, informed decision. Patients who are likely to have a history of elevated exposure to PFAS include those who have

pinnacle of patient-centered care: "The process by which the optimal decision may be reached ... is called shared decision-making and involves, at minimum, a clinician and the patient.... In shared decision-making, both parties share information: the clinician offers options and describes their risks and benefits, and the patient expresses his or her preferences and values. Each participant is thus armed with a better understanding of the relevant factors and shares responsibility in the decision about how to proceed" (p. 780).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- **had occupational exposure to PFAS (such as those who have worked with fluorochemicals or served as a firefighter);**
- **lived in communities where environmental and public health authorities (Centers for Disease Control and Prevention [CDC], Agency for Toxic Substances and Disease Registry [ATSDR], U.S. Environmental Protection Agency [EPA], state and local environmental or health authorities), or academic researchers have documented PFAS contamination; or**
- **lived in areas where PFAS contamination may have occurred, such as near facilities that use or have used fluorochemicals, commercial airports, military bases, wastewater treatment plants, farms where sewage sludge may have been used, or landfills or incinerators that have received PFAS-containing waste.**

When clinicians discuss results of PFAS with patients, the results will be most useful if accompanied by information on how exposure occurs, the potential associated health effects, and strategies that may reduce exposure—the same contextual information included in the report-back literature reviewed by the committee. Clinicians may also want to consider the frequency of PFAS testing based on the considerations in Box 5-3.

BOX 5-3
Considerations for Frequency of PFAS Testing

- Consider confirmatory retesting when the result is much higher or lower than anticipated given exposure history.
- Consider retesting if exposure changes because
  - public health actions (such as drinking water treatment programs or site cleanup are taken to reduce exposure);
  - the patient takes action(s) to reduce exposure (such as installing water filters, moving from a community with known high levels of PFAS in drinking water, or modifying occupational exposures); or
  - the patient moves into a community with known high levels of PFAS or otherwise has a suspected increase in exposure risk.
- For follow-up testing of PFAS with a long half-life, allow at least a year before retesting.
- Retesting is of no or limited value if initial serum levels are low and exposure does not change.

STRATEGIES FOR INTERPRETING BIOMONITORING DATA

There are two general strategies for interpreting chemical concentrations for exposure biomonitoring: reference-based (or descriptive) and risk-based (NRC, 2006). Both approaches can be useful to inform clinical care of exposed patients. Reference-based approaches can allow a clinician to understand whether the concentration of a chemical in the patient's biological sample is within or outside of the normal background range, while risk-based approaches can allow a clinician to determine whether a patient's biological concentration is below or above a value associated with tolerable, negligible, or minimal risk. Note that comparing concentrations of individual PFAS against reference- or risk-based levels may underestimate overall exposure to a complex mixture of PFAS and associated risk, such as in areas contaminated with PFAS used to replace other PFAS that have been phased out.

Figure 5-2 illustrates the distribution of biomarker concentrations in a generic reference population, expressed as cumulative frequency. As is commonly done in a clinical test, the 95th percentile of the distribution can be used to determine the upper-limit value of the test result. However, a different percentile may be chosen, depending on the circumstances, the characteristics of the reference population, the distribution of the results, and the purpose of the study. It is important to be aware that a particular

KD2436

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

cutpoint does not represent a level that separates the population into typical versus highly exposed (NRC, 2006). Box 5-4 describes the use of reference ranges to interpret other environmental exposures, such as exposures to lead and arsenic (see Box 5-4).

Reference-Based Approaches

Use of a reference-based approach to interpret biomonitoring data requires descriptive statistics from a reference population against which to compare the data. Typically, an individual's result would be compared with a statistical review of the reference data, typically in the form of a data distribution, such as 10th, 25th, 50th, 75th, and 95th percentiles within the reference population. The reference range offers a point of comparison, although some people or subgroups within that range may be subject to more or less exposure. This section describes a number of interpretive issues that arise with this approach. The validity and utility of biomonitoring values for use as reference ranges depend on the design of the studies from which those values were derived and the quality of the data, with special attention to the availability and comparability of data on the reference population in relation to the study population (NRC, 2006).

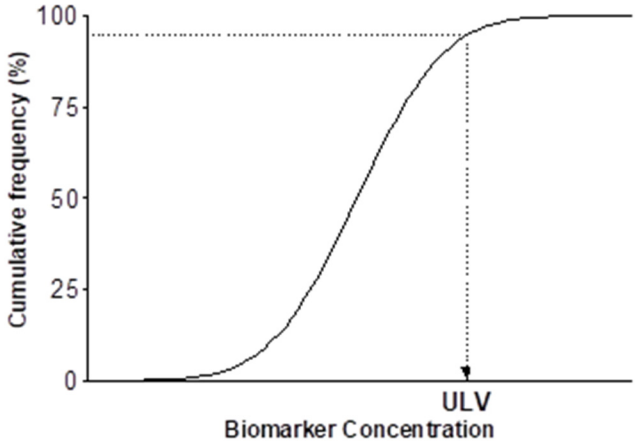

FIGURE 5-2 Distribution of biomarker concentrations in a generic reference population.
NOTE: ULV = upper limit value.
SOURCE: NRC, 2006.

BOX 5-4
Clinical Use of Reference Ranges

The examples of lead and arsenic may serve to illustrate the clinical use of biomonitoring results and reference ranges. In 2009, an elevated blood lead level (BLL) was defined by the Council of State and Territorial Epidemiologists as 10 micrograms per deciliter (µg/dL) or greater for children and adults. Subsequently, additional research documented health effects at BLLs below 10 µg/dL. In 2012, the Centers for Disease Control and Prevention (CDC) and the Advisory Committee on Childhood Lead Poisoning recommended that a BLL of 5 µg/dL or greater be defined as elevated. This reference range value was based on the 97th percentile of the BLL distribution for children aged 1–5 years, using 2007–2010 National Health and Nutrition Examination Survey (NHANES) data. This reference range value can be updated every 4 years using the two most recent NHANES surveys.[a] In May 2021, a BLL reference value of 3.5 µg/dL was set using the two most recent NHANES surveys to identify children with BLLs higher than those of most children. The adult elevated level was set at 5 µg/dL in 2012 on the basis of evidence of adverse health effects with no BLL threshold identified. The mean BLL at that

continued

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

BOX 5-4 *continued*

time was 1.09 µg/dL for U.S. adults older than age 20, with a 95th percentile value of 3.36 µg/dL. When a patient presents with a BLL above this reference value, the clinician, often in conjunction with public health officials, will initiate medical surveillance that includes repeated testing at intervals based on the level, history taking as to potential sources of the lead exposure, evaluation for signs and symptoms of lead toxicity, and treatment if necessary.[b]

Reference ranges are not used as commonly to interpret urinary arsenic levels. NHANES reports urinary total arsenic results (inorganic arsenic and methylated metabolites) to survey participants based on the following categories: ≤50 micrograms per liter (µg/l) is considered normal; >50 to <200 µg/L is considered high normal; and ≥200 µg/L is considered high. NHANES recommends that participants with a "high" result consult their medical provider. In a clinical setting, when the level of urinary arsenic is high normal (above 50 µg/dL or 100 µg/dL depending on the laboratory), the clinician will search for sources of exposure to arsenic and evaluate for signs and symptoms of arsenic toxicity. Diagnosis of arsenic toxicity is based on integration of exposure history, clinical findings, and laboratory results. In acute arsenic toxicity, total urine arsenic is typically greater than 1000 µg/L. In chronic arsenic toxicity, simple comparison with the "normal range" is not sufficient. It is important to evaluate for signs of arsenic toxicity and compare urine levels with a toxicity threshold from the literature (Baker et al., 2018).

[a] See https://www.cdc.gov/niosh/topics/ables/ReferenceBloodLevelsforAdults.html#_ftn3 (accessed June 17, 2022).
[b] See https://cdn.ymaws.com/www.cste.org/resource/resmgr/PS1/15-EH-01_revised_12.4.15.pdf (accessed June 17, 2022).

The reference range approach depends on data availability and data comparability for both the method used to measure PFAS and the population with which the results are being compared. Ideally, the reference population includes people similar in age, race or ethnicity, sex, and other demographic factors to the person whose PFAS testing result is being interpreted. Additionally, it is important that the PFAS be analyzed in the same tissues or fluids (blood, serum, breast milk, urine, etc.) and that the chemical analysis methods used are comparable and measure the same PFAS (NRC, 2006).

Note that interindividual variability in PFAS testing results may be a function of differences not only in exposure but also in pharmacokinetics with respect to excretory clearance. Such host factors as parity, breastfeeding status, menstrual status, age, genetic polymorphisms, concurrent acute or chronic disease, and medication use can affect pharmacokinetics.

Because NHANES is conducted in only a few communities each year, regional estimates or even urban versus rural comparisons cannot be made. Table 5-1 provides the most recent years of NHANES data (in serum ng/mL) for the total population sampled (ages 12 and older) for the four most predominant PFAS: PFOA, PFOS, PFHxS, and PFNA. These PFAS have been detected in almost all NHANES participants. Since the production and use of PFOS and PFOA were phased out, their levels have been declining (Brennan et al., 2021). Important limitations of NHANES data are that data for vulnerable populations, such as children younger than 12 years old and pregnant persons, are not always available. Children younger than 12 also are not included in the *National Report on Human Exposure to Environmental Chemicals*, although there are published estimates of PFAS exposure for children aged 3–11 years for 2013 and 2014 (Ye et al., 2018). Pregnant people are also not included in large numbers in NHANES, so multiple years of NHANES data will need to be combined to obtain a large enough sample for comparison (Watson et al., 2020); it may be more appropriate to compare pregnant people with the data for females in the same age range and time period. NHANES also does not specifically enroll participants in PFAS-exposed communities.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Distribution of PFAS Concentrations in Exposed Communities

While NHANES provides descriptive statistics for the general U.S. population, it is noteworthy that clinicians in exposed communities will likely encounter higher PFAS levels in their patients. Discussed below are examples from some of the contaminated communities throughout the United States. The first community identified as having known PFOA (C-8) exposure was residents living near the DuPont Teflon-manufacturing plant in Parkersburg, West Virginia. Contamination of six nearby public water districts and hundreds of private drinking water wells in West Virginia and Ohio was discovered, leading to public health concerns. As part of a settlement for a large class action lawsuit against DuPont, the C-8 Science Panel was established to determine potential health effects of PFOA exposure, and a 1-year cross-sectional survey (2005–2006), known as the C-8 Health Project, was conducted among approximately 70,000 residents with contaminated drinking water (Frisbee et al., 2009). The average measured serum PFOA level among residents in Little Hocking, Ohio, with the highest PFOA drinking water contamination was 227.6 ng/mL; for the entire C-8 Health Project survey, the average value for PFOA was 82.9 ng/mL. For comparison, the average PFOA serum level in the general U.S. population was 4.2 (ng/mL) in 2005 (CDC, 2015).

The 3M Company (Maplewood, Minnesota) produced PFAS at its Cottage Grove facility from the late 1940s until 2002. PFOA was a prominent PFAS made at this site. In late 2003, the Minnesota Pollution Control Agency discovered groundwater contamination near Cottage Grove and several other sites in the suburbs east of St. Paul, Minnesota (the 3M Chemolite site, 3M Woodbury site, and 3M Oakdale site, as well as the Washington County Landfill).[7] In 2006, water filtration systems for polluted public and private wells were installed to reduce PFAS exposure. The Minnesota Department of Health completed three projects to test blood levels of PFAS in people living in the east metro area of St. Paul (see Figure 5-3).

TABLE 5-1 Distributions of Serum PFAS Concentration (nanograms per milliliter [ng/mL]) in Four Cycles of the National Health and Nutrition Examination Survey (NHANES), 2011–2018

PFAS Chemical	NHANES Survey Years	Geometric Mean (95% confidence interval [CI])	50th Percentile (95% CI)	95th Percentile (95% CI)
PFOA	2011–2012	2.08 (1.95–2.22)	2.08 (1.96–2.26)	5.68 (5.02–6.49)
	2013–2014	1.94 (1.76–2.14)	2.07 (1.87–2.20)	5.57 (4.60–6.27)
	2015–2016	1.56 (1.47–1.66)	1.57 (1.47–1.77)	4.17 (3.87–4.67)
	2017–2018	1.42 (1.33–1.52)	1.47 (1.37–1.57)	3.77 (3.17–5.07)
PFOS	2011–2012	6.31 (5.84–6.82)	6.53 (5.99–7.13)	21.7 (19.3–23.9)
	2013–2014	4.99 (4.50–5.52)	5.20 (4.80–5.70)	18.5 (15.4–22.0)
	2015–2016	4.72 (4.40–5.07)	4.80 (4.40–5.30)	18.3 (15.5–22.7)
	2017–2018	4.25 (3.90–4.62)	4.30 (3.80–4.90)	14.6 (13.1–16.5)
PFNA	2011–2012	0.881 (0.801–0.968)	0.860 (0.750–0.960)	2.54 (2.28–2.89)
	2013–2014	0.675 (0.613–0.742)	0.700 (0.600–0.800)	2.00 (1.80–2.30)
	2015–2016	0.577 (0.535–0.623)	0.600 (0.500–0.600)	1.90 (1.50–2.20)
	2017–2018	0.411 (0.364–0.464)	0.400 (0.400–0.500)	1.40 (1.10–1.80)
PFHxS	2011–2012	1.28 (1.15–1.43)	1.27 (1.11–1.45)	5.44 (4.61–6.82)
	2013–2014	1.35 (1.20–1.52)	1.40 (1.20–1.60)	5.60 (4.70–7.10)
	2015–2016	1.18 (1.08–1.30)	1.20 (1.10–1.40)	4.90 (4.10–5.80)
	2017–2018	1.08 (0.996–1.18)	1.10 (1.00–1.20)	3.70 (3.30–5.60)

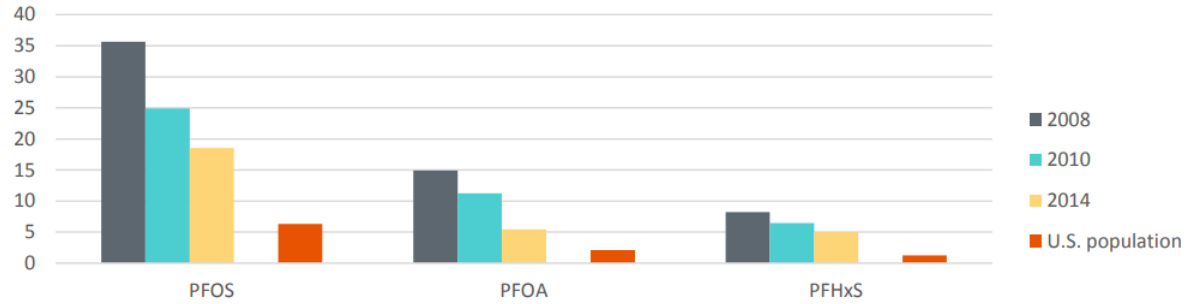

FIGURE 5-3 Geometric means of PFAS in blood from east metro St. Paul biomonitoring, in nanograms per milliliter (ng/mL).
SOURCE: U.S. population levels are from the 2011–2012 National Health and Nutrition Examination Survey (NHANES).

In Hoosick Falls, New York, high PFOA levels in water led to a public outcry, and a federal class action lawsuit was filed against Saint-Gobain Performance Plastics and Honeywell International. In 2016, the geometric mean PFOA serum level among participants in the Hoosick Falls Biomonitoring Study who used village water was 43.5 ng/mL (N = 1,640).[8] In the aftermath of Hoosick Falls, impacted community members voiced significant concern that the EPA's recommended health advisory level for drinking water at the time (400 ng/L[9]) provided insufficient protection. In January 2016, the EPA recommended that the community not drink water with PFOA in excess of 100 ng/L,[10] and in May 2016, after reviewing the existing body of PFOA and PFOS data,[11] it revised its health advisory level for drinking water to 70 ng/L for the sum of PFOA and PFOS. In New Hampshire, the state conducted biomonitoring in Merrimack Village District, where another Saint-Gobain plant had contaminated local drinking water. The average PFOA serum levels among participants was 3.9 ng/mL (N = 217).

In 2014, it was discovered that a public water supply well in Pease, New Hampshire, was contaminated with PFOS, PFOA, and PFHxS as a result of the use of firefighting foams at Pease Tradeport, a former Air Force Base. Beginning in April 2015, the New Hampshire Department of Health and Human Services conducted blood testing for people in communities where PFAS had been found in drinking water above lifetime health advisory levels. Between April and October 2015, 1,578 members of the Pease Tradeport community had their blood tested for PFAS. Results of biomonitoring from all individuals in the study showed that the geometric mean of PFAS exceeded that of the general U.S. population for PFOS (Pease: 8.59 ng/mL, NHANES: 6.31 ng/mL), PFOA (Pease: 3.09 ng/mL, NHANES: 2.08 ng/mL), and PFHxS (Pease: 4.12 ng/mL, NHANES: 1.28 ng/mL).[12]

Communities in Bucks and Montgomery counties in Pennsylvania have detected PFOS in their drinking water from use of firefighting foams during military activities. In response to this water contamination, the state health department conducted biomonitoring for PFOS exposure. The average PFOS serum level in this community was 10.2 ng/mL (N = 235).[13] A military base in Newburgh, New

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

York, also contaminated drinking water in that community, resulting in a median PFOS serum level of 16.3 ng/mL (N = 1,917).[14]

The primary manufacturer of PFOS, 3M, has also been implicated in drinking water contamination, in Decatur, Alabama. In a community study there, the median level was 39.3 ng/mL (N = 121) among participants with contaminated drinking water.[15]

Risk-Based Approaches

The most complex approaches for interpreting biomonitoring data are those that evaluate the risk associated with a biomonitoring result. Evaluation of risk may be desirable given the importance of the question of how risky a blood concentration is, as well as the fact that the descriptive approaches provide only relative information without assessing the risk to human health (NRC, 2006). Some exposure disease processes are thought to have a "threshold" or exposure level that needs to be exceeded before a response occurs, while others are thought to have a "nonthreshold" response such that there is no level at which no harm occurs. Examples of nonthreshold dose responses at a population level include lead, particulate matter, radon, and secondhand smoke. To set standards for nonthreshold effects, an acceptable risk needs to be determined (NRC, 2009). The standard reflects the expected daily intake associated with an acceptable risk for one or more adverse outcomes. Drinking water health advisories are risk-based standards that use dose estimates associated with daily consumption to predict long-term health effects. As a result, they should not be used to interpret biomonitoring results that represent an integration of multiple exposure sources over different periods depending on PFAS-specific half-lives (see Box 5-5).

BOX 5-5
PFAS Serum Levels Are Not Directly Comparable to PFAS Drinking Water Levels

In an effort to interpret PFAS testing results, members of the lay public sometimes compare PFAS levels in serum with PFAS drinking water advisory levels. This comparison may involve converting the units of the PFAS serum levels (usually given in nanograms per milliliter [ng/mL] of blood) to align with how PFAS drinking water advisory levels are generally reported (as nanograms per liter [ng/L] of water). The committee strongly discourages this comparison. Drinking water advisory levels reflect the levels of PFAS (in ng/L of water) that are assumed to represent a tolerable, negligible, or minimal risk for daily consumption in addition to other sources of exposure. In contrast, PFAS serum (ng/mL) levels are an integration of multiple exposure sources representing different periods of exposure, depending on PFAS-specific half-lives.

The committee also strongly recommends against translating a drinking water advisory level into a "safe" serum PFAS level. Using an online resource (https://www.ics.uci.edu/~sbartell/pfascalc.html [accessed June 16, 2022]; Bartell et al., 2017; Lu and Bartell, 2020), calculations can be made to answer such questions as "How long will it take for my serum PFOA levels to return to normal now that there's no more PFOA in my water?" or "My water has PFOA in it, but my blood hasn't yet been tested; do you expect my serum PFOA levels to be elevated?" The online calculator includes four PFAS chemicals (PFOA, PFOS, PFHxS, and PFNA) and an optional physiological adjustment to the serum half-life for menstruation. Although informative for some questions, the calculator does not allow users to include exposure sources other than drinking water. In contrast, agencies typically account for the contribution of drinking water to total exposure (e.g., 20 percent) when determining drinking water advisory levels. Serum PFAS levels reflect an integration of multiple exposure sources at a single time and are distinct from recommended levels in water for daily consumption.

Instead of comparing PFAS serum levels with PFAS drinking water levels, the committee recommends that individuals refer to health-based and reference-based serum levels.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

There are several options for deriving serum or plasma concentrations that are consistent with health-based guidance values. In the most straightforward risk-based approach, epidemiologic studies with exposure-response relationships could be used to conduct biomonitoring-based risk assessment. As presented below, the German Human Biomonitoring Commission (HBM Commission) reviewed the epidemiologic literature to compile serum or plasma levels with and without observable effects. Contrasting patient serum PFAS levels with levels with or without effects in an epidemiologic study can facilitate understanding risk for the given response endpoint (Apel et al., 2020).

Another option is to derive serum or plasma concentrations that are consistent with health-based guidance values such as reference doses (RfDs) and tolerable daily intakes (TDIs), commonly referred to as biomonitoring equivalents (BEs) (Hays et al., 2008). Because these values are frequently based on animal experiments, some with no measure of serum concentrations, pharmacokinetic modeling is often used to translate a point of departure (e.g., the benchmark dose) into animal serum levels, which can be converted into BEs by adjusting for uncertainty factors. For this report, the committee focused on the human data to evaluate risk levels.

The committee reviewed the International Human Biomonitoring (i-HBM) Working Group dashboard to search for biomonitoring guidance values for PFAS and found that the only risk-based standards were the German HBM values for PFOS and PFOA. The committee also searched for RfDs based on human data in the tables in the *Environmental Council of the States White Paper on Setting State PFAS Standards* and in the authoritative reviews considered in the committee's review of PFAS health effects (see Chapter 3). The committee found that only the European Food Safety Authority (EFSA) scientific opinion contained a risk-based value estimated in humans.

German HBM Values

The German HBM Commission develops human biomonitoring (HBM) values for interpretation of the concentrations of environmental chemicals measured in biological samples. These values, which are derived for the general population (including vulnerable subgroups) with chronic exposure, represent concentrations below which no observed risk of adverse health effects is expected (HBM-I) or above which adverse health effects are possible (HBM-II) (Schulz et al., 2011).

In 2021, the HBM Commission published HBM-I values for PFOS and PFOA in plasma, which is assumed to have concentrations similar to those of serum (Ehresman et al., 2007; Hölzer et al., 2021). To derive HBM-I values, the HBM Commission conducted a literature review for studies of the health effects of PFOS and PFOA. It then selected epidemiological studies and identified points of departure for various health effects for use in quantifying an association between exposure and critical effects. The determination of these points of departure varied depending on the methods of each study. Where epidemiological analyses were based on quantiles of exposure, the point of departure represented the lower limit of the quantile for which significantly increased risk was observed. For studies using continuous measures of exposure, points of departure were based on either benchmark dose-response modeling or a qualitative assessment of the effects and dose-response relationship. Health outcomes in the reviewed studies included fertility (time to pregnancy), pregnancy-induced hypertension and diabetes, reduced birthweight, serum cholesterol concentrations, serum uric acid concentrations, reduced antibody response to vaccination, pubertal development, thyroid metabolism, and onset of menopause. Once points of departure for each compound, study, and outcome had been selected, HBM-I values were selected in the low range of points of departure for both chemicals. The points of departure identified represented a wide range of exposure values. It was determined that the HBM-1 values were 2 ng/mL for plasma PFOA and 5 ng/mL for plasma PFOS. The HBM Commission considers these HBM-I values to be precautionary. Exceedance of these levels should not be interpreted as increasing risk, but may warrant efforts to reduce exposure (Hölzer et al., 2021).

The HBM Commission also established HBM-II values in 2021, based on epidemiological studies on PFOA or PFOS and adverse health outcomes, including reduced birthweight, developmental effects, reduced fertility, reduced antibody response to vaccination, increased cholesterol concentrations

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

(low-density lipoprotein [LDL] and total cholesterol), and type 2 diabetes. Because HBM-II values represent levels above which adverse health effects are possible, the points of departure for those values differed from those identified for HBM-I values. Where appropriate, benchmark dose-response modeling was used to determine a level for a given effect level. For studies with continuous exposure data in which benchmark dose-response modeling could not be performed, risk estimates from adjusted regression analyses were used. In the case of studies in which analyses were based on quantiles of exposure, the median value of the lowest quantile with a significant association with an adverse health outcome was used as the point of departure.

The points of departure chosen represent quantitatively defined changes (such as 5–10 percent, calculated with a confidence interval for a population) in certain target parameters (e.g., morbidity, laboratory values). In the evaluation of reduced birthweight, for example, the points of departure of 10 ng PFOA/mL and 15 ng PFOS/mL were determined from a meta-analysis that observed a reduction in birthweights by approximately 20 g per ng PFOA/mL and 20 g per ng PFOS/mL. Compiled points of departure were 3–10 ng/mL for PFOA and 1–30 ng/mL for PFOS. HBM-II values for plasma PFOA (10 ng/mL) and PFOS (20 ng/mL) were established as the mid- to high values in these ranges for the general population, excluding women of childbearing age. Lower values were derived for plasma PFOA (5 ng/mL) and PFOS (10 ng/mL) in women of childbearing age, mainly because studies indicated associations with developmental toxicity, reduced fertility, and increased incidence of gestational diabetes. However, the HBM Commission indicated that there is ample uncertainty around HBM-II values for PFOA and PFOS (Schümann et al., 2021).

European Food Safety Authority's Human Point of Departure

In 2020, EFSA published a scientific opinion on the derivation of a tolerable weekly intake for the sum of four predominant PFAS: PFOA, PFOS, PFHxS, and PFNA. Following a review of the animal and epidemiological literature on adverse health effects of PFAS, immunological endpoints were considered the most robust and sensitive for risk assessment. An epidemiological study in German children was used as the critical study for deriving the health-based guidance value. In this study, children's serum PFAS levels at 1 year of age were associated with lower antibody titers against diphtheria at a $BMDL_{10}$ (the lower one-sided confidence limit of the benchmark dose for a 10 percent response) value of 17.5 ng/mL for the sum of PFOS, PFOA, PFHxS, and PFNA (Abraham et al., 2020). Physiologically based pharmacokinetic (PBPK) modeling was used to translate this value in children's serum into a daily dose in their mothers, assuming that levels at 1 year of age in breastfed children reflect primarily the body burden acquired through placental and lactational transfer. To reach this $BMDL_{10}$ value in children's serum at the end of 12 months of breastfeeding, EFSA estimated that the maternal level at 35 years of age would need to be 6.9 ng/mL for the sum of the four PFAS, a level associated with an estimated maternal intake of 0.631 ng/kg body weight/day. Although EFSA did not specifically aim to determine acceptable serum PFAS levels, the 6.9 ng/mL serum concentration could be considered a serum level for women of reproductive age below which risk is negligible.

PFAS Concentrations That Could Inform Clinical Care: Findings and Recommendations

The HBM Commission has identified risk-based levels for two PFAS chemicals—PFOS and PFOA—while EFSA has established such values for the sum of PFOA, PFOS, PFHxS, and PFNA. No individual values are available for PFHxS and PFNA, and no values could be found for methyl-perfluorooctane sulfonamide (MeFOSAA), perfluorodecanoic acid (PFDA), and perfluoroundecanoic acid (PFUnDA). The lowest PFAS risk-based level is 2 ng/mL (HBM-I for PFOA), and the highest PFAS risk level is 20 ng/mL (HBM-II for PFOS in the general population), demonstrating that risks are unexpected below 2 ng/mL and that the risk of PFAS-associated effects at the population level is increased at 20 ng/mL. The risk-based levels for sensitive populations fall between 2 ng/mL and 20 ng/mL (see Figure 5-4).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

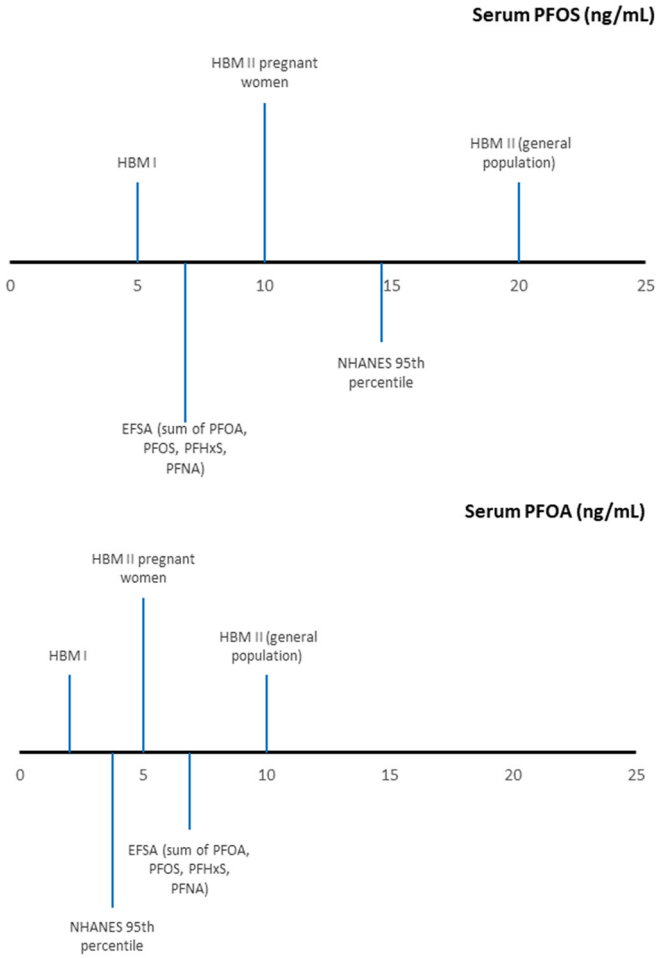

FIGURE 5-4 Reference- and risk-based serum PFOS and PFOA concentrations that could inform clinical assessments.
NOTES: Human biomonitoring (HBM) values are risk-based values derived from a compilation of epidemiological studies and represent levels at which no effect is expected (HBM-I) and above which effects are possible (HBM-II). The European Food Safety Authority (EFSA) risk-based value is a maternal serum PFAS concentration derived from an epidemiological study of children's prenatal and postnatal PFAS exposure and decreased antibody response to vaccines; maternal levels below this value are expected to have negligible impact on children's response to vaccines. The National Health and Nutrition Examination Survey (NHANES) reference-based serum concentration represents the 95th percentile of serum levels in a representative sample of the population aged 12 and older. PFHxS = perfluorohexanesulfonic acid; PFNA = perfluorononanoic acid; PFOA = perfluorooctanoic acid; PFOS = perfluorooctanesulfonic acid.

The committee used weighted data from NHANES to estimate PFAS exposures in the U.S. population. The HBM-I value, or the value below which effects are not expected, for PFOA (2 ng/mL) is the 73rd percentile, and the corresponding value for PFOS (5 ng/mL) is the 57th percentile. The HBM-II value, or the value above which effects may be expected for PFOA (10 ng/mL) is the 99th percentile and for PFOS (20 ng/mL) is the 98th percentile. For women of childbearing age (15–49), the HBM-II values for pregnant women for PFOS and PFOA are the 99th and 98th percentile, respectively. The committee observed that 25 percent of the U.S. population is exposed to PFAS above the EFSA point of departure (6.9 ng/mL sum of PFOA, PFOS, PFHxS, and PFNA).

Given the large number of PFAS and the fact that all humans are exposed to mixtures of PFAS, an approach that accounts for mixtures of PFAS would better inform clinical care than do single-chemical

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

exposure values. Because the toxicities of different PFAS may not be equal, an approach using potency factors (e.g., dioxins) may be optimal for determining how a mixture of PFAS may exert its toxic effects. However, EFSA did not identify studies comparing the dose-response curves for different PFAS that would allow derivation of their potencies, and interspecies and sex differences also would complicate that effort. Thus EFSA assumed equal potencies for the four selected PFAS, which in humans share half-lives on the order of years. To facilitate easier comparison with estimated exposure, this calculation was performed on a weight rather than a molar basis. Bil and colleagues (2021) recently developed relative potency factors for several PFAS, which when applied result in the sum of PFOA equivalents in a mixture. Overall, the approach entails uncertainties, as the potency factors are derived from animal studies using mainly liver endpoints, which may correlate with effects in humans but to what degree is unknown. The additive approach used by EFSA has advantages. It is simple to apply and has been used in other efforts to regulate exposures to mixtures.[16] Also, there is evidence that many PFAS have similar toxic effects (Kwiatkowski et al., 2020). The committee believes the additive approach could be applied to the PFAS currently measured in the NHANES (MeFOSAA, PFHxS, PFOA [linear and branched isomers], PFDA, PFUnDA, PFOS [linear and branched isomers], and PFNA). Applying this approach of weight-based dose additivity, and using the HBM Commission's values, the committee makes the following recommendations (see Figure 5-5):

Recommendation 5-3: Clinicians should use serum or plasma concentrations of the sum of PFAS* to inform clinical care of exposed patients, using the following guidelines for interpretation:

- **Adverse health effects related to PFAS exposure are not expected at less than 2 nanograms per milliliter (ng/mL).**
- **There is a potential for adverse effects, especially in sensitive populations, between 2 and 20 ng/mL.**
- **There is an increased risk of adverse effects above 20 ng/mL.**

*** Simple additive sum of MeFOSAA, PFHxS, PFOA (linear and branched isomers), PFDA, PFUnDA, PFOS (linear and branched isomers) and PFNA in serum or plasma. Caution is warranted when using capillary blood measurements as levels may differ from serum or plasma levels.**

The committee estimated that for the sum of PFAS in the NHANES, 2 ng/mL corresponds to the 2nd percentile, and 20 ng/mL corresponds to the 91st percentile, indicating that 89 percent of the U.S. population falls in the orange area in Figure 5-5, and 9 percent in the red area. Choosing cutoffs, as the committee has done, reflects ethical decisions and risks overstating or understating the risk of PFAS exposure given the uncertainty of the available information. Values suggested herein were derived from epidemiological studies evaluating associations at the population level, and the relevance of these values to interpret risk in individuals is uncertain. Also, these values were derived in part from studies in vulnerable populations (e.g., children, pregnant women), and so should account for many sensitive populations, but they may not protect all populations. Moreover, the assumption of weight-based dose additivity is likely an oversimplification. The molar sum may be more appropriate if the equal potency of all PFAS is assumed, and future research to produce toxic equivalency data or identify relevant potency factors could help refine the calculation (Bil et al., 2021). Furthermore, regardless of how the dose is calculated, there may not even be a level of PFAS exposure without some biological effect. Still, the increased risk from low levels of exposure is better addressed through population-health efforts than through individual action. The cutoff levels should be updated as more information becomes available.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

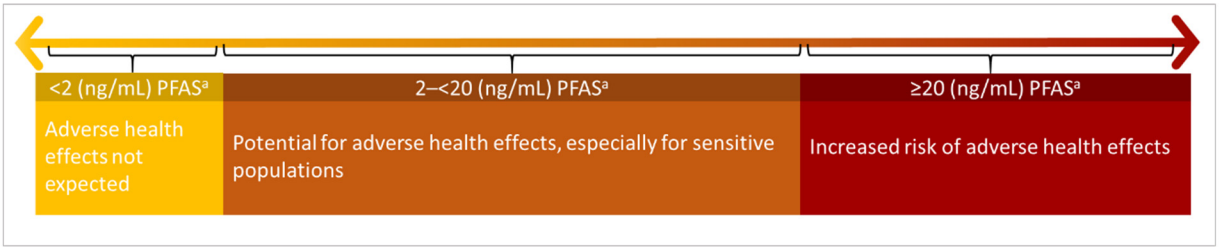

FIGURE 5-5 Graphical display of levels of PFAS to inform clinical care for the sum of MeFOSAA, PFHxS, PFOA (linear and branched isomers), PFDA, PFUnDA, PFOS (linear and branched isomers), and PFNA in serum or plasma.

The committee acknowledges that, in many communities, a large percentage of the population may have exposures to PFAS that would be considered high using the cutoffs presented here. This does not mean that health effects will occur, but likely relates to increased risk. More reference- and risk-based values are needed for other PFAS and other biological matrices, but given the expansiveness of the class, approaches based on relative potency factors may be more successful than developing risk-based levels for each PFAS in addressing this gap.

The committee also acknowledges the existence of data gaps with respect to reference populations. Appropriate PFAS reference populations may not be available for vulnerable populations such as pregnant people and young children, as pregnant people are included in low numbers in NHANES, and children younger than 12 are not routinely included in the publicly available data. Therefore, the committee makes the following recommendation:

Recommendation 5-4: The National Health and Nutrition Examination Survey should begin collecting and sharing more data on children younger than 12 years of age and pregnant people to generate reference populations for those groups.

CONCLUSION

Determining options and considerations to guide decision making for PFAS testing and PFAS concentrations that could inform clinical care of exposed patients will be beneficial in helping communities identify those who have elevated exposure to those chemicals. Testing for PFAS offers an opportunity to identify those who may be at increased risk of certain health outcomes. The recommendations in this chapter could expand PFAS testing among people already integrated into the health system (i.e., those with reliable insurance or other health care coverage). The committee acknowledges, however, that PFAS testing is expensive. Race, age, and other social and demographic characteristics already have disadvantaged many patients from accessing clinical preventive services. That disadvantage would be compounded by the expansion of PFAS testing services, as those services should be linked to counseling on steps for mitigating exposure and its impacts. Therefore, encouraging testing primarily among people with relatively stable access to care could have the unintended effect of aggravating disparities in exposure to PFAS, a severe disadvantage of encouraging testing without a funded, national PFAS testing program.

Guidance for Clinicians on Exposure Determination, PFAS Testing, and Clinical Follow-Up

Despite continued uncertainty about the exact nature of risks from PFAS exposure, clinicians will need to advise and make decisions with patients regarding their exposure. While there is evidence of an association of PFAS with several health outcomes, the likelihood that a particular individual will have any specific adverse health outcome following exposure to PFAS cannot currently be determined with great specificity. There are also gaps in knowledge about how individuals can reduce any potential risks related to PFAS exposure. Despite these gaps, however, many individuals and communities expect clinicians to address PFAS-associated risks as part of routine health care delivery. Although close monitoring and exposure mitigation might prevent or lessen the severity of health effects for those exposed to PFAS, aggressive clinical follow-up could lead to unnecessary treatment, with attendant risk of treatment-related adverse effects; increase patients' anxiety; and even provide false assurance. For these reasons, trust and clear communication between clinicians and patients are of the utmost importance as they face the task of making decisions that consider all options and incorporate informed preferences, although how best to include children, especially adolescents, in shared decision making is a complicated matter and an active focus of research (Boland et al., 2019). Ongoing and future research should eventually guide clinicians in predicting patient risk and provide an understanding of the benefits and harms of interventions designed to avoid adverse health outcomes.

CRITERIA FOR SCREENING

Screening is the process of testing to identify individuals at high risk for developing a clinical condition or those who have a condition for which signs or symptoms may not be evident. Population screenings are one type of clinical preventive services recommended by health and medical professional agencies and organizations such as the American Academy of Family Physicians (AAFP), the American College of Obstetricians and Gynecologists (ACOG), the American Academy of Pediatrics (AAP), the American Heart Association (AHA), the Health Resources and Services Administration (HRSA), and the U.S. Preventive Services Task Force (USPSTF). These organizations usually recommend population-level screenings as part of routine clinical care when it is clear that they offer a net benefit (compared with potential harms of the screening itself and any subsequent treatment). Although there are different frameworks for determining when to adopt population-level screening, the criteria articulated by Wilson and Jungner (1968) are a common platform for these frameworks:

- The condition should be an important public health concern.
- There should be a treatment for the condition.
- Facilities for diagnosis and treatment should be available.
- There should be a latent stage of the condition.
- There should be a test or examination for the condition.
- The test should be acceptable to the population.
- The natural history of the disease should be adequately understood.
- There should be an agreed-upon policy on whom to treat.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- The total cost of finding a case should be economically balanced in relationship to medical expenditure as a whole.
- Case finding should be a continuous process.

The degree to which these criteria are applied and how they are weighted must be tailored to the particular clinical issue and the perspective of those developing the preventive service. For example, the degree to which the evidence base must be clear can vary based on the urgency of the clinical context, and cost is often not explicitly considered because cost/benefit data from the societal perspective are rarely available. Despite this variation, a key common theme across all frameworks is the need to assess whether the expected benefits of population screening exceed the potential harms. This assessment can be challenging when significant scientific uncertainty exists, as is the case for population screening for PFAS exposure. The committee faced challenges in making population-level recommendations related to the following issues:

- PFAS testing could identify risks for many diverse health outcomes, as opposed to the usual case in which screening identifies one condition or a group of related conditions. Assessment of benefit and harm is difficult if the various potential health outcomes differ in this regard. Furthermore, developing recommendations for clinical follow-up after PFAS exposure is challenging because of the heterogeneity of potential health outcomes.
- The benefits of screening might accrue to individuals other than those who would be screened. For example, determining that an individual had a harmful environmental exposure might not help that person but could lead to broader public health measures that could protect the community.

When there are gaps in knowledge about the benefits and harms of screening or when benefits and harms are closely matched, clinicians should assess individual patient preferences. Informed decision making can be challenging given the above gaps and the limited time clinicians and patients have together. Because standard screening criteria have important limitations in settings of substantial scientific uncertainty, such as PFAS-related health effects, this chapter offers recommendations for basing screening decisions on the principles the committee proposes in Chapter 2.

PFAS-ASSOCIATED HEALTH OUTCOMES

The committee identified several health outcomes associated with PFAS exposure (see Chapter 5). Many are common diseases in the general population, and all have multiple known risk factors (Schrager, 2018). The committee believed it was important to categorize the strength of the evidence for each outcome, but concluded that all conditions with an association should be considered for patient follow-up, as acknowledging the potential risk may make doctors and patients more likely to prioritize screenings. If a patient has a known or suspected exposure to PFAS, the committee encourages clinicians to prioritize screenings for those conditions related to PFAS when relevant and possible. The committee encourages clinicians to use evidence-based best practices and strategies when speaking with patients to support shared decision making and clear health risk communication. Resources such as the Consumer Assessment of Healthcare Providers and Systems (CAHPS) Ambulatory Care Improvement Guide can provide evidence-based trainings, tools, and strategies for shared decision making and clear communication (AHRQ, 2020). The committee did not conduct a meta-analysis to determine the level of increased risk posed by PFAS exposure for each health outcome. Risks vary by exposure level, life stage, and whether patients have other risk factors for developing a health effect. These uncertainties make it infeasible to determine the optimal screening tests and their frequency.

The committee found sufficient evidence of increased risk for the following health outcomes with exposure to PFAS:

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

- reductions in birthweight;
- dyslipidemia in children and adults;
- kidney cancer in adults; and
- decreased antibody response in children and adults, but with insufficient evidence of an increase in risk or severity of infection or differences in vaccine effectiveness.

The committee found limited suggestive evidence of increased risk for the following health outcomes with exposure to PFAS:

- breast cancer in adults,
- pregnancy-induced hypertension (gestational hypertension and preeclampsia),
- liver enzyme elevations (in children and adults),
- testicular cancer (in adults),
- thyroid dysfunction (in adults), and
- ulcerative colitis (in adults).

For many of these adverse health effects, however, including cancers, it is unclear what clinicians and individuals can do to monitor for their development and intervene to lower the risk related to PFAS exposure. Guidance for clinicians' engagement in sharing decision making with their patients regarding follow-up care for PFAS-associated health outcomes is included later in this chapter.

Clinical Practice Guidelines for PFAS-Associated Health Outcomes

The committee reviewed clinical practice guidelines for the health effects associated with PFAS exposure, as well as the recommendations from the C-8 Medical Panel (see Table 6-1). The C-8 Medical Panel developed a medical monitoring protocol for a community with high PFAS exposure surrounding Parkersburg, West Virginia. The protocol specifies follow-up for human diseases for which the C-8 Science Panel found a probable link: dyslipidemia, kidney cancer, pregnancy-induced hypertension (gestational hypertension and preeclampsia), testicular cancer, thyroid disfunction, and ulcerative colitis.

Outcomes with Sufficient Evidence of Association

Dyslipidemia in Children and Adults

In the United States, blood testing for lipid and cholesterol levels is recommended throughout the life course based on age and risk factors. AAP recommends that all children be screened once between ages 9 and 11 years and again between 17 and 21 years, with selective screening for children over 2 years of age with a family history of lipid and cholesterol disorders or heart disease (Richerson et al., 2017). AHA recommends screening every 4–6 years for people aged 20 or older who are at low risk for cardiovascular disease (Grundy et al., 2019). The C-8 Medical Panel provided cholesterol screening starting as early as 2 years of age, which is similar to the age recommended for cholesterol screening for children with a family history of lipid disorders (C-8 Medical Panel, 2013).

Reductions in Birthweight

Birthweight is an important and well-established pregnancy outcome. Clinical prevention guidance for reductions in birthweight is to screen for risk factors that lead to reductions in birthweight. Common prenatal exposures associated with a risk of reduced birthweight in full-term newborns include use of tobacco, alcohol, or other drugs.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

TABLE 6-1 An Overview of Screening Recommendations for the Health Effects Associated with Exposure to PFAS

Recommendations for the General Population[a]	C-8 Medical Panel Recommendation[b,c] for Class Members
Lower birthweight	
Screen for risk factors for low birthweight in pregnant persons during prenatal well visit[d]	No screening recommended for C-8 class members[e]
Dyslipidemia (in adults and children)	
Screen all children once between ages 9 and 11 years and again between ages 17 and 21; among those with a familial history, begin screening at age 2 years and follow up yearly[f]	Screen children for cholesterol levels at age 2 years and older unless already screened during the prior 5 years, already diagnosed, or receiving treatment
Screen adults aged 40–75 with no history of cardiovascular disease (CVD), one or more CVD risk factors, and a calculated 10-year CVD event risk of 10% or greater[g]	
American Heart Association recommends all adults aged 20 or older have their cholesterol and other traditional risk factors checked every 4–6 years as long as their risk remains low[h]	
Kidney cancer (in adults)	
No routine screening recommended	Screen individuals aged 20–39 years with a symptom questionnaire; follow up with abdominal exam and urine test if symptoms present
	Screen individuals aged 40 or older with a symptom questionnaire, abdominal exam, and urine testing
Decreased antibody response (in adults and children)	
No routine screening recommended	No screening recommended for C-8 class members[e]
Breast cancer in adults	
U.S. Preventive Services Task Force (USPSTF): Screen average-risk women aged 50–74 with mammography every 2 years[i]	No screening recommended for C-8 class members[e]
Women's Preventive Services Initiative (WPSI): Screen average-risk women with mammography; mammography should be initiated no earlier than age 40 and no later than age 50 and occur annually or biennially until age 74[j]	
Pregnancy-induced hypertension (gestational hypertension and preeclampsia)	
Screen pregnant persons for hypertension and preeclampsia throughout pregnancy[k,l]	Screen pregnant persons for hypertension and proteinuria throughout pregnancy
Liver enzyme alterations in children and adults	
No routine screening recommended	No screening recommended for C-8 class members[e]
Testicular cancer in adults	
American Academy of Family Physicians (AAFP) and USPSTF recommend against screening asymptomatic adolescents and adults for testicular cancer[m]	Screen for testicular cancer with a physical exam and questionnaire
Thyroid dysfunction in adults	
Screen newborns as part of recommended uniform screening panel[n]	Screen adults' serum thyroid-stimulating hormone; otherwise test based on signs and symptoms of thyroid dysfunction
No routine screening recommended[o]	
Ulcerative colitis in adults	
No routine screening recommended	Screen for symptoms with questionnaire starting at age 15 years

[a] In cases in which conflicting or differing recommendations for population-level screenings have been issued, the clinical practice guideline developers have been identified for clarity.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

[b] C-8 Medical Panel, 2013.
[c] The C-8 Medical Panel recommended that members of the class action lawsuit, *Jack W. Leach et al. v. E.I. du Pont de Nemours & Company* (no. 01-C-608 W.Va., Wood County Circuit Court, filed April 10, 2002), be screened once in 2013; the panel has since updated its guidance, and now recommends that class members be screened three times, 3 years apart (C-8 Medical Panel, 2022). See Chapter 1 for more details about the lawsuit.
[d] Hagan et al., 2017.
[e] The C-8 Medical Panel was allowed to develop recommendations only for the six conditions identified by the C-8 Science Panel in 2013: pregnancy-induced hypertension, kidney cancer, testicular cancer, thyroid disease, ulcerative colitis, and hypercholesterolemia. The C-8 Medical Panel did not deliberate about screenings for lower birthweight, decreased antibody response, breast cancer, or liver enzyme functions (C-8 Medical Panel, 2013).

[o] USPSTF, 2015.

Kidney Cancer in Adults

There are no effective screening approaches for identifying kidney cancer early in its course, and therefore no authoritative clinical screening recommendations. Urinalysis is effective at finding blood in the urine, which can be a sign of advanced kidney cancer but is also indicative of other disorders, such as infections and kidney stones. The C-8 Medical Panel recommends that clinicians ask about family history, symptoms of kidney cancer (gross hematuria, chronic abdominal pain, recent involuntary weight loss, unexplained fever for 1 week), conduct a physical exam for abdominal mass, and check a urine dipstick for blood (C-8 Medical Panel 2013, 2022). Although palpation for an abdominal mass is not harmful, it is unlikely to lead to early detection and may provide false reassurance.

Decreased Antibody Response in Children and Adults

The predictive value of antibody titers after vaccination or infection is usually unclear, and the evidence for an association between PFAS exposure and infection risk or severity is insufficient. Nor are there any evidence-based recommendations or other clinical guidance for addressing decreased antibody response. This is an important area for additional research.

Outcomes with Limited Suggestive Evidence of Association

Breast Cancer in Adults

The USPSTF recommends biennial mammographic screening for all average-risk women aged 50–74 (USPSTF, 2016a). For women aged 40–49, the USPSTF states that the decision to start screening mammography should be an individual one, and that women who place a higher value on the potential benefit than on the potential harms may choose to begin biennial screening. For women aged 75 and older, the USPSTF makes no recommendation because of insufficient evidence (USPSTF, 2016a). The HRSA-supported Women's Preventive Services Initiative recommends that average-risk women initiate "mammography screening no earlier than age 40 and no later than age 50," that "screening mammography should occur at least biennially and as frequently as annually," and that it "should continue through at least age 74 and age alone should not be the basis to discontinue screening" (WPSI, 2019).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Pregnancy-Induced Hypertension

Pregnancy-induced hypertension, including gestational hypertension and preeclampsia, affects about 1 in every 12–17 pregnant persons aged 20–44 in the United States, and poses serious health risks for pregnant persons and fetuses during pregnancy (Bateman et al., 2012). As part of standard prenatal care, pregnant persons seeing a clinician will have their blood pressure monitored routinely throughout their pregnancy to reduce various risks to both parent and fetus associated with high blood pressure (Kilpatrick, 2017). This standard measurement is feasible, and its benefits outweigh its harms. The C-8 Medical Panel reinforces the standard blood pressure monitoring recommendations (C-8 Medical Panel 2013, 2022).

Elevated Liver Enzymes in Children and Adults

Elevated liver enzymes do not represent a health outcome by themselves, although they generally indicate a level of liver inflammation. Elevations are often found incidentally with multiphasic blood test panels administered as part of routine medical care or as part of an assessment of patient symptoms or concerns. Elevated liver enzymes have many causes, the most common of which include use of over-the-counter pain medications (particularly acetaminophen) and certain prescription medications (including statin drugs), alcohol consumption, heart failure, viral hepatitis, fatty liver disease, and obesity. There are no authoritative recommendations for screening for liver enzyme alterations in otherwise healthy patients who are not being monitored for liver dysfunction, and follow-up recommendations for elevations depend on which enzymes are affected, the degree of elevation, and characteristics of the individual patient.

Testicular Cancer in Adults

Testicular cancer, though rare, is the most common cancer in American males aged 15–25 (NCI, n.d.). Most cases of testicular cancer are discovered incidentally by patients or their partners. The USPSTF found that there is inadequate evidence that screening by clinician examination or patient self-examination has a higher yield or greater accuracy for detecting testicular cancer at earlier stages. It is also not known whether earlier detection would lead to better health outcomes. The USPSTF concludes that there is no benefit of screening for testicular cancer in the general population and recommends against it (USPSTF, 2011). The C-8 Medical Panel recommends a risk questionnaire and clinical testicular exam, considering ultrasound if additional risk factors are identified (C-8 Medical Panel, 2013, 2022).

Thyroid Disease and Dysfunction in Adults

There are well-defined approaches for identifying and treating thyroid hormone dysfunction, especially among older adults and women (CDC, 2014). The standard clinical practice for identifying thyroid dysfunction is to order blood testing for levels of thyroid-stimulating hormone (TSH) when there are signs or symptoms that could be attributable to hypo- or hyperthyroidism (NIDDK, 2017). Standard approaches exist for diagnosis and treatment of thyroid disorders. In its review, however, the USPSTF concluded that the current evidence is insufficient to assess the balance of benefits and harms of screening for thyroid dysfunction in nonpregnant, asymptomatic adults. The C-8 Medical Panel recommends that adults in PFAS-contaminated communities receive TSH-level screening in addition to testing based on signs and symptoms (C-8 Medical Panel 2013, 2022).

Ulcerative Colitis in Adults

Ulcerative colitis is a chronic bowel disease with a prevalence of 1.3 percent among U.S. adults that results in inflammation and sores in the lining of the large intestine (colon) and rectum (Dahlhamer et

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

al., 2016). It can be debilitating and lead to life-threatening complications. In addition to such generalized symptoms as fatigue, fever, and weight loss, affected individuals experience abdominal pain; blood or pus in stool; rectal bleeding; and frequent, recurring diarrhea. Diagnosis requires endoscopy and laboratory testing (Hanauer, 2004). There are no authoritative recommendations for screening for ulcerative colitis. The C-8 Medical Panel recommends that clinicians administer a questionnaire to elicit symptoms of the condition beginning at age 15 (C-8 Medical Panel, 2013, 2022); however, no information is available regarding the accuracy of the questionnaire.

RECOMMENDATIONS FOR PATIENT FOLLOW-UP

Where appropriate, the committee developed recommendations for patient follow-up for PFAS-associated health outcomes that should be offered to patients based on shared, informed decision making between patient and clinician. The clinical practice guidelines for standard medical care and the C-8 Medical Panel recommendations served as the basis of these recommendations. Some conditions associated with PFAS exposure have no established clinical prevention guidance, while other clinical prevention recommendations are beneficial when applied in cases of increased risk. There is value in specifying follow-up that is part of the standard of care as defined by authoritative clinical professional groups because clinicians often are unable to deliver all recommended preventive services during primary care visits (Privett and Guerrier, 2021) and must decide with patients which services to focus on considering both evidence and patient values and preferences (USPSTF et al., 2022).

The committee used its three established cutoff levels for PFAS in serum or plasma (detailed in Chapter 5) to determine follow-up based on PFAS exposure level, although the risks are not the same within each of these three categories. The risks from PFAS likely increase with increased exposure thus PFAS levels of 3 nanograms per milliliter (ng/mL) and 19 ng/mL do not represent the same risk. PFAS blood testing measures burden at the time of sample collection. For example, a person with low blood levels today may have had higher levels in the past. Clinicians should use judgment and shared decision making in making follow-up decisions based on PFAS exposure and other risk factors. Figure 6-1 suggests that clinicians engage in shared, informed decision making with their patients regarding follow-up care for PFAS-associated health outcomes.

Recommendation 6-1: Clinicians should treat patients with serum PFAS concentration below 2 nanograms per milliliter (ng/mL) with the usual standard of care.

Recommendation 6-2: For patients with serum PFAS concentration of 2 nanograms per milliliter (2 ng/mL) or higher and less than 20 ng/mL, clinicians should encourage PFAS exposure reduction if a source of exposure is identified, especially for pregnant persons. Within the usual standard of care clinicians should:

- **Prioritize screening for dyslipidemia with a lipid panel (once between 9 and 11 years of age, and once every 4 to 6 years over age 20) as recommended by the American Academy of Pediatrics (AAP) and the American Heart Association (AHA).**
- **Screen for hypertensive disorders of pregnancy at all prenatal visits per the American College of Obstetricians and Gynecologists (ACOG).**
- **Screen for breast cancer based on clinical practice guidelines based on age and other risk factors such as those recommended by the U.S. Preventive Services Task Force (USPSTF).**

Recommendation 6-3: For patients with serum PFAS concentration of 20 nanograms per milliliter (ng/mL) or higher, clinicians should encourage PFAS exposure reduction if a source of exposure is identified, especially for pregnant persons. In addition to the usual standard of care, clinicians should:

- **Prioritize screening for dyslipidemia with a lipid panel (for patients over age 2) following American Academy of Pediatrics (AAP) guidelines for high-risk children and American Heart Association (AHA) guidance for high-risk adults.**
- **At all well visits:**
  - **conduct thyroid function testing (for patients over age 18) with serum thyroid stimulating hormone (TSH),**
  - **assess for signs and symptoms of kidney cancer (for patients over 45), including with urinalysis, and**
  - **for patients over 15, assess for signs and symptoms of testicular cancer and ulcerative colitis.**

APPLYING THE COMMITTEE'S EXPOSURE, TESTING, AND CLINICAL FOLLOW-UP RECOMMENDATIONS

The Committee created a flow chart summarizing PFAS education, exposure assessment, and clinical follow-up (see Figure 6-2). In communities where PFAS exposure has been identified, the Agency of Toxic Substances and Disease Registry (ATSDR) and other government entities should support local clinicians with educational materials about PFAS exposure and testing. Clinicians should then determine whether a particular patient is likely to have a history of elevated exposure to PFAS. If so, the clinician should offer PFAS testing and make a shared, informed decision on that testing. If testing is chosen, the labs should be ordered (Test Code 39307, Current Procedural Terminology [CPT] Code 82542). Test results should be interpreted by summing the concentrations of MeFOSAA, PFHxS, PFOA (linear and branched isomers), PFDA, PFUnDA, PFOS (linear and branched isomers), and PFNA. The laboratory may not report results for all PFAS considered by the committee or may include different PFAS in their panel. In that case, the sum of PFAS should include only the PFAS in the analyte list considered by the committee. For example, if the lab tests for PFOA, PFOS, PFHxS, PFNA, and PFBS, the summation should include PFOA, PFOS, PFHxS, and PFNA. Differing analyte lists may cause some variation in test results. Still, as long as PFOA, PFOS, PFHxS, and PFNA are included in the analyte list, the results may not vary too greatly, as these four analytes are the ones most commonly detected in the United States. If any analyte is below the limit of detection, the clinician should calculate the analyte limit of detection divided by the square root of 2 and use this value in the summation. The summation should then be compared against Figure 6-2 to determine an appropriate clinical follow-up plan based on shared, informed decision making between patient and clinician.

CONCLUSION

The committee believes its clinical follow-up recommendations may be helpful to clinicians who have been asked to address PFAS-associated risks as part of routine health care delivery. There are potential harms both from aggressive clinical follow-up and from ignoring the risks of PFAS exposure. Clinicians and patients should decide which screening practices and services to pursue through a process of shared, informed decision making, along with consideration of the patients' level of PFAS exposure and other risk factors they may have. For young children, these discussions will likely take place with the parents; for adolescents, shared, informed decision making is complicated and an active area of research (Boland et al., 2019). The committee's patient follow-up recommendations should be updated as clinical practice guidelines change and as more is learned about the health effects of PFAS.

Revising ATSDR's PFAS Clinical Guidance

Since the potential for harmful effects of per- and polyfluoroalkyl substances (PFAS) exposure were made known to the public in 2000, clinicians have increasingly needed guidance on advising their communities regarding sources, routes, and effects of exposure, even as significant uncertainty about the health effects of exposure remains (see Chapter 3). The C-8 Medical Panel was the first body to offer clinical guidance regarding PFAS exposure, but the guidance was limited to members of the class action lawsuit (C-8 Medical Panel, 2013).[1] In response to this increasing need from clinicians for advice about responding to this environmental hazard, the Agency for Toxic Substances and Disease Registry (ATSDR) published clinical guidance regarding PFAS exposure in December 2019 (ATSDR, 2019).

RECOMMENDATIONS FOR CHANGES TO ATSDR'S CLINICAL GUIDANCE

In accordance with its Statement of Task (see Chapter 1), the committee in this chapter recommends several changes to ATSDR's guidance to ensure consistency with the conclusions, findings, and recommendations in this report. The Statement of Task specifies three main considerations regarding changes to the guidance. The first two—decision making for PFAS testing and PFAS concentrations informing clinical care of exposed patients—are discussed in Chapter 5; the third—clinical follow-up care specific to PFAS exposure—is addressed in Chapter 6.

The following recommendations illustrate the potential use of the information presented in previous chapters of this report:

Recommendation 7-1: The Agency for Toxic Substances and Disease Registry (ATSDR) should update its PFAS clinical guidance to make it more succinct and accord with the review of PFAS-associated health effects, exposure reduction considerations, PFAS testing recommendations and interpretation, and recommendations for clinical follow-up presented in this report. When describing the health effects of PFAS, ATSDR should avoid using terms typically used to categorize toxicants, such as "endocrine disrupter" or "neurotoxin," because they are vague and not necessarily clinically meaningful. When discussing the strength of the association between PFAS and a health outcome, ATSDR should use standard categories of association (such as sufficient evidence of an association, limited or suggestive evidence of an association, inadequate or insufficient evidence of an association, and limited or suggestive evidence of no association).

Recommendation 7-2: The Agency for Toxic Substances and Disease Registry (ATSDR) should incorporate a reader-centered approach when developing its guidance, with the knowledge that many different audiences will turn to its clinical guidance document to prepare for discussions with their clinicians. ATSDR should also solicit feedback on the guidance from a variety of stakeholders, such as

[1] See Chapter 1 for a brief overview of the lawsuit, *Jack W. Leach et al. v. E.I. du Pont de Nemours & Company* (no. 01-C-608 W.Va., Wood County Circuit Court, filed April 10, 2002), and Chapter 6 for details regarding the clinical guidance for class members.

KD2463

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

community groups, practicing clinicians, and medical associations. In addition, ATSDR should encourage clinicians to use evidence-based organizational health literacy strategies to support shared, informed decision making; patient-centered care; cultural humility; and accessible language when communicating with patients about potential health risks.

Recommendation 7-3: The Agency for Toxic Substances and Disease Registry (ATSDR) should develop a process for updating its PFAS guidance that adheres to criteria for making guidelines trustworthy, such as being based on a thorough, transparent, unbiased review of the evidence and being developed by a knowledgeable panel of experts free from strong biases and conflicts of interest. A review of the evidence on the health effects of PFAS should be completed by an authoritative neutral party every 2 years, and the clinical guidance should be updated every 5 years or sooner if warranted by the evidence on the health effects of PFAS. Clinicians and members of communities with elevated PFAS exposure should be engaged to inform the problem and review updated guidance.

In addition to these considerations, the committee believed it would be useful to address some more technical aspects of the ATSDR guidance document, including its writing and design and its dissemination and implementation. To this end, the committee referred to existing clinical guidance on PFAS exposure, as well as materials on health literacy and health communication, including the Agency for Healthcare Research and Quality's (AHRQ's) Health Literacy Universal Precautions Toolkit (Brega, 2015) and the Centers for Medicare & Medicaid Services' (CMS's) Toolkit for Making Written Material Clear and Effective (McGee, 2010). Given the Centers for Disease Control and Prevention's (CDC's) long-standing commitment to effective health communication (Donovan, 1995; Gagen and Kreps, 2019; Roper, 1993; Tinker and Silberberg, 1997), the committee decided not to focus on the finer details of these considerations but on their high-level aspects.

The committee reviewed several other materials published by other organizations to aid clinicians in addressing exposure to PFAS and determining options for clinical follow-up. Table 7-1 describes the clinical guidance documents published by the Pediatric Environmental Health Specialty Units (PEHSUs), and PFAS Research, Education, and Action for Community Health (PFAS-REACH) and identifies the strengths of each.

TABLE 7-1 Description of PFAS Clinical Guidance Documents

Clinical Guidance Document	Description of Content	Strengths of Document
How to Conduct a Clinical Visit with Patients Concerned About PFAS (PEHSU, 2021)	Includes a numbered list of five strategies for clinicians to use in discussing PFAS exposure with concerned patients and provides some detail on how to apply them. Also provides some references to other materials with further detail.	Focuses on empathy and shared decision making and the potential need for exposure reduction. Offers advice only for overall approaches to navigating discussions with patients, and directs clinicians to supplementary Pediatric Environmental Health Specialty Units (PEHSUs) and Agency for Toxic Substances and Disease Registry (ATSDR) resources.
PFAS Exposure: Information for Patients and Guidance for Clinicians to Inform Patient and Clinician Decision Making: For Clinicians (PFAS-REACH, 2021)	Summarizes clinical services recommended by other trustworthy groups for adults and children with above-average PFAS exposure. Categorizes information by type of service—laboratory tests, exams, or counseling topics	Accessible summary of material produced by others. Does not claim to provide rigorous analysis of others' findings. Does provide more information than the PEHSU document in an accessible format.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

WRITING AND DESIGN OF ATSDR'S CLINICAL GUIDANCE

The CMS Toolkit for Making Written Material Clear and Effective provides advice about paying attention to content, organization, writing style, engagement, and motivation (McGee, 2010):

- "Content" relates to what readers want and need to know and whether the information provided is accurate and up to date.
- The "organization" of the written material involves how well the material paces readers by grouping information in meaningful sections.
- "Writing style" refers to whether the text is conversational and uses the active voice, is specific and concrete, and uses familiar and culturally appropriate terms.
- "Engagement and motivation" refers to whether the material has a positive and friendly tone, offers trustworthy information sources, provides relatable statistics, or offers information about how readers can learn more.

The CMS Toolkit also includes "design" principles related to such matters as

- overall design and page layout;
- font, size of print, and contrast;
- headings, lists, and blocks of text;
- use of color;
- photographs and illustrations; and
- tables, charts, and diagrams (McGee, 2010).

As noted above, the committee limited its attention to design intricacies and overall layout, other than noting that the ATSDR guidance document is likely too long for the target audience of clinicians. Best practices for guidance (AAFP, 2021) include providing recommendations that are specific, offer clear direction, and are succinct—principles consistent with comments made to the committee by community members and clinicians (see Appendix B). Incorporating such best practices and using a reader-centered approach will allow ATSDR's clinical guidance to reach and support as many clinicians (and other community members) as possible.

DISSEMINATING AND IMPLEMENTING ATSDR'S CLINICAL GUIDANCE

Process for Updating the Guidance

In addition to updates to the ATSDR guidance stemming from this report, the committee proposes the establishment of a process for regularly updating the guidance (see Figure 7-1). The first step in that process is engaging with impacted communities to inform understanding of the issue at hand. It will also be important for ATSDR to update its reviews regarding PFAS-associated health effects, as well as to catalyze future research by identifying gaps in the evidence. This process should include both a review of guidelines issued by other authoritative bodies reflecting decisions about the health effects of PFAS and a review of the epidemiologic literature to identify any new studies that may warrant updating or revising ATSDR's own authoritative guidance. These reviews should be conducted by a neutral party every 2 years, or sooner if a watershed study, such as a large cohort or nested case-control study, on PFAS exposure and health effects is published before the next review is scheduled. AHRQ, the U.S. Preventive Services Task Force (USPSTF), and other organizations use similar processes that may be informative. One such process includes conducting "living" systematic reviews to continually update an existing review as new evidence becomes available (Elliott et al., 2017). It will be important in this process to incorporate reviews conducted by the U.S. Environmental Protection Agency, the National

KD2465

Copyright National Academy of Sciences. All rights reserved.

Toxicology Program, and other authoritative bodies. The committee proposes that ATSDR revise its guidance within 5 years of its 2021 analysis, consistent with the timelines for updating of the National Guideline Clearinghouse (NGC) and the USPSTF recommendations. The process for updating the literature review should encompass studies on PFAS exposure reduction, including those evaluating behavior change, interventions, or clinical measures, as well as studies on risk-based levels of PFAS to inform clinical care. It will also be important to review recommendations on standard care, as clinical follow-up recommendations would change if, for example, a beneficial screening test existed for a PFAS-associated health outcome. Finally, as noted above, the updating process should incorporate approaches for assembling feedback from clinicians and community members prior to each review. It should also include processes for updated documents to be reviewed by clinicians, in consultation with community members impacted by PFAS (see Figure 7-1 for an overview of this proposed updating process).

Transparency and Trustworthiness

Transparency enhances the trust clinicians and others place in clinical guidance. To advise ATSDR in this regard, the committee turned to the Institute of Medicine's (IOM's) standards for developing trustworthy clinical practice guidelines (CPGs) (IOM, 2011). The 2011 IOM report *Clinical Practice Guidelines We Can Trust* defines CPGs as

> statements that include recommendations intended to optimize patient care. They are informed by a systematic review of evidence and an assessment of the benefits and harms of alternative care options. (p. 15)

FIGURE 7-1 Suggested framework for updating the Agency for Toxic Substances and Disease Registry's clinical guidance based on new evidence.

Copyright National Academy of Sciences. All rights reserved.

The definition also includes six attributes required to make CPGs trustworthy, including that they

- are based on a systematic review of the existing evidence;
- are developed by a knowledgeable, multidisciplinary panel of experts and representatives from key affected groups;
- consider important patient subgroups and patient preferences, as appropriate;
- are based on an explicit and transparent process that minimizes distortions, biases, and conflicts of interest;
- provide a clear explanation of the logical relationships between alternative care options and health outcomes, and provide ratings of both the quality of evidence and the strength of recommendations; and
- are reconsidered and revised as appropriate when important new evidence warrants modifications of recommendations (p. 26).

The above definition of and standards for trustworthiness are intended to distinguish CPGs as transparent and methodologically rigorous, evidence-based guidelines as compared with other important forms of clinical guidance, such as expert advice, consensus statements, and practice bulletins. CPGs provide recommendations based on the balance of benefits and harms of different interventions for preventing or treating disease. Although ATSDR may be unable to issue CPGs regarding general PFAS exposure, as the complexity of the data may make a formal systematic review to inform such CPGs difficult, it should still strive to ensure that its clinical guidance reflects these criteria when possible.

CONCLUSION

The need for clear clinical guidance regarding PFAS exposure has only increased, despite the remaining uncertainties regarding the specific health risks of exposure. Yet it is difficult to distill the necessary information for effective clinical practice with respect to PFAS exposure, its possible health effects, and options for shared decision making once exposure has been confirmed. In addition to the distillation of the information itself, moreover, the writing, design, and general implementation of the clinical guidance are as important and as complex as the distillation of the information itself. This chapter offers recommendations that, if implemented, may assist ATSDR in its efforts to offer the guidance needed by clinicians. The committee believes ATSDR can continue to offer up-to-date, useful, and trustworthy clinical guidance by incorporating the updated data on the health effects of PFAS exposure presented in earlier chapters of this report, as well as adhering to the important risk communication and health literacy principles discussed above.

Implementing the Committee's Recommendations to Improve Public Health

Improving public health requires the use of multifaceted approaches to emerging health issues. In environmental health—the subset of public health focused on environmental factors—mitigation of potential harms associated with chemical exposures is often complicated because there is no exposure surveillance system for most chemicals. To address per- and polyfluoroalkyl substances (PFAS) effectively as a public health issue, it will be important to identify the people and communities with high exposures to PFAS, improve environmental health education for both clinicians and the public, and prevent exposures. Thus, the committee's recommendations would be most effective if implemented as part of a larger national effort toward increased PFAS-focused biomonitoring, exposure surveillance, and education around environmental health.

To promote a coordinated response to PFAS exposures, the committee makes the following recommendations:

> **Recommendation 8-1: Laboratories conducting PFAS testing of serum or plasma should report the results to state public health authorities, following the respective states' statutes and reporting regulations. This reporting would improve PFAS exposure surveillance; it could be linked with the Centers for Disease Control and Prevention's environmental public health tracking network and help build capacity for improvements in the state-based national biomonitoring network.**

BIOMONITORING AND SURVEILLANCE

PFAS exposure is nearly ubiquitous, but individual levels of exposure are not consistently measured or documented (CDC, 2021; NASEM, 2020, 2021a). Given the persistence of most PFAS in the human body, biomonitoring will likely produce meaningful exposure data, especially for those PFAS with longer half-lives. Collecting these data is critical to identifying communities and other areas with elevated PFAS exposure. Failing to identify such communities magnifies existing disparities for those that already have limited access to health care, live in areas of high exposure, and do not know that they may be at elevated risk for PFAS-associated health outcomes. Using biomonitoring data to establish exposure surveillance programs while also ensuring that medical professionals and the public have access to clear, accurate information about the risks of PFAS exposure will improve public health overall while also empowering people and communities to safeguard their own health.

According to the 2006 report by the National Research Council *Human Biomonitoring for Environmental Chemicals*:

> Identifying, controlling, and preventing population exposures to potentially harmful environmental chemicals have been cornerstones of U.S. environmental health efforts. Biomonitoring has become a tool that is central to these efforts. (NRC, 2006, p. 1)

While aggregate PFAS biomonitoring data can be used to promote population health, individual PFAS biomonitoring can provide people with information about their personal exposures, which is

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

important in informing clinical care (see Chapter 5). Therefore, access to PFAS blood tests for patients likely to have a history of elevated exposure as well as the results of those tests can help individuals better understand and, if possible, address their personal risk from PFAS exposure. Additionally, while biomonitoring studies are important to identify exposed communities and study potential health outcomes, PFAS testing intended to inform an individual's medical care should be coordinated by clinicians to ensure appropriate care and follow-up.

Improving access to PFAS blood testing for individuals could also allow for the collection of aggregate biomonitoring data if the results were compiled into a database. As discussed in Chapter 5, public health professionals can use those data to determine reference ranges of PFAS exposure in the general population. Understanding those ranges of exposure would support prioritization and allocation of funding and resources for preventive medicine or public health actions. Other high-profile cases demonstrate this powerful use of biomonitoring data to improve public health practice, as occurred in 2015 when Dr. Mona Hanna-Attisha began reviewing her patients' medical records and realized that the percentage of patients with elevated blood lead levels had increased after the city of Flint, Michigan, changed its water source.[1]

In addition to informing clinical care, biomonitoring data can be used in establishing exposure surveillance programs. Biomonitoring-based exposure surveillance enables public health practitioners and policy makers to identify exposure trends, mitigate ongoing exposures, and study associations between exposures and disease outcomes (Goldman et al., 1995; Thacker et al., 1996). In contrast with agencies' ongoing monitoring of environmental contaminants in air, soil, and water, there are few comprehensive databases or collection strategies for measuring and tracking levels in exposed people (Latshaw et al., 2017). The data that are currently collected, such as measurements from the National Health and Nutrition Examination Survey (NHANES),[2] often provide a snapshot of exposure that is useful in tracking nationwide trends in exposure over time, but cannot inform a localized public health response or help identify potential exposure "hot spots." Additionally, unlike the National Health Interview Survey,[3] the NHANES does not list urban versus rural as a publicly available variable, which limits researchers' ability to identify potential location-based disparities in PFAS exposure. Without collecting and compiling comprehensive PFAS biomonitoring data, federal agencies are less able to prioritize highly exposed communities in their mitigation strategies. Additionally, a lack of biomonitoring data limits studies on putative health effects, resulting in continued uncertainty that hinders public health response. As Kristen Mello stated during the committee's April 7, 2021, town hall, "Don't avoid taking our data and then complain about data gaps."

An effective strategy for PFAS exposure surveillance would involve multiple levels of public health response (Colles et al., 2021; Eatman and Strosnider, 2017). As with U.S. programs on pediatric monitoring for lead exposure, laboratories would report the biomonitoring results, zip code, and demographic information to state health departments, which in turn would report the data to the federal government. Data collected by states could be more geographically granular than the data typically accessible through NHANES, thereby enabling localized public health responses for highly contaminated areas (Nassif et al., 2021). Additionally, hierarchical data collection and reporting processes might include repeated stopgaps and promote oversight to ensure that clinicians, researchers, and public health agencies were using the data as effectively as possible.

ENVIRONMENTAL HEALTH EDUCATION

If the use of biomonitoring data and environmental surveillance programs is to be most effective at preventing or at least minimizing clinical disease associated with exposure, clinicians and the public

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

must have access to the information and know what to do with it. From a clinical perspective, providers need a better working knowledge of environmental health and chemical exposures. At the committee's town halls, speakers described their frustration with trying to obtain medical care from practitioners who were unfamiliar with PFAS and did not understand the environmental health contexts of the communities in which they practiced. At the town hall on April 7, 2021, Hope Grosse said:

> When I would go to the doctors and tell them about some of the exposures of over 50 chemicals that I was exposed to, the doctors would laugh and say no. Clearly, they didn't have any information about environmental components [of disease]. They made me feel small; they made me feel stupid and embarrassed even just asking the question.

The National Academies has previously acknowledged the issue of limited clinical education in environmental health. The 1991 Institute of Medicine (IOM) report *Addressing the Physician Shortage in Occupational and Environmental Medicine: Report of a Study* notes that all levels of medical education, from undergraduate to graduate and continuing education programs, provide limited, if any, training in occupational and environmental medicine. The report recommends that occupational and environmental medicine concepts be introduced early and continuously during medical education (IOM, 1991). Likewise, *Environmental Medicine: Integrating a Missing Element into Medical Education* notes a need for more environmentally literate physicians (IOM, 1995a). Decades later, however, Green-McKenzie and colleagues (2021) found that only 70 percent of medical students had heard of occupational and environmental medicine, and most of them had received only one lecture on the topic. After medical school, residency programs align with specialty requirements, which may not include further training in environmental and occupational medicine. In addition to the more formal medical training doctors receive in medical school and residency programs, professional associations such as the American Medical Association,[4] the American College of Preventive Medicine,[5] and the American College of Occupational and Environmental Medicine[6] offer continuing medical education modules on environmental health. However, these modules are optional, meaning that physicians may not learn about environmental and occupational medicine after medical school, either.

Physicians are not alone in their limitations with respect to environmental health education. According to the 1995 IOM report *Nursing, Health, and the Environment: Strengthening the Relationship to Improve the Public's Health*, "environmental health currently receives scant attention in nursing education and research" (IOM, 1995b, p. 14). The report calls for more nurses with education in environmental health, given that nurses represent the largest proportion of the health care workforce. Similarly, a recent commentary on the nursing profession notes that most nurses do not see themselves as environmental health practitioners or scientists (McCauley and Hayes, 2021). To address this shortcoming, environmental health is now a recommended domain for nursing education (NASEM, 2021b); in addition, nurses may need additional continuing education on environmental health topics.

Continuing education of clinicians is important to address knowledge gaps in environmental health. Increasing the opportunities for clinician education in environmental and occupational medicine; promoting collaborative, interdisciplinary environmental health networks; and framing environmental health as a tenet of preventive medicine and primary care are essential to ensure proper medical care for those facing environmental exposures and to assist families in reducing exposures when possible. One resource that can be leveraged to help respond to environmental exposures is the Pediatric Environmental Health Specialty Units (PEHSUs). ATSDR funds the PEHSUs with support from EPA. The PEHSUs are a "national network of experts in the prevention, diagnosis, management, and treatment of health issues that arise from environmental exposures from preconception through adolescence."[7] While the primary

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

focus is reproductive and children's health, clinicians will work with the whole family in determining exposure pathways and reducing these exposures. The PEHSU network includes nurses, physicians, medical toxicologists, and public health professionals and promotes collaboration among these diverse groups of practitioners. The network provides continuing education opportunities and information on PFAS for both health care professionals and community members. PEHSU-affiliated practitioners have proposed concrete environmental health competency areas for medical education programs (Goldman et al., 2021). Similarly, the Alliance of Nurses for Healthy Environments (ANHE)[8] addresses environmental exposures and health, including PFAS and related clinical care, in various online resources and engages with universities to integrate environmental health into their nursing education curricula. Other organizations, such as the Children's Environmental Health Network,[9] also provide educational materials in environmental health for health care providers.

Many public health practitioners have received training in environmental health because until recently, it was a required component of master of public health (M.P.H.) programs; however, the curriculum for public health is changing. In 2016, the Council on Education for Public Health (CEPH) released new accreditation criteria, aimed at offering schools of public health greater flexibility in course offerings and students a more applied, practice-based education.[10] With these more flexible coursework requirements, the CEPH removed the explicit requirement for education in environmental health sciences, replacing it and the other core disciplines with a series of competencies. This change may inadvertently lead to reduced environmental health training for public health professionals.[11] Indeed, by December 2019, just 91 percent of accredited M.P.H. programs continued to offer a concentration in environmental health sciences.[12] Addressing such challenges as PFAS requires a public health workforce with competency in environmental health sciences, toxicology, and epidemiology, which is why the Association for Prevention Teaching and Research calls on schools and programs in public health to maintain existing environmental health content and develop such content if previously eliminated or never offered (Levy et al., 2022).[13]

The public's environmental health literacy complements clinician education in environmental health by promoting individuals' personal health decision making while galvanizing communities to demand population-level public health responses. Historically, health literacy as a concept centered on individual decision making based on an understanding of health information. In Healthy People 2030, however, the U.S. Department of Health and Human Services (HHS) expanded the definition to encompass organizations' responsibility to ensure that individuals have access, understanding, and services to inform their health decisions, a concept HHS refers to as organizational health literacy.[14]

The term *health literacy* as used in this report focuses on Nutbeam's (2000) second and third levels of health literacy—interactive and critical literacy—which emphasize empowerment, autonomy, and action. More specifically, National Institute of Environmental Health Sciences (NIEHS) authors Finn and O'Fallon (2017) describe environmental health literacy as

> a philosophical perspective, a public health policy to improve literacy and health literacy in the general public, and a set of strategies to empower individuals and communities to exert control over the environmental exposures that may lead to adverse health outcomes. (p. 495)

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Building on the concept of health literacy, environmental health literacy has three dimensions: (1) awareness and knowledge of an environmental exposure, (2) skills and self-efficacy that allow individuals to make decisions to protect their own health, and (3) community change based on actions that reduce environmental exposures and protect public health (Gray, 2018). The committee recognizes that many exposures to PFAS are beyond individual control, and placing the onus for action on individuals often imposes an undue burden. Nevertheless, environmental health literacy can empower people to understand their own risks and ask their providers informed questions. As demonstrated by the community liaisons and town hall speakers who contributed to this study, many individuals have already worked especially hard to access information and educate themselves on PFAS.

In keeping with the principle of reducing the burden on exposed community members, PFAS-related environmental health literacy should center on making PFAS research publicly available and understandable for general audiences. Open access publication platforms are more accessible than those that are behind paywalls. Summaries written in plain language for the lay public, as blogs, news articles, and podcasts would be even better for increasing awareness about PFAS. Such resources as ATSDR's ToxFAQs[15]; Northeastern University's PFAS-TOX Database[16]; the PFAS Research, Education, and Action for Community Health PFAS Exchange[17]; and the Environmental Working Group's PFAS Contamination in the U.S. map[18] distill key information for the public and may serve as models for other environmental health literacy work. Other online resources, such as Purdue University's Online Writing Lab, describe considerations for evaluating the credibility of online sources that can serve as a guide for both those developing and those using the resources.[19] People must have access to information that can help them make health decisions and advocate for the health of their communities.

BARRIERS TO IMPLEMENTATION

Barriers to the committee's proposed implementation approach include difficulties with PFAS testing, lack of data standardization, poor coordination among experts from different disciplines, and a lack of funding for and availability of education in environmental and occupational medicine and environmental health literacy activities. Few laboratories currently have the capability to test for PFAS. The testing methodology is complex, and not all PFAS can be detected in serum or plasma. Data standardization is also a challenge (Latshaw et al., 2017) given the variability in testing methods, participant demographics, and exposure sources. As noted in Chapter 5 of this report, PFAS testing is expensive, and limiting the availability of testing based on access to consistent clinical care and insurance coverage could exacerbate health disparities in exposed communities. Furthermore, comprehensive PFAS exposure surveillance requires collaboration among a range of experts across different fields (Nassif et al., 2021); training in environmental and occupational medicine and environmental health is lacking; and support for PFAS health literacy is limited.

Given widespread PFAS exposure and the putative health effects associated with these chemicals, public health authorities would do well to prioritize addressing these barriers. Laboratory capacity to test for PFAS could be increased through coordination with the Association of Public Health Laboratories. Biomonitoring data and exposure surveillance programs could be standardized as long as they were developed with structures in place to ensure that the data were collected with the intent of their being comparable. The Network Steering Committee of the National Biomonitoring Network provides a template for successful implementation (Nassif et al., 2021).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Finally, continuing education opportunities such as "train-in-place" programs allow clinicians to learn environmental and occupational medicine concepts during the course of their ongoing practice (Green-McKenzie et al., 2021). Optimizing these programs and other innovative education strategies, as well as planning communication efforts as part of biomonitoring studies (NRC, 2006), can increase environmental health knowledge without requiring unattainable funding allocations.

MOVING FORWARD

Based on the recommendations and conclusions of this report, ATSDR, NIEHS, environmental health organizations, and bodies responsible for clinical education can take specific actions to address issues of PFAS contamination and clinical care, which will ultimately lead to improved public health (see Figure 8-1). By updating its PFAS clinical guidance according to the recommendations in Chapter 7, ATSDR will lay the groundwork for clinicians to participate in shared decision making and provide informed care for individuals exposed to PFAS. Access to informed care will allow communities with elevated exposure to PFAS to receive relevant medical advice, testing, screening, and treatment. In addition to improved guidance on clinical care, coordination between ATSDR and the National Biomonitoring Network will allow for the expansion of testing and surveillance. Additional communities identified as having elevated PFAS exposures can then receive informed care.

Additionally, NIEHS can use the information in this report to translate the research gaps identified in Chapter 3 into research needs, prioritizing research on potential associations between PFAS exposure and adverse health outcomes where the evidence is limited. As the research gaps narrow, ATSDR can update its clinical guidance to ensure that clinicians' knowledge and monitoring of PFAS-associated health outcomes remain current.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Environmental health education for clinicians and the public is key to reducing PFAS exposure and ensuring shared decision making and appropriate follow-up. Introductory environmental health training provides the foundation for PFAS-specific clinical education. Given this, the Liaison Committee on Medical Education,[20] the Accreditation Council for Graduate Medical Education,[21] the American Board of Medical Specialties,[22] the Accreditation Commission for Education in Nursing,[23] and other bodies responsible for curricula and accreditation of clinician education programs may consider incorporating environmental health into clinician training. Input from such interdisciplinary organizations as PEHSUs and ANHE can support these efforts. State and local health departments may serve as a link between the public and clinicians and proactively provide current information about environmental exposures to the communities they serve. Health departments could receive support for this work through liaison organizations funded by the Centers for Disease Control and Prevention, including the National Association of County and City Health Officials[24] and the Association of State and Territorial Health Officials.[25] Intentional collaboration at every level—from clinician education; to community partnerships; to local, state, and federal government initiatives—will begin closing the gaps in environmental health infrastructure and training, facilitating the overdue coordinated response and clinical care that people with elevated PFAS exposures deserve.

These efforts in environmental exposure surveillance, environmental health literacy, and improved environmental health tracking will aid in continuing to identify communities impacted by PFAS, which in turn will support exposure mitigation and effective preventive medicine responses. As the committee looks forward, it sees a pressing need for a robust environmental health infrastructure to continue to respond to PFAS, as well as to address other complex emerging and persistent environmental challenges.

Appendix A

Committee Member, Staff, and Community Liaison Biographies

COMMITTEE MEMBERS

Bruce N. Calonge, M.D., M.P.H. (NAM) (*Chair*), is an associate professor of family medicine at the Colorado School of Medicine, University of Colorado Denver, and an associate professor of epidemiology at the Colorado School of Public Health. He most recently served as the president and chief executive officer of The Colorado Trust, a private grant-making foundation dedicated to achieving health equity for all Coloradans. Nationally, Dr. Calonge chairs the Centers for Disease Control and Prevention's (CDC's) Task Force on Community Preventive Services; chairs the National Academies of Sciences, Engineering, and Medicine's Board on Population Health and Public Health Practice; and is a member of the National Academies' Roundtable on the Promotion of Health Equity. He is the past chair of the U.S. Preventive Services Task Force, the past chair of the CDC's Evaluation of Genomic Applications in Practice and Prevention Working Group, and a past member of the Secretary of Health and Human Services' Advisory Committee on Heritable Disorders in Newborns and Children. Prior to coming to The Colorado Trust, Dr. Calonge was the chief medical officer of the Colorado Department of Public Health and Environment. He received his B.A. in chemistry from Colorado College; his M.D. from the University of Colorado; and his M.P.H. from the University of Washington, where he also completed his preventive medicine residency. Additionally, Dr. Calonge completed his family medicine residency at the Oregon Health & Science University.

Laura Anderko, Ph.D., RN, is an environmental health nurse consultant and the co-director of the Federal Region 3 Pediatric Environmental Health Specialty Unit (PEHSU) of the Mid-Atlantic Center for Children's Health and the Environment at the M. Louise Fitzpatrick College of Nursing, Villanova University. Prior to joining Villanova University, she held the Robert and Kathleen Scanlon Chair in Values Based Health Care and was a professor at the School of Nursing & Health Studies at Georgetown University. Dr. Anderko is an educator, clinician, and scholar in public health, nursing, and environmental health. Over the past 8 years in her role with the Region 3 PEHSU, she has consulted with and educated local governments, communities, families, and health professionals about potential health impacts and risk-reduction strategies for PFAS. She has published extensively on PFAS, focusing on the clinicians' role in addressing health impacts and strategies for reducing risks. Dr. Anderko has served on several federal advisory committees, including the Children's Health Protection Advisory Committee for the U.S. Environmental Protection Agency, and is a founding member and steering committee member of the Alliance of Nurses for Healthy Environments. She currently serves as a special advisor for the National Environmental Health Partnership Council, coordinated by the American Public Health Association. Dr. Anderko was recognized by the Obama White House as a Champion of Change for her efforts in climate change and public health. She received her M.S. in nursing from Northern Illinois University and her Ph.D. in public health from the University of Illinois Chicago.

Erin M. Bell, Ph.D., is a professor in the Department of Epidemiology and Biostatistics and the Department of Environmental Health Sciences in the School of Public Health of the University at Albany. She joined the faculty at the University at Albany after completing her postdoctoral training at the National Cancer Institute's Occupational and Environmental Epidemiology Branch. Dr. Bell has taught

KD2477

Copyright National Academy of Sciences. All rights reserved.

epidemiology and environmental health to undergraduate and graduate students for almost 20 years, serving most recently as the faculty director of the undergraduate program in public health at the University at Albany. She is also an affiliate with the Center for Social and Demographic Analysis. Her research studies focus on environmental exposures as they relate to reproductive, immune, and cancer outcomes. Dr. Bell is currently the co–principal investigator of two cohort studies: the Upstate KIDS study, which follows more than 6,000 children to identify potential risk factors for developmental health effects, and the Health Study of New York State Communities Exposed to PFAS Contaminated Drinking Water, funded by the Agency for Toxic Substances and Disease Registry as one of seven sites participating in the Multi-site PFAS Health Study. She has served on several committees with the National Academies of Sciences, Engineering, and Medicine, including the Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides: Seventh, Eighth, and Tenth Biennial Updates. Dr. Bell received her M.S. in epidemiology and biostatistics from the University of Massachusetts Amherst and her Ph.D. in epidemiology from the University of North Carolina at Chapel Hill.

Dana Boyd Barr, Ph.D., is a research professor at the Emory University Rollins School of Public Health, where she co-directs the Laboratory for Exposure Assessment and Development in Environmental Research and leads research within the National Institutes of Health–funded Human Exposome Research Center: Understanding Lifetime Exposures (HERCULES). Her research focuses on using analytical chemistry techniques to assess exposure to toxicants, primarily related to maternal and child health. Prior to joining the faculty at Emory, Dr. Boyd Barr worked for 23 years at the Centers for Disease Control and Prevention (CDC), where she devoted much of her time to the development of methods for assessing human exposure to a variety of environmental toxicants. She is the past president of the International Society of Exposure Science (ISES), former editor-in-chief of the *Journal of Exposure Science and Environmental Epidemiology*, and the current deputy editor for *Environmental Health Perspectives*. Dr. Boyd Barr has received many awards for her research, including ISES's Daisy Award for Outstanding Investigator, two awards from the Secretary of Health and Human Services for exposure-health investigations involving diethylene glycol and methyl parathion poisoning, the 2004 Federal Scientific Employee of the Year award, the CDC's Mackel Award for outstanding collaboration among epidemiology and laboratory, and the U.S. Environmental Protection Agency's Silver Medal for outstanding service to environmental health. In 2014, 2015, and 2016, she was designated by Thomson Reuters as a Highly Cited Scientist in environment/ecology, representing the top 1 percent of scientists in her field. She recently became a member of the National Academies of Sciences, Engineering, and Medicine's Division on Earth and Life Studies' Board on Environmental Studies and Toxicology. Dr. Boyd Barr received her Ph.D. in analytical chemistry from Georgia State University.

Kevin C. Elliott, Ph.D., is a professor at Michigan State University (MSU) with joint appointments in the Lyman Briggs College, the Department of Fisheries and Wildlife, and the Department of Philosophy. His research lies at the intersection of the philosophy of science, research ethics, and environmental ethics, exploring the roles of ethical and social values in scientific research on environmental pollution, as well as ethical issues related to science communication, science policy, and team science. Dr. Elliott has authored a wide range of articles and book chapters and has published two books with Oxford University Press: *Is a Little Pollution Good for You?: Incorporating Societal Values in Environmental Research* (2011) and *A Tapestry of Values: An Introduction to Values in Science* (2017). He has also co-edited two books: *Exploring Inductive Risk: Case Studies of Values in Science* (with Ted Richards, Oxford University Press, 2017) and *Current Controversies in Values and Science* (with Dan Steel, Routledge Press, 2017). Dr. Elliott served as the program committee chair for the 2018 meeting of the Philosophy of Science Association and is the associate editor for the journal *Philosophy of Science*. He served as a member of the advisory council for the National Institute of Environmental Health Sciences from 2014 to 2018 and is currently a member of the MSU Center for PFAS Research. Dr. Elliott has served on organizing committees and workshops with the National Academies of Sciences, Engineering, and

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Medicine, including the Committee on the Use of Emerging Science for Environmental Health Decisions. He received his Ph.D. and M.A. in history and philosophy of science from the University of Notre Dame.

Melissa Gonzales, Ph.D., M.S., is a professor and the chair in the Department of Environmental Health Sciences at the Tulane University School of Public Health and Tropical Medicine. She formerly was a professor in the Division of Epidemiology, Biostatistics, and Preventive Medicine at the University of New Mexico (UNM) School of Medicine. At UNM she was the co-director of UNM's Center for Native Environmental Health Equity Research; director of evaluation for the vice chancellor's Office of Diversity; and associate vice chancellor for research and evaluation in the Office of Diversity, Equity and Inclusion at the UNM Health Sciences Center. As an environmental health scientist with expertise in exposure assessment and epidemiology, Dr. Gonzales's community-engaged, translational research focuses on understanding the contribution of environmental exposure to health disparities, rural and minority health, and the translation of research for improved health equity through informed policy. Her research and leadership roles at UNM include serving in the Metal Exposure Toxicity Assessment on Tribal Lands in the Southwest Superfund Center, and the Transdisciplinary Research, Equity, and Engagement Center for Advancing Behavioral Health. Her work includes the Albuquerque Hispanic Moms Study, the Zuni Exposure Study, the Colorectal Disease Prevention Study, and the UNM–University of Texas at El Paso ARCH study of asthma and air pollution among children living on the U.S.-Mexico border. Dr. Gonzales has previously served on two committees with the National Academies of Sciences, Engineering, and Medicine: the Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides: Tenth Biennial Update, and the Committee to Evaluate the Potential Exposure to Agent Orange/TCDD Residue and Level of Risk of Adverse Health Effects for Aircrew of Post-Vietnam C-123 Aircraft. She received her M.S. in toxicology/industrial hygiene at the University of Arizona College of Pharmacy and her Ph.D. in environmental health at the University of California, Berkeley, School of Public Health.

Erin N. Haynes, Ph.D., is the Kurt W. Deuschle Professor in Preventive Medicine and Environmental Health and the chair of the Departments of Epidemiology and Preventive Medicine and Environmental Health within the University of Kentucky (UK) College of Public Health. She is the deputy director of the National Institutes of Health's (NIH's) National Institute of Environmental Health Sciences' (NIEHS's) UK Center for Appalachian Research in Environmental Sciences; associate director of the UK Center for Clinical and Translational Science; co-chair of the NIEHS Disaster Research Response Committee; and senior associate editor of the *Journal of Appalachian Health*. Her current research, funded by NIEHS, focuses on investigating the effects of neurotoxicant exposure, particularly metals, on neurodevelopment in rural adolescents, and development and validation of a real-time, lab-on-a-chip sensor for blood metals detection. Dr. Haynes works with community members to address environmental health issues and develops citizen science tools to enable environmental health research. She also serves on the NIH/NIEHS Environmental Health Sciences study section and as an academic counselor for the International Society of Exposure Science. Dr. Haynes received her M.S. in environmental genetics and molecular toxicology from the University of Cincinnati, and her Dr.P.H. in environmental health sciences from the University of Michigan.

Jane Hoppin, S.M., Sc.D., is a professor of biological sciences and the deputy director of the Center for Human Health and the Environment at North Carolina State University. Her research focuses on how epidemiologic evidence can inform mechanisms of disease from environmental exposures. Dr. Hoppin is currently leading a National Institutes of Health–funded study of PFAS exposures in the Cape Fear River basin, as well as a study evaluating the impact of pesticide exposure to residents in the banana-growing region of Costa Rica. She has authored more than 200 publications related to exposure assessment for chemicals in the environment and health outcomes. Dr. Hoppin previously spent almost 15 years at the National Institute of Environmental Health Sciences, working on the Agricultural Health Study. She

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

received her S.M. and Sc.D. in environmental health and epidemiology from the Harvard T.H. Chan School of Public Health.

Tamarra James-Todd, Ph.D., M.P.H., is the Mark and Catherine Winkler Assistant Professor of Environmental Reproductive and Perinatal Epidemiology at the Harvard T.H. Chan School of Public Health, an associate epidemiologist at Brigham and Women's Hospital, and an instructor in medicine at Harvard Medical School. Her research expertise is in reproductive and developmental outcomes following exposure to environmental risk factors. Specifically, she evaluates the impact of pregnancy as a sensitive period of environmental chemical exposure for women's cardiometabolic health across the reproductive life course. Dr. James-Todd is the principal investigator (PI) of the Environmental Reproductive and Glucose Outcomes (ERGO) Study, which evaluates the impact of environmental chemicals and glucose metabolism during the perinatal period. She is also the PI of a study evaluating the effects of PFAS exposure on maternal cardiometabolic health across the reproductive life course within the Project Viva pregnancy/birth cohort. Dr. James-Todd has a particular focus on racial and ethnic disparities in environmental exposures and women's reproductive health outcomes. She has served on the U.S. Environmental Protection Agency's Scientific Advisory Board for the Chemical Assessment Advisory Committee and on the National Academies of Sciences, Engineering, and Medicine's Committee for Gulf War and Health: Volume 11: Generational Health Effects of Serving in the Gulf War. Dr. James-Todd received her M.P.H. in international health from the Boston University School of Public Health and her Ph.D. in epidemiology from Columbia University.

Alex R. Kemper, M.D., is the division chief of primary care pediatrics at Nationwide Children's Hospital and a professor of pediatrics at The Ohio State University College of Medicine. The focus of his research is the evaluation of preventive services delivered in the primary care setting. Dr. Kemper currently serves as the chair of the Evidence Review Workgroup for the Secretary of Health and Human Services' Advisory Committee on Heritable Disorders in Newborns and Children and as the deputy editor of *Pediatrics*. He is a former member of the U.S. Preventive Services Task Force and has served on the National Academies of Sciences, Engineering, and Medicine's Planning Committee on Examining Special Nutritional Requirements for Disease States. Dr. Kemper received his M.D. from Duke University, where he also completed his pediatric residency training, followed by combined fellowship training in health services research and medical informatics, and residency training in preventive medicine at the University of North Carolina.

Brian Linde, M.D., M.P.H., is an assistant professor in the Yale Occupational and Environmental Medicine Program at the Yale School of Medicine, where he oversees medical education and training and has designed curricula for physicians in training. He is also the chief of occupational health services at the Veterans Affairs Connecticut Healthcare System, where he oversees more than 3,000 employees, offering services including medical surveillance, work injury evaluation and management, infection prevention, and employee health and well-being. As a board-certified occupational and environmental physician, Dr. Linde also provides patient consultations to evaluate health effects of occupational and environmental exposures. He received his M.P.H. in occupational and environmental medicine from the Yale School of Public Health and his M.D. from Albert Einstein College of Medicine, Yeshiva University.

Marc-André Verner, Ph.D., M.S., is an associate professor in the Department of Occupational and Environmental Health, School of Public Health, Université de Montréal (Canada). He is also a member of the Centre for Public Health Research. Dr. Verner's expertise is in human health risk assessment, toxicology, biological modeling, and environmental epidemiology. His current research projects focus primarily on developmental exposure to environmental chemicals in the womb and postnatally through breastfeeding in the context of epidemiologic studies and risk assessment, including estimating gestational and lactational exposure to PFAS. Namely, he participated in the Minnesota Department of Health reevaluation of water guidance values for perfluorooctanoic acid and perfluorooctane sulfonic

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

acid. In 2016, Dr. Verner received the Joan M. Daisey Outstanding Young Scientist Award for his studies using pharmacokinetic modeling to assess exposures during hypothesized windows of susceptibility to contaminants. He received his M.S. and Ph.D. from the Université du Québec à Montréal.

Veronica M. Vieira, D.Sc., M.S., is a professor in and the chair of the Department of Environmental and Occupational Health at the University of California, Irvine (UC Irvine), Program in Public Health. Her current work includes evaluating birth defects and infant morbidity in relation to air pollution using generalized additive models, and she has worked with the Boston University Superfund Research Program. She works extensively with reconstructing historic environmental exposures using geographic information systems and has experience with groundwater modeling and perfluorooctanoic acid. Dr. Vieira collaborated on the C-8 Health Project, contributing to several health and exposure studies, and is currently an investigator on the UC Irvine PFAS Health Study, part of a multisite study sponsored by the Centers for Disease Control and Prevention and the Agency for Toxic Substances and Disease Registry. She has served on the National Academies of Sciences, Engineering, and Medicine's Committee to Review Possible Toxic Effects from Past Environmental Containment at Fort Detrick. Dr. Vieira received her M.S. in environmental engineering from Stanford University and her D.Sc. in environmental health from the Boston University School of Public Health.

Xiaobin Wang (NAM), M.D., M.P.H., is the Zanvyl Krieger Professor in Children's Health, the director of the Center on the Early Life Origins of Disease at the Johns Hopkins Bloomberg School of Public Health, a professor of pediatrics at the Johns Hopkins University School of Medicine, and an American Board of Pediatrics–certified pediatrician at Johns Hopkins Hospital. Her work unites biomarkers, clinical medicine, epidemiology, and disease prevention. Dr. Wang served as the principal investigator in a number of molecular epidemiological studies funded by the National Institutes of Health and led multi-institution, multidisciplinary teams to investigate environmental, nutritional, genetic, and epigenetic factors during critical developmental windows (preconception, in utero, infancy, and childhood). Her team has conducted a series of studies in three unique study cohorts (Boston Birth Cohort, Chicago Family Cohort, and Chinese Twin Cohort). Dr. Wang has served on two committees with the National Academies of Sciences, Engineering, and Medicine: the Committee on Food Allergies: Global Burden, Causes, Treatment, Prevention, and Public Policy, and the Committee on Understanding Premature Birth and Assuring Healthy Outcomes. She is also a member of the National Academy of Medicine. Dr. Wang received her M.D. from Beijing Medical University, her M.P.H. from the School of Public Health and Tropical Medicine at Tulane University, and her Sc.D. from the Johns Hopkins School of Hygiene and Public Health. She completed a 3-year research fellowship in environmental epidemiology at the Harvard T.H. Chan School of Public Health and a residency in pediatrics at the Boston University Medical Center.

Chris J. Wiant, Ph.D., M.P.H., is the founding president and the former chief executive officer of the Caring for Colorado Foundation, serving from 2000 until his retirement in 2020. Previously the executive director of Colorado's Tri-County Health Department, Dr. Wiant is experienced in risk assessment and communication, exposure science, and environmental policy, as well as in collaborating with communities dealing with environmental contamination. He also served as the chief of the Environmental Chemistry Section of the Illinois Department of Public Health. Dr. Wiant was appointed to five terms on the Colorado Water Quality Control Commission and has served on the U.S. Environmental Protection Agency's National Drinking Water Advisory Council, the federal advisory committee for development of regulations for disinfection by-products in drinking water (Stages I and II), and he was the chair of the National Science Foundation's International Council of Public Health Consultants. Dr. Wiant is also the past president of both the National Environmental Health Association and the Colorado Public Health Association, and was a key participant in the negotiation of the cleanup (Record of Decision) at the Rocky Mountain Arsenal Superfund site. He has been appointed to and recognized for his service on a variety of other local, state, and national advisory committees and boards, and as a facilitator of solutions to community public health challenges. Dr. Wiant received his M.S. in health services administration,

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

M.P.H. from the University of Illinois, and Ph.D. in public policy with an emphasis in environmental policy from the University of Colorado.

STAFF

Elizabeth Barksdale Boyle, M.P.H., is a senior program officer in the National Academies of Sciences, Engineering, and Medicine's Health and Medicine Division's Board on Population Health and Public Health Practice. She previously served for several years as a program officer with the National Academies' Board on Environmental Studies and Toxicology. Formerly, she was an environmental health scientist at Westat, where she supported the U.S. Environmental Protection Agency, the National Institute of Child Health and Human Development, and the National Cancer Institute. Before her tenure at Westat, Ms. Boyle was a student epidemiologist at the Minnesota Department of Health and an industrial hygienist at a consulting firm in Cincinnati, Ohio. She is a fellow of the Bloomberg American Health Initiative at the Johns Hopkins Bloomberg School of Public Health, where she is pursuing a Dr.P.H. in environmental health. Ms. Boyle has an M.P.H. in environmental health from the University of Minnesota and a certificate in risk sciences and public policy from the Johns Hopkins Bloomberg School of Public Health, and is a certified industrial hygienist.

Marilee Shelton-Davenport, Ph.D., is a senior program officer at the National Academies of Sciences, Engineering, and Medicine, where she serves as the director of the innovative, cross-institutional Environmental Health Matters Initiative. Since 1999, Dr. Shelton-Davenport has worked to guide the country's best scientists and practitioners in providing authoritative advice to agencies and other organizations interested in biomedical research and regulatory issues. Specifically, she has experience developing and executing impactful activities that serve the National Institutes of Health, the U.S. Environmental Protection Agency, the U.S. Department of Defense, and the U.S. Food and Drug Administration. Her work with the National Academies' Board on Life Sciences and Board on Chemical Sciences and Technology has focused on emerging science related to the impact of environmental exposures on human health and defense. A leader of multidisciplinary and multisector teams, Dr. Shelton-Davenport is skilled at guiding experts in drilling down to the root of issues, generating strategies, and developing creative solutions. She has a B.S. in biochemistry from Clemson University and a Ph.D. in pharmacology from the University of North Carolina.

Kate Guyton, Ph.D., is a senior program officer with the Board on Environmental Studies and Toxicology within the Division on Earth and Life Studies at the National Academies of Sciences, Engineering, and Medicine. She has more than 20 years of experience applying her expert knowledge in mechanistic toxicology and carcinogenesis, and has been certified as a diplomate of the American Board of Toxicology since 1998. Her prior experience includes service as a senior toxicologist at the International Agency for Research on Cancer with the World Health Organization in Lyon, France (2014–2020). Previously, Dr. Guyton served as a toxicologist in the Office of Research and Development at the U.S. Environmental Protection Agency (2005–2014) and as the director of scientific affairs at CCS Associates (1998–2005), a woman-owned small business. She has authored more than 90 scientific articles in her areas of expertise with an overall h-index of 46. Dr. Guyton received her B.A. (cum laude) in biology from Johns Hopkins University, her Ph.D. in toxicological sciences from the Johns Hopkins Bloomberg School of Public Health, and her postdoctoral training at the National Institutes of Health.

Kaley Beins, M.P.H., is a program officer with the Board on Environmental Studies and Toxicology within the Division on Earth and Life Studies at the National Academies of Sciences, Engineering, and Medicine. Previously, she worked as a federal contractor for Abt Associates, where she supported the development of toxicological profiles for the Agency for Toxic Substances and Disease Registry, as well as green chemistry and product labeling programs for the U.S. Environmental Protection Agency. Ms. Beins focuses on the intersection of public health and toxicology, and has conducted research and led

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

community engagement initiatives with nongovernmental organizations and local health departments, including service as a Fulbright Research Fellow. She is a board member for DC EcoWomen and the vice president of the Washington, DC, chapter of Sigma Xi Scientific Research Honor Society. Ms. Beins has a B.S. in environmental biology from Georgetown University and an M.P.H. in environmental health sciences from the University of Maryland.

Alexis Wojtowicz is an associate program officer who has supported the National Academies of Sciences, Engineering, and Medicine's Board on Population Health and Public Health Practice since 2016. She has also supported the Roundtable on Health Literacy, an action collaborative on preventing firearm violence, and consensus studies about Medicare payment and the public health effects of e-cigarettes. Before joining the National Academies, Ms. Wojtowicz conducted recruitment and intake at a culinary job training program in Washington, DC, and prior to that, coordinated an AmeriCorps VISTA program that placed summer associate members at anti-hunger nonprofit organizations across the United States. Ms. Wojtowicz has a B.A. in art history from the University of Maryland and is currently pursuing an M.P.H. at the Johns Hopkins Bloomberg School of Public Health, where she is a Bloomberg American Health Initiative fellow.

Alexandra McKay, M.A., is a senior program assistant in the Health and Medicine Division of the National Academies of Sciences, Engineering, and Medicine. During her graduate and undergraduate careers, she worked in museums and cultural heritage institutions, focusing on public education and assisting in database creation and exhibit curation. Ms. McKay also has experience working for the National Park Service as an interpretation ranger, concentrating on science education and public engagement. She received her M.A. in archaeological studies from Yale University.

COMMUNITY LIAISONS

Laurene Allen is a resident of Merrimack, New Hampshire, who co-founded the community group Merrimack Citizens for Clean Water after learning, in March 2016, that the water she and her family drank for decades was contaminated by PFAS. She has been an advocate for the needs of her PFAS-impacted community for the past 6 years, engaging local, state, and federal officials, and bringing together residents to work together on both a local and national level. After working to gather health data in her community, Ms. Allen co-authored an article in the journal *Environmental Health* titled "Making the Invisible Visible: Results of a Community-Led Health Survey following PFAS Contamination of Drinking Water in Merrimack, New Hampshire." Additionally, she co-founded and continues to serve in leadership of the National PFAS Contamination Coalition, composed of community members from across the nation working together to attain mutual federal needs.

Andrea Amico is the co-founder of the Testing for Pease community action group at the former Pease Air Force Base in Portsmouth, New Hampshire. In 2014, after learning her husband and two small children were impacted by drinking water highly contaminated by PFAS, she began advocating for her community and others, raising awareness and providing education, to achieve a common goal of reducing PFAS exposure to impacted communities. Ms. Amico testified at U.S. Senate hearings on PFAS in September 2018 and again in December 2021. She received the Citizen Excellence in Community Involvement Award from the U.S. Environmental Protection Agency Region 1 in November 2018. Ms. Amico attended the President's State of the Union Address as Senator Jeanne Shaheen's guest in February 2019 to raise awareness of PFAS contamination. She is the co-founder of the National PFAS Contamination Coalition, formed in June 2017 to bring PFAS advocates from around the country to organize for change at the federal level. Additionally, Ms. Amico helped organize the first two National PFAS Conferences held at Northeastern University in Boston, Massachusetts, in June 2017 and June 2019. She has given a TEDx talk on PFAS and presented at the Centers for Disease Control and Prevention's first Public Health Grand Rounds on PFAS in Atlanta, Georgia. Ms. Amico serves on the

KD2483

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Pease Community Assistance Panel with the Agency for Toxic Substances and Disease Registry and is community co-chair of the Pease Restoration Advisory Board with the U.S. Air Force. She is also a community co-chair on the City of Portsmouth Safe Water Advisory Group. Ms. Amico has a master's degree in occupational therapy.

Stel Bailey is the chief executive director of Fight For Zero and the co-facilitator of the National PFAS Contamination Coalition, is certified in wildlife monitoring, and is a content administrator behind several online publications. Her life took a dramatic turn in 2013 when she and her father, brother, and uncle, as well as the family dog, were diagnosed with cancer. Her family's case was so unique that a genetic counselor invited them to do genetic testing, which showed no mutation genes, indicating they did not have an increased risk of developing the disease. Determined to find answers, Ms. Bailey began to crowdsource information about other cancer cases in her hometown on Florida's space coast. As she spoke out about her family's case, she connected with many others affected by diseases in unusual ways. As a cancer survivor and military dependent, Ms. Bailey is passionate about helping families and veterans prevent disease by sharing her insights about harmful toxins, including PFAS, and their health effects. Her broad knowledge in coordinating community engagement projects has resulted in various opportunities to share environmental health information, such as contributing to local publications and speaking at events. She has led additional efforts focused on harmful contaminants, such as assisting in getting a state health assessment, collecting water samples for countywide projects, and developing partnerships that will help improve understanding of the burdens of PFAS contamination and related chronic diseases.

Kyla Bennett, Ph.D., is the director of science at Public Employees for Environmental Responsibility (PEER), a national nonprofit service organization for environmental and public health professionals, land managers, scientists, enforcement officers, and other civil servants dedicated to upholding environmental laws and values. Prior to working at PEER, Dr. Bennett was an environmental scientist and attorney for the U.S. Environmental Protection Agency (EPA) for 10 years. Her work at PEER includes the investigation of sources of PFAS contamination in artificial turf and pesticides, and of impacts on endangered species, such as the North Atlantic right whale, manatee, and Louisiana black bear. Dr. Bennett is currently working on exposing the effects of aerial pesticide spraying and investigating faulty risk assessments of pesticides and other chemicals at EPA. She has a Ph.D. in ecology and evolutionary biology from the University of Connecticut, and a law degree with a certificate in environmental and natural resources law from Lewis and Clark Law School.

Karen Blondel is an environmental organizer/advocate for the Fifth Avenue Committee. She has conducted field trainings and has a background in health and engineering. A native of Brooklyn, Ms. Blondel has led the Gowanus Neighborhood Coalition for Justice activist group to demand the city include the neighborhood's New York City Housing Authority (NYCHA) houses in its development plan. During her tenure with AmeriCorps, she coordinated a women's history event at the Red Hook Library; started a volunteer program to escort seniors on their errands; and launched a summer Safe Streets program, facilitating a shutdown of local roads for recreational use for local residents. In 2018, Ms. Blondel began a "Know Your Rights" workshop for Red Hook public housing residents to inform them on bylaws, requirements, and deadlines. In her current role as an environmental organizer, she educates public housing residents on environmental burdens within and near NYCHA housing developments that are often overlooked by the city.

Phil Brown, Ph.D., is a university distinguished professor of sociology and health science at Northeastern University, where he directs the Social Science Environmental Health Research Institute and co-directs its PFAS Lab, which has grants from the National Science Foundation to study social policy and activism concerning PFAS, and from the National Institute of Environmental Health Sciences (NIEHS) to study children's immune responses and community's responses to PFAS contamination, and

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

to develop a nationwide report-back and information exchange. He directs an NIEHS T-32 training program, "Transdisciplinary Training at the Intersection of Environmental Health Science and Social Science," heads the Community Outreach and Translation Core of Northeastern's Children's Environmental Health Center (Center for Research on Early Childhood Exposure and Development in Puerto Rico, orCRECE), and is the research translation director and the community engagement core co-director of Northeastern's Superfund Research Program (Puerto Rico Testsite to Explore Contamination Threats, or PROTECT). Dr. Brown is a past member of the NIEHS Council. His books include *No Safe Place: Toxic Waste, Leukemia, and Community Action*; *Toxic Exposures: Contested Illnesses and the Environmental Health Movement*; and *Contested Illnesses: Citizens, Science and Health Social Movements*. Dr. Brown earned his Ph.D. in sociology from Brandeis University.

Alberto J. Caban-Martinez, D.O., Ph.D., M.P.H., is a public health board-certified faculty member in the Department of Public Health Sciences at the University of Miami with an educational background in medicine, epidemiology, and public health and more than 10 years of domestic and international practice and research experience. He is the assistant provost for research standards and an associate professor of public health sciences and physical medicine and rehabilitation at the University of Miami Miller School of Medicine; the deputy director of the Firefighter Cancer Initiative at the Sylvester Comprehensive Cancer Center; and the co-director and principal investigator of the national Federal Emergency Management Agency–funded Fire Fighter Cancer Cohort Study. He is a former fellow of the National Academies of Sciences, Engineering, and Medicine's Gulf Research Program, and in 2014, he was appointed to the Institute of Medicine's Committee on Gulf War and Health for 2 years to provide scientific expertise on occupational exposures and work-related health conditions. He also served on the National Occupational Research Agenda committee of the National Institute for Occupational Safety and Health (NIOSH), helping to set the national research agenda on worker health and safety. He served 4 years as a standing member of the NIOSH study section and 1 year as the chair. He has published more than 120 peer-reviewed publications and shared more than 215 scientific presentations on a wide range of occupational health and safety topics.

Cheryl Cail is a small business owner in Myrtle Beach, South Carolina, the vice chief of the Waccamaw Indian People, and the chair for SC Idle No More, a committee within the South Carolina Indian Affairs Commission. In December 2018, after her 20-year-old son was diagnosed with testicular cancer, Ms. Cail became aware of PFAS contamination in the groundwater at the former Myrtle Beach Air Force Base, and later learned of the extent of contamination from the use of aqueous film-forming foam at other U.S. Department of Defense sites throughout the state. She joined the National PFAS Contamination Coalition in 2019, and is currently working to raise awareness of the impact of PFAS contamination of both the environment and people in South Carolina. Ms. Cail received associate degrees from Horry-Georgetown Technical College in both legal studies and human services and received the Phi Theta Kappa Society's All-State Academic Team award.

Courtney Carignan, Ph.D., is an exposure scientist and an environmental epidemiologist at Michigan State University (MSU). Her research helps protect reproductive and child health by investigating exposure to contaminants in food and water, and consumer and personal care products. She currently helps lead biomonitoring studies (PFAS UNITEDD and PFAS REACH) funded by the U.S. Environmental Protection Agency and the National Institutes of Health, investigating PFAS exposure and immunotoxicity for communities impacted by drinking water contamination. Dr. Carignan is on the organizing committee for the National PFAS Conference and helps lead MSU's Center for PFAS Research. She received her Ph.D. in environmental health from the Boston University School of Public Health and completed postdoctoral training at Dartmouth College and the Harvard T.H. Chan School of Public Health.

Tracy Carluccio is the deputy director of the Delaware Riverkeeper Network (DRN), where she has worked as an environmental advocate since 1989. DRN is a nonprofit membership organization working throughout the entire length and breadth of the Delaware River Watershed to defend its outstanding values and restore them where needed. Ms. Carluccio works for the Watershed's protection in New Jersey, Pennsylvania, New York, and Delaware, addressing issues that include water quality; healthy habitats and communities; environmental regulation and policy; clean, efficient, and renewable energy; and biodiverse ecosystems. She has also worked on PFAS issues since 2005 and has commented and written extensively on community and regulatory matters related to these compounds in New Jersey, Pennsylvania, and Delaware. Ms. Carluccio serves on the New Jersey Department of Health Centers for Disease Control and Prevention Biomonitoring Advisory Committee on PFAS.

Jamie DeWitt, Ph.D., is an associate professor in the Department of Pharmacology & Toxicology of the Brody School of Medicine at East Carolina University. Her research focuses on the effects of environmental contaminants on the adult and developing immune systems, as well as on interactions between the immune and nervous systems. She is the principal investigator, co–principal investigator, and co-investigator on several funded studies concerning the immune effects of PFAS, especially those considered novel or understudied. Dr. DeWitt received her Ph.D.s in environmental science and neural science from Indiana University Bloomington and completed postdoctoral training in immunotoxicology at the U.S. Environmental Protection Agency under a cooperative training agreement with the University of North Carolina.

Emily Donovan is the co-founder of Clean Cape Fear. She is a tireless advocate for clean water, spending her free time educating the public on the dangers of PFAS and other toxins in drinking water and the environment. Ms. Donovan has testified before Congress twice regarding the influence of the DuPont/Chemours facility in Fayetteville, North Carolina, which is contaminating the downstream drinking water supply for 250,000 residents, including giving testimony during the first-ever congressional hearing on PFAS contamination. She participated in a *Washington Post Live* panel discussion with actor Mark Ruffalo and lawyer Rob Bilott. Most recently, Ms. Donovan worked to secure reverse osmosis filling stations in 49 public schools impacted by PFAS contamination in Brunswick and New Hanover counties. She regularly travels the country sharing her personal impact story, as well as those of her friends and neighbors. Ms. Donovan frequents Washington, DC, and Raleigh, North Carolina, pressuring lawmakers and regulators for swifter responses to the growing PFAS public health crisis.

Alan Ducatman, M.D., M.S., is a Mayo Clinic–trained internist and occupational physician, and a professor emeritus in the West Virginia University School of Public Health and School of Medicine. His clinical career has focused on medical screening related to environmental exposures, with research addressing environmental disease and disease prevention, including health communications to affected populations. He has designed community studies and actively published on population aspects of exposure to PFAS, and many of his more than 30 publications concerning PFAS are highly cited. As a clinical consultant to industry, labor, nonprofit organizations, and government organizations, Dr. Ducatman has also worked with a variety of community groups to provide information concerning PFAS clinical science. In addition, he has an active research program in quality assurance concerning clinician laboratory orders and interpretation, which informs his community service. His other public service has included serving as the chair of the external science advising committee to the National Center for Environmental Health and the Agency for Toxic Substances and Disease Registry of the Centers for Disease Control and Prevention, and as the chair of the Residency Review Committee in Preventive Medicine for the Accreditation Council for Graduate Medical Education.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Patrick Elder is the director of Military Poisons, an organization that works to draw attention to the role of the military in the environmental contamination through the use of PFAS in firefighting foams and other applications. Two hundred of his articles on PFAS have been published in several dozen publications, including *Global Geneva*, *Truthout*, *Consortium News*, *Common Dreams*, and *LA Progressive*. Mr. Elder seeks to draw public attention to food, especially seafood, as the primary pathway of human exposure to PFAS. He receives support from the Women's International League for Peace and Freedom (WILPF); WILPF US Earth Democracy; the Patagonia Foundation; the Peace Development Fund; and the Center for Health, Environment & Justice. Mr. Elder is presently working on campaigns in several New England states and Maryland, as well as in Germany and Japan, to influence policy makers to take steps to protect public health from the scourge of PFAS. He has toured the United States and Europe several times, speaking on contamination at military bases. Mr. Elder holds an M.A. in government from the University of Maryland and a B.A. in political science/education from St. Mary's College of Maryland.

Teresa Gerade is an advisory member of a Vermont-Canadian volunteer organization in the Northeast Kingdom known as DUMP (Don't Undermine Memphremagog's Purity), which came into being in June 2018 to appeal the application for a 51-acre expansion of Vermont's only permitted, privately owned landfill. The group's goal is to restore and protect the waters and watershed of Lake Memphremagog, an international lake located in the northeast corner of Vermont. The appeal was unsuccessful because of a lack of funding for legal representation. However, the group participated in a mediation session with the owners of the landfill and achieved a 4-year moratorium on the discharge of landfill leachate (the garbage juice that is created in landfills) into the Lake Memphremagog watershed. DUMP is now actively pursuing a state legislative designation of "Lake in Crisis" to garner funding and additional support for restoring and protecting the waters of Lake Memphremagog.

Hope Grosse is the co-founder of Buxmont Coalition for Safer Water and serves on the National PFAS Contamination Coalition, working to establish enforceable federal and state drinking water standards for this chemical class. She acts as the community liaison for outreach and leads social media efforts, updating residents about PFAS water contamination and related issues. Ms. Grosse has been featured on WHYY's *Radio Times, Live with Marty Moss-Coane,* discussing PFAS chemicals health and regulations. She also serves as a community representative on the Warminster Naval Airbase Technical Review Committee, which is charged with oversight of the environmental cleanup under the Comprehensive Environmental Response, Compensation, and Liability Act. Ms. Grosse grew up directly across the street from Warminster Naval Base and worked on the base after high school graduation. Her father died of cancer at age 52, and she was diagnosed with stage 4 cancer at age 25, which quickly spread to her lymph system. Other unexplained tumors have also been removed from her body over the years. After learning that the Warminster Naval Base was named a Superfund National Priority site, she began to get involved in environmental advocacy and is committed to bringing awareness of PFAS and other contaminants to others in her community.

Loreen Hackett has been advocating for families in Hoosick Falls, New York, since the discovery of severe contamination more than 6 years ago led to issuance of the first National Priorities List Federal Superfund Site declarations for PFOA. Through biomonitoring, her family exhibited some of the highest levels of perfluorooctanoic acid tested in the area. In June 2016, she created #PfoaProjectNY, which has gone worldwide, and continues to share information on PFAS. Ms. Hackett is the co-chair of the Hoosick Falls Community Action Working Group established for the superfund sites, serves on the Community Action Partnership Committee for the Centers for Disease Control and Prevention–awarded site study, and is on the Committee of the National PFAS Contamination Coalition. She has attended and submitted testimony in two congressional hearings in Washington, DC, and continues working with elected officials on bills regulating PFAS, as well as with various environmental organizations. She survived cancer that may have been linked to PFAS exposure.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Ayesha Khan worked at Vitamin Water in New York City for a decade before moving to the island of Nantucket, Massachusetts, where she worked for a local surgeon. Currently, she is a stay-at-home mom for her two young children. Her husband Nate, who works as a firefighter, was recently diagnosed with testicular cancer and is in remission. As Ms. Khan researched about her husband's cancer, she learned about PFAS and their connections to aqueous film-forming foam and firefighter gear. She co-founded Nantucket PFAS Action Group as an educational resource about the hazards of PFAS and as a space for local community members to openly discuss concerns, thoughts, and experiences. Ms. Khan holds a B.A. in applied mathematics and statistics from Boston University.

Rainer Lohmann, Ph.D., is a professor of oceanography and the director of the University of Rhode Island Superfund Research Center, where he and his group conduct research into the sources, transport, and bioaccumulation of anthropogenic pollutants, often relying on the use of passive samplers. In addition to PFAS, his research covers dioxins, polychlorinated biphenyls, legacy pesticides, and emerging contaminants. Dr. Lohmann is a scientific counselor for the U.S. Environmental Protection Agency's Sustainable and Healthy Communities Subcommittee and a speaker at the National Academies of Sciences, Engineering, and Medicine's Environmental Health Matters Initiative on PFAS. He was selected as an Alexander von Humboldt fellow, and as a Fulbright fellow for the 2021–2022 Arctic Initiative. Dr. Lohmann serves as the editor for *Environmental Toxicology and Chemistry* and is on the editorial boards of publications including *Environmental Science & Technology* and *Environmental Science & Technology Letters*.

Samraa Luqman works in social services with the federal government. A native of Dearborn, Michigan, she has experience working in public schools and serving in community hospitals and cultural centers, including the Arab Community Center for Economic and Social Services and the American Yemeni Women's Association, where she is the secretary and a board member. Ms. Luqman has observed a multitude of community members becoming ill with cancers, asthma, and other illnesses attributable to pollution, and has become involved in pursuing environmental justice, speaking at community meetings and town halls. In 2019, she joined the Environmental Health Research to Action Steering Committee, which educates high school students about the impacts of pollution, and the PFAS Alliance shortly thereafter. By 2020, Ms. Luqman also joined the Clean Air Council and presented to multiple audiences on the effects and existence of PFAS in both air and water. She has also worked with the Concerned Residents for South Dearborn, the University of Michigan's Environmental Interpretive Center, and Friends of the Rouge to raise awareness on the environmental issues of her community. Her most recent endeavors include providing input on the enactment and enforcement of a fugitive air dust ordinance; fighting for cumulative health impact studies; and partnering with organizations, universities, and other entities to add greenspace, trees, and rain gardens to the area. Ms. Luqman completed her bachelor's degree in psychology at the University of Michigan.

Beth Markesino is the founder of North Carolina Stop GenX in Our Water, advocating for regulations on GenX, PFAS, and perfluorooctane sulfonic acid in North Carolina. She is a participant in the first ever GenX human health study. Ms. Markesino has multiple endocrine issues associated with PFAS, including a thyroid tumor, an adrenal tumor, and placenta problems during her pregnancy that resulted in the death of her son. She actively advocates in her community for clean water and regulatory action addressing endocrine disruptor chemicals. With a grant from Hydroviv, she provided 120 filters for low-income residents in the Lower Cape Fear region. Additionally, she has lobbied against DuPont scientist Michael Dourson's appointment to the U.S. Environmental Protection Agency.

Aaron Maruzzo worked as a water lab analyst for a public utility company in the Northern Mariana Islands, serving the islands of Saipan, Tinian, and Rota. He is currently working toward an M.P.H. in environmental health science at the University of California (UC), Berkeley. In 2020, Mr. Maruzzo co-authored a report for the Berkeley Center for Green Chemistry to identify nontoxic alternatives to short-

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

chain PFAS in molded fiber food packaging. His current interests are in community exposure to PFAS in drinking water, green technology, environmental epidemiology, and environmental justice, where he aims to leverage academic resources at UC Berkeley to benefit science and policy actions toward a PFAS-free future in the Western Pacific U.S. territories. Mr. Maruzzo received his B.A. in biology and comparative literature, with a concentration in public health, from Williams College, where he developed a strong interdisciplinary approach to diverse public health issues.

Tobyn McNaughton is a resident of Belmont, Michigan, who has been affected by PFAS. She is a former elementary teacher and now stays home with her two sons. Ms. McNaughton has become an activist and voice for people affected by PFAS.

Kristen Mello, M.S., is the director of Westfield Residents Advocating for Themselves (WRAFT), a community group formed in response to PFAS contamination of the drinking water in Westfield, Massachusetts, caused by the use of aqueous film-forming foam at the Barnes Air National Guard Base. With WRAFT, Ms. Mello has led efforts to get PFAS blood testing for Westfield residents and has served on the Massachusetts Department of Environmental Protection's PFAS MCL (Maximum Contaminant Level) Stakeholder Group. Her advocacy work on PFAS, in large part, led to her being elected a Westfield City Councilor At-Large in 2019 and 2021. Ms. Mello has a bachelor's degree in chemistry and a master's degree in analytical chemistry, specializing in chemometrics.

Pamela K. Miller is founder and Executive Director of Alaska Community Action on Toxics (ACAT). ACAT is an environmental health and justice research, policy, and advocacy organization. She brings more than 30 years of research, education, and advocacy experience to her present work. She serves as Principal Investigator for community-based participatory research projects funded by the National Institute of Environmental Health Sciences. Ms. Miller received a Meritorious Service Award from the University of Alaska and Alaska Conservation Foundation's Olaus Murie Award in recognition of her "long-term outstanding professional contributions to the conservation movement in Alaska." She holds a bachelor's degree in biology from Wittenberg University and a master's degree in environmental science from Miami University. Prior to coming to Alaska, she served as Ocean Issues Technical Coordinator for the Washington Department of Ecology and Director of a marine science education center at Nisqually Reach in southern Puget Sound. She received the Governor's Award for Environmental Excellence in Washington State.

Elizabeth Neary, M.D., is a pediatrician, as well as an educator and scholar in public and environmental health. Having practiced general pediatrics for 15 years, she has devoted herself to educating students, residents, legislators, and the general public about environmental health issues. Dr. Neary is the co-president of the Wisconsin Environmental Health Network, part of Physicians for Social Responsibility–Wisconsin. She is an adjunct assistant clinical professor of pediatrics at the University of Wisconsin–Madison School of Medicine and Public Health and the Wisconsin representative to the Region 3 Pediatric Environmental Health Specialty Unit. For the past 5 years, she has taught environmental health to pediatric residents. Dr. Neary has testified on the health effects of PFAS to the Wisconsin state legislature and to the Madison Water Utility Board.

Laura Olah is the executive director and the co-founder of Citizens for Safe Water Around Badger, a community-based group that organized in 1990 when the community learned that a plume of cancer-causing chemicals had poisoned private drinking water wells near Wisconsin's Badger Army Ammunition Plant. A member of the Sokaogon Ojibwa Community Mole Lake Band, Ms. Olah defines her role as part of a community "undefined by geography" that shares a deep concern for the human environment and the need to empower affected tribes and stakeholders in the decision-making process, ensuring powerful, long-term solutions to military and industrial toxins in our rural communities. She

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

views the past 30 years of accomplishments not as hers alone but as shared with the many individuals who have and who continue to be at her side in the work for environmental justice.

Jacob Park, Ph.D., is an associate professor in the Castleton University College of Business. He specializes in innovation, entrepreneurship, and community health issues, with special focus and expertise in emerging and developing economies in Africa, Asia Pacific, and the Caribbean islands. Dr. Park is also a visiting professor at the University of Johannesburg (South Africa); a former Kevin Ruble fellow in conscious capitalism at the Rutgers University School of Management and Labor Relations; the Edmond J. Safra Network Fellow at Harvard University; and a research fellow in the Oxford University Smith School of Enterprise and the Environment. He has served as the coordinating lead author of the report for the United Nations (UN) Environment Programme's Global Environment Outlook (GEO-6); as lead author for the UN Millennium Ecosystem Assessment initiative; and as an expert reviewer for a number of Intergovernmental Panel on Climate Change publications, including the Sixth Assessment Report. Dr. Park is a former member of the Renewable Energy and Adaptation to Climate Technologies Investment Committee of the Africa Enterprise Challenge Fund, and the chair of the U.S. Sustainable and Responsible Investment Forum's International Working Group Steering Committee. He received his master's degree in city planning from the Massachusetts Institute of Technology and his Ph.D. in social sciences/public administration from the Erasmus University of Rotterdam.

Sue Phelan[1] was the co-founder and the volunteer director of GreenCAPE, a nonprofit community advocacy organization formed to educate Cape Cod residents about the hazards of pesticides and other harmful chemicals (including PFAS) being used above the Cape Cod's vulnerable sole source aquifer. The focus of GreenCAPE's work is the community's exposure to PFAS via the public drinking water system and other as-yet-unidentified sources. Its major concerns include that PFAS-exposed Hyannis residents have not been provided with blood testing and the lack of health-protective PFAS regulations nationwide. Ms. Phelan was a board member of the Alliance for a Healthy Tomorrow/Boston and Clean Water Action/Mass, as well as a member of the Cape Chapter of the Sierra Club, the Sierra Club Toxics Team, and the National PFAS Coalition. She served as a community project partner and a member of the Cape Cod Advisory Committee for the Sources, Transport, Exposure, and Effects of PFAS Research Center and was one of only two community representatives invited to be on the Massachusetts Department of Environmental Protection's PFAS MCL (Maximum Contaminant Level) Stakeholder Group. After working as a medical microbiologist/virologist, Ms. Phelan returned to the University of Connecticut College of Agriculture, graduated from the environmental horticulture program, and worked in research and development on insect pheromones and light-mediated changes in plant growth and development.

Andrea Rich is an active participant in fighting for clean water in Wisconsin. She works with S.O.H2O (Save Our Water) to bring the impacts of PFAS to light, and share relevant information with the community in Marinette. Marinette is the third-largest PFAS contamination site in the nation. Ms. Rich has been researching PFAS and its health impacts, as well as filtration methods, for several years. She has been an active participant in public hearings and Department of Natural Resources presentations, and has provided testimony to Senate and Assembly committees on multiple bills proposed to regulate PFAS. Ms. Rich was also instrumental in bringing into the spotlight the contamination of farm fields and dozens of contaminated wells in rural Marinette County, some of which may otherwise still be unidentified. Her current focus is trying to get testing for PFAS in the agricultural goods coming from the contaminated farm fields, and blood testing for the community to determine exposure levels, and possibly identify additional sources of exposure. She is an honors graduate of Lakeland College, with a double major in business administration and marketing.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Dana Sargent is the executive director of the environmental nonprofit Cape Fear River Watch (CFRW), based in Wilmington, North Carolina, where she works to protect and improve the water quality of the Cape Fear River basin for all people through education, advocacy, and action. Her work on PFAS began in 2017 when her community learned that DuPont and then Chemours had polluted their drinking water supply for more than 40 years. Her organization sued the polluter and the state regulatory body, which culminated in a Consent Order, parts of which she, along with her CFRW partners and their legal counsel, maintain oversight, ensuring the polluter and the regulatory agency are upholding the requirements of the Order. In addition, CFRW partners with academia on several PFAS research grants including the GenX exposure study, along with several ecological studies and outreach grants. She works among a coalition of advocates in North Carolina pushing for strong PFAS legislation and regulatory action and her organization is one of six that has sued the U.S. Environmental Protection Agency after it refused to hold a PFAS polluter accountable for funding health and toxicity studies. Ms. Sargent has published two websites and numerous articles and op-eds on PFAS, including an op-ed in which she questions whether PFAS exposure caused the brain cancer that took her brother's life in December 2019. He had been exposed for decades in the line of duty as a Chicago firefighter and a former U.S. Marine. She holds an M.S. in environmental sciences and policy from Johns Hopkins University and a B.A. in journalism with a music minor from San Diego State University.

Laurel Schaider, Ph.D., M.S., is a senior scientist in environmental chemistry and engineering at the Silent Spring Institute, where she leads water quality research on PFAS and other contaminants of emerging concern. Her research focuses on characterizing PFAS exposures from drinking water, diet, and consumer products; understanding health effects associated with PFAS; investigating socioeconomic disparities in exposures to drinking water contaminants; and working with communities to develop research studies and resources to address their concerns. Dr. Schaider is the principal investigator for the PFAS-REACH (Research, Education, and Action for Community Health) study, a researcher–community partnership that is evaluating PFAS exposures and immune system effects in children in communities with PFAS water contamination, and developing an online resource center for PFAS-affected communities. She is also the principal investigator of the Massachusetts PFAS and Your Health Study, one of seven projects within the Centers for Disease Control and Prevention PFAS Multi-site Health Study. Dr. Schaider co-leads the Community Engagement Core for the STEEP (Sources, Transport, Exposure, and Effects of PFAS) Superfund Research Program at the University of Rhode Island, including a study to evaluate PFAS levels in private wells on Cape Cod and identify contamination sources. Before joining the Silent Spring Institute, she was a research associate at the Harvard T.H. Chan School of Public Health, where she currently holds an appointment as a visiting scientist. Dr. Schaider served as a member of the planning committee for the 2020 National Academies of Sciences, Engineering, and Medicine's Workshop on Federal Government Human Health PFAS Research. She earned her master's degree and Ph.D. in environmental engineering at the University of California, Berkeley, and a bachelor's degree in environmental engineering science from the Massachusetts Institute of Technology.

Linda Shosie, a proud Latina woman, is a mother, grandmother, wife, and the founder and organizer of the grassroots community organization Mothers for Safe Air & Safe Water Force in Tucson, Arizona. In her fight for the human right to clean and safe water she has dedicated her entire life to protecting public health. Ms. Shosie has become one of the leading voices nationally regarding PFAS exposures in Latino barrios. In 2007, she lost her child to a rare disease she believes was caused by exposures to numerous toxic chemicals in the drinking water in the Tucson South-Side barrio. More recently Ms. Shosie has begun initiating a community-led PFAS health study in her community to assess for PFAS in human blood. She is also part of the National PFAS Contamination Coalition.

Lenny Siegel is the executive director of the Center for Public Environmental Oversight, where he has been serving since 1994. He is one of the American environmental movement's leading experts on both military facility contamination and the vapor intrusion pathway. Mr. Siegel runs two Internet newsgroups for his organization: the Military Environmental Forum and the Brownfields Internet Forum, as well as activist discussion lists on trichloroethylene and PFAS. He has served on several Interstate Technology and Regulatory Council work teams on environmental remediation, as well as a dozen National Academies of Sciences, Engineering, and Medicine committees addressing military environmental issues. In July 2011, Mr. Siegel was awarded the U.S. Environmental Protection Agency's Superfund Citizen of the Year award. In 2018, he served as mayor of Mountain View, California.

Mike Watters is a community organizer in the Fayetteville, North Carolina, area. After learning his well was contaminated with more than 16 PFAS, Mr. Watters set up a community outreach group. He created a Facebook group with more than 2,700 members and actively provides information to the community, ensuring wells are tested in a rapidly growing area around the Fayetteville Works Facility in North Carolina. Mr. Watters provides input at all North Carolina Science Advisory committee meetings, leads teams in assisting in research with the NC PFAS Testing Network, and works actively with North Carolina State University research teams. Additionally, he engages with state and federal authorities to ensure that violations and spills are documented and action is taken; two notices of violation are directly tied to his actions. Mr. Watters also works with the North Carolina Department of Environmental Quality, having participated in the Granular Activated Carbon Pilot Test. He currently has a state PFAS air monitoring station on his property and assists the state in gathering information. While in the military, Mr. Watters was trained and certified as a U.S. Department of Defense hazardous materials handler. He has college degrees in information technology and firearms technology.

La'Meshia Whittington is a professor in the Division of Sociology at Meredith College. She is also the deputy director for Advance Carolina and the campaigns director for the North Carolina Black Alliance. She is the co-convener of the North Carolina Black and Brown Policy Network, a former national democracy campaigner for Friends of the Earth, the chair of the FRENC Fund Administration, a founding member of Democracy Green, a member of the Burke Women's Fund in Western North Carolina, and a former North Carolina spokesperson on fair courts for The Leadership Conference on Civil and Human Rights. A leader in intersectional democracy and environmental justice, Ms. Whittington was the co-author of North Carolina Senate Bill 673, prioritizing environmentally contaminated communities of color in voting rights, and the co-author in several Pro-Democracy North Star legislation bills. She is a member of the NC PFAS Testing Network, anchoring legislation on aqueous film-forming foam, and she is a convener of the Black Firefighters Fighting PFAS Collective. Ms. Whittington has created and co-convened national, regional, and statewide tours and workshops on environmental justice, focusing on chemical contaminants and dirty corporations. She works continually with the Brody School of Medicine at East Carolina University, the U.S. Department of Health and Human Services, and other government agencies to ground community needs and strategies in alleviating health disparities in Black and Brown communities. Ms. Whittington led the development of a statewide map to highlight the intersection of environmental justice contamination zones and the frequency in which they are located within gerrymandered Black majority voting districts. She is a petitioner in two active petitions to the U.S. Environmental Protection Agency. Ms. Whittington is an Afro-Indigenous woman from North Carolina, hailing from a former environmental justice settlement: The Kingdom of the Happy Land. She received her education at Western Piedmont Community College and Meredith College.

Alan Woolf, M.D., is a professor of pediatrics at Harvard Medical School, a board-certified pediatrician and medical toxicologist, and a senior attending physician at Boston Children's Hospital (BCH). He is the director of the Pediatric Environmental Health Center at BCH, directing its fellowship training program in pediatric environmental health and the Region 1 New England Pediatric Environmental Health Specialty Unit. Dr. Woolf is a member of the Executive Committee of the Council on Environmental Health of the

Copyright National Academy of Sciences. All rights reserved.

American Academy of Pediatrics and a past president of both the American Association of Poison Control Centers and the American Academy of Clinical Toxicology. He is the editor and author of two books: *The Children's Hospital Guide to Your Child's Health and Development* (Perseus Publishers) and *History of Modern Clinical Toxicology* (Academic Press) and has authored or co-authored more than 300 scientific publications.

Cathy Wusterbarth is a registered dietitian nutritionist, and the co-leader and founder of NOW (Need Our Water) in her hometown, Oscoda, Michigan. NOW was created in 2017 to give Oscoda-AuSable and surrounding communities a voice. Its mission is to be a reliable resource and catalyst for education and communication while advocating for long-term health and environmental welfare plans on behalf of those affected by water contamination from the former Wurtsmith Air Force Base in Oscoda, Michigan. Ms. Wusterbarth and other NOW members have consistently demanded that the State of Michigan and the Air Force address the PFAS contamination that affects her community, as well as more than 700 military installations. She was invited to the 2019 State of the Union by Congressman Dan Kildee to represent communities affected by PFAS contamination and support the newly created Congressional PFAS Task Force. In addition to testing and monitoring the health of Oscoda residents, Ms. Wusterbarth believes the federal government should conduct the necessary epidemiological studies to correlate health outcomes among veterans and their families.

Sandy Wynn-Stelt is a clinical psychologist in private practice. In 2017, she learned that her groundwater had been contaminated by PFAS from a landfill that had been used by Wolverine Worldwide to dispose of Scotchgard-laden tannery waste. Since then, Ms. Wynn-Stelt has become an advocate for preventing similar contamination in other communities. She has spoken with several state and local legislators and the Michigan attorney general, and has testified in Washington, DC, at hearings on PFAS contamination. Ms. Wynn-Stelt currently participates on the leadership team of the local Wolverine Community Advisory Committee, as well as on the Michigan PFAS Action Response Team. She also participates in the Michigan Department of Health and Human Services' Health Study as a stakeholder for both the state PFAS study and the Agency for Toxic Substances and Disease Registry's Multisite PFAS Study. Ms. Wynn-Stelt participates in training with U.S. Environmental Protection Agency (EPA) staff on effective communications with community members. In 2020, she was awarded the Citizen Excellence in Community Involvement Award by the EPA for her work in the community and state in advocating for stronger regulation of this class of chemicals.

Appendix B

Summary of the Committee's Town Halls

As noted in Chapter 1, the committee engaged with community members throughout the study process. A key component of the community engagement was the conduct of three town halls, held on April 7, May 6, and May 25, 2021. The town halls were conducted remotely, because of the COVID pandemic, and designated Eastern, Middle, and Western. In total, they featured 36 people affected by PFAS.[1]

This appendix summarizes the discussions at the town halls. It was prepared by Anna Ruth Robuck, Ph.D., as a factual summary of what occurred. The statements made are those of the rapporteur or individual meeting participants and do not necessarily represent the views of all town hall participants, the study committee, or the National Academies of Sciences, Engineering, and Medicine.

OVERVIEW

The town halls included presentations by invited community representatives detailing information about exposures, health effects, and health care needs; discussion sessions enabled exchange between committee members and participants. The presenters described frustrating and harrowing ordeals navigating PFAS exposure and related health issues and concerns. Several key themes were echoed by multiple presenters and in discussion sessions, including:

- an immediate need for accessible PFAS blood testing,
- continued assessment of PFAS health effects,
- the need for equitable action that best supports the people who are most vulnerable and disproportionately affected, and
- a continuing need for comprehensive exposure assessments.

Accessible Testing Multiple speakers highlighted the importance of readily available, affordable PFAS blood testing. Such testing would serve to establish baselines of exposure, provide agency to exposed communities and families, show respect for community concerns, and inform precautionary health care. They stressed that testing must be financially accessible and recognized by insurance coverage. Many recounted reluctance or refusal by health care providers to order such testing because of the inability to definitively relate blood concentrations to health effects. While acknowledging pervasive exposure to PFAS in the U.S. population, speakers suggested that exposed communities and vulnerable populations should be prioritized for PFAS blood testing, using equity as a guide to design testing protocols.

Continued Assessment of Health Effects Many speakers highlighted the lack of studies detailing health outcomes related to PFAS exposures, citing this as a glaring and troubling data gap, given the long list of health concerns and trends identified by and in exposed communities. Presenters pointed out that the lack of identified health effects often gets cited as a reason not to perform research or desired testing, leading to a circular situation in which health effects are not identified because of a lack of study, and studies are not conducted because of a lack of identified health effects.

[1] PFAS are chemicals known as perfluoroalkyl and polyfluoroalkyl substances; see Chapter 1.

KD2494

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Equitable Action Numerous presenters acknowledged the importance of considering systemic inequities when designing health care interventions or protocols related to PFAS exposure. They noted that minority communities often bear disproportionate burdens of exposure, magnified by inequitable sociocultural and economic frameworks. Health care workers seeking to mitigate and address PFAS exposure must consider such compounding effects of inequity, relying on community participation and input to guide intervention. Some speakers pointed out that children, pregnant women, transient populations (such as service members and migrant workers), and people without health insurance or lacking accessible health care need to be considered given the demonstrated burden of PFAS on these populations. Moreover, information about PFAS and appropriate health care options must be framed and presented in culturally appropriate ways across the continuum of both formal and informal health care settings.

Comprehensive Exposure Assessment Throughout the town halls, speakers provided background information about PFAS exposure scenarios in their community or region. These descriptions revealed vast uncertainty about the scope and scale of exposure. Speakers suggested that exposure vectors beyond drinking water should be explored, including air, cooking and washwater, fish and seafood, wildlife products, garden vegetables, and other foods and agricultural products. Speakers also stated that a larger number of PFAS should be included in monitoring efforts considering the ever-expanding number of compounds included in the PFAS class.

EASTERN TOWN HALL

Laurene Allen (Merrimack Citizens for Clean Water)

Laurene Allen shared perspectives from the extensively exposed community of Merrimack, New Hampshire. Residents of this area learned about their exposure to PFAS, in 2016, related to local industrial activities. PFAS have since been found regionally in air, soil, groundwater, and drinking water across an area of more than 65 miles containing five towns. The community is therefore aware of their past exposure and frustratingly continues to grapple with current exposure from ongoing PTFE[2] used in fabric and film coating by a local manufacturing facility. Allen stated the community finds the continuing exposure to unregulated PFAS troubling, particularly in the absence of appropriate health care that considers both the history and current extent of PFAS exposure.

Allen described the inaccessibility of blood testing for PFAS and health screenings for PFAS-related ailments, with feedback from physicians that such information is expensive to obtain and may be unhelpful or difficult to frame. However, Allen asserted that such testing is important and validating to the community, and a key "piece of the puzzle" to establish baseline information about the evolving understanding of the nature of exposure. Allen also stated that the community sees patterns of disease and illness related to source proximity that are not currently acknowledged or understood by health care practitioners. Given the documented link between PFAS and specific health effects, including immune function and endocrine health, blood testing is vital for matched, relevant health care based on exposure history.

Allen noted a link between COVID-19 cases and PFAS exposure in New Hampshire, with the further suggestion that information about patient and community PFAS exposure should be incorporated into COVID-19 responses, vaccination protocols, and other public health considerations. Allen also underscored the importance of integrating environmental health and exposure history into health records to increase the capacity to monitor for PFAS-related health effects over time. Allen concluded by emphasizing the importance of improved guidance and support for physicians as to how to best incorporate PFAS exposure into clinical care and patient risk reduction to ensure support for highly exposed communities desperate for appropriate care.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

"It's been really difficult to get chronic PFAS exposure and risks posed from this chemical class acknowledged by health care providers." *Laurene Allen*

Teresa Gerade (Don't Undermine Memphremagog's Purity)

Teresa Gerade provided information about landfills as sources of PFAS contamination and her Vermont community's concern about an adjacent landfill. PFAS-enriched landfill leachate is often treated by nearby wastewater treatment plants. Wastewater treatment plants are typically not designed to remove PFAS, resulting in the generation of effluent and biosolids enriched in PFAS. PFAS are then reintroduced to the water cycle through effluent discharge or may enter plants grown in soils amended with sludge-derived biosolids.

Gerade focused on information about Vermont's landfill neighboring Lake Memphremagog, a lake spanning the border of the United States and Canada. The community surrounding Lake Memphremagog is particularly concerned about the local and regional PFAS exposure associated with the Vermont landfill and how it affects the health of both the lake and the community. Malignant melanoma has been found in a certain species of lake fish, raising questions about the health of fish populations. The surrounding community has related concerns about the safety of eating freshwater fish from the lake and crops grown in biosolid-amended soils. Gerade suggested the need for PFAS screening levels in human blood, like those in place for cholesterol or glucose, to allow for exposure monitoring over time and related risk mitigation.

Ayesha Khan (Nantucket PFAS Action Group)

Ayesha Khan provided insight about the experiences of the firefighting community and specifically the firefighting and AFFF-exposed[3] community on Nantucket, Massachusetts. Firefighters are routinely exposed to PFAS through both their gear and firefighting foams. Although the Centers for Disease Control and Prevention (CDC) recommends limiting exposure to PFAS, many firefighters are unaware of PFAS or their unique occupational exposure to the pollutants. As a result, firefighters often receive little or no training to mitigate the risk related to gear handling and foam use. This unawareness has led to previous practices that caused undue PFAS exposure, such as using AFFF to clean vehicles or allowing children to play in AFFF.

Khan emphasized the importance of medical monitoring and PFAS bloodwork for firefighters and other PFAS-exposed communities. Khan asserted that such access would establish exposure baselines, raise awareness, and empower people who are exposed to be proactive in reducing exposure and managing risk. Khan illustrated the limited and frustrating accessibility of bloodwork by recounting an experience with a physician, one who is aware of the PFAS crisis and lectures on PFAS exposures. During care for a child, the patient's parent requested PFAS bloodwork. The physician responded by trying to dissuade the parent from seeking the testing, saying if PFAS measurements in blood were carried out it would be difficult to frame the information, especially since the child was currently healthy. Khan also recounted that the doctor misquoted data from studies by the Agency for Toxic Substances and Disease Registry (ATSDR) that measured PFAS in residents of exposed communities throughout the United States, stating these studies "did not find much."

The physician went so far as to jokingly cite a study that found higher reading ability in children whose mothers were prenatally exposed to PFAS. Khan stated the doctor's response felt as though they were vastly minimizing exposure concerns to the detriment of informed health care for the patient and parent. Khan went on to assert the importance of improving CDC guidance about PFAS provided to clinicians, as the current guidance recommends limiting exposure with little or no information about how to do so in practice. Khan stated that the vagueness of the current guidance can result in situations in which clinicians become barriers to information or action, thereby imposing a burden on concerned

[3] AFFF are aqueous film-forming foams, used in firefighting, that often contain PFAS.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

patients to figure out how to reduce exposure and advocate for themselves in a health care setting. Khan reiterated the importance of providing candid information about PFAS to exposed communities, as well as to health care providers, lawmakers, union leaders, and other decision makers in order to help exposed communities and families rectify their burden of contamination.

> "We are not scientists or doctors. We assume our government is keeping us safe, and when there is a possible link to adverse health risks, we are led to believe that issue is promptly resolved and not with a regrettable substitution."

> "My hope is that [the committee] will educate physicians to be honest with those of us who have been exposed." *Ayesha Khan*

Kristen Mello (Westfield Residents Advocating for Themselves [WRAFT])

Kristen Mello offered perspectives from a PFAS-impacted community as a representative of Westfield, Massachusetts. Mello provided context about her experience with PFAS exposure by explaining she learned about her community's AFFF-contaminated drinking water in 2016 and founded WRAFT in response. An ATSDR study of 459 Westfield residents subsequently found that 92 percent of the city's residents had serum concentrations of at least one PFAS that exceeded the national average.

In considering the committee's task regarding challenges related to PFAS encountered in health care settings, Mello cited the frustrating lack of clinical guidance for health care providers as a major challenge. She noted that the current paucity of clinical guidance contrasts sharply with the availability of scientific information describing exposure assessment of specific human populations, animal studies, and toxicological models, and the rigorous collation of such scientific information provided by the ATSDR toxicological profile for PFAS.

Mello strongly stressed the need to collect data about PFAS exposure and associated health effects in exposed communities, citing the inherent disrespect of the plight of exposed communities when testing efforts are denied or discouraged. Without paired assessment of PFAS exposure and associated health outcomes, Mello suggested, the true scope of adverse health effects associated with specific PFAS thresholds cannot be identified, further limiting the advancement of clinical guidance for health care practitioners.

Mello highlighted health conditions of concern observed in her own community, including allergies, autoimmune and immune disorders, asthma and pulmonary disease, colon diseases, reproductive cancers, menstrual and fertility issues in women, diabetes and metabolic disorders, thyroid disease, cholesterol and liver disease, osteoarthritis and osteoporosis, cognitive and developmental disorders, neurological issues, brain cancer, kidney diseases, and bladder cancer. Mello further argued for the benefits of data collection in exposed communities by highlighting the value of PFAS exposure and health assessment in a tailored public health response. For example, Mello said, blood testing could facilitate identification of communities more likely to be immunocompromised due to PFAS exposure when designing COVID-19 intervention or protocols.

Even in the absence of information framing PFAS exposure levels in relation to specific health outcomes, however, Mello said exposure assessment is critical for affected communities. Mello described the contamination occurring in exposed communities as an intentional crime, without the same protections afforded to victims of equally degrading crimes. Mello argued that the accessibility and implementation of such testing validates and respects the plight of those contaminated without their knowledge or consent, akin to respecting the rights of a crime victim.

Mello also commented on the ubiquity of PFAS exposure in the general population, pointing out that scientists have identified thousands of PFAS while only nine are being considered as part of the committee's study. She further pointed out exposure vectors relevant to the general public, including the air and consumer products.

KD2497

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Mello encouraged the committee to recommend amending guidance for health care practitioners to better support exposure reduction, ensure respect and support for those exposed, and enable equitable and voluntary data collection to assess PFAS levels and associated health effects. Additionally, Mello emphasized the importance of patient agency and fully informed consent during the care process. She also stressed the immediate need to use existing knowledge to revise clinician guidance and treatment plans for those currently exposed to PFAS, rather than waiting for further data. She also recommended the utility of future monitoring and a voluntary national database of exposure and health effects information so exposure and health data can be stored and further explored.

> "So we were asked as community liaisons what challenges we have had with our medical providers in dealing with PFAS exposure, and the challenge is that there's just no helpful information."

> "You don't have a problem getting an insurance assessor when your car is hit, you don't have a problem getting an insurance assessor when you have a tornado, but this slow-motion unfolding environmental and public health disaster … is intentionally keeping the information from us so that we cannot take action." *Kristen Mello*

Tracy Carluccio (Delaware Riverkeeper Network)

Tracy Carluccio summarized perspectives as a community activist and advocate based in New Jersey. Carluccio contextualized her perspectives by describing the scope of ongoing PFAS contamination and action in New Jersey. She acknowledged the state's heavy burden of legacy and novel environmental contamination, including prolific PFAS contamination, caused by several companies such as DuPont, 3M, and Solvay. In response, the state has taken ground-breaking regulatory steps to address PFAS, and it was the first to adopt maximum contaminant levels (MCLs) for drinking water that were lower than the health advisory guidelines proposed by the U.S. Environmental Protection Agency (EPA).

Despite New Jersey's progressive stance on PFAS, however, Carluccio said that the narrative in the state is primarily driven by affected communities, and large information gaps still exist. Some blood testing has been carried out in specific localities, but there has been limited blood testing across the state or near specific industrial sites. The PFAS crisis in New Jersey cannot be fully understood until the public has access to data claimed as confidential business information by companies producing or using PFAS, she said. Additionally, Carluccio argued, thorough exposure assessment, health studies, and medical monitoring must be carried out to fully characterize the scope of PFAS contamination and related effects for New Jersey residents.

Carluccio provided two specific examples to underscore the importance of community access to information and monitoring in pursuit of the most appropriate health care. She described legacy and emerging PFAS contamination originating from Solvay, an industrial user of PFAS located in West Deptford. Industrial activities by the company were found to contaminate the drinking water of 50,000 residents of the surrounding area with legacy PFNA,[4] first identified in 2013. Since that time, the company has shifted to new PFAS to replace legacy compounds, while providing little information to the community about the occurrence and health implications of these new compounds. Carluccio also stated that the company has thus far refused to comply with a state directive requiring PFAS users and producers to provide information about production activities to the state, prompting a lawsuit.

The lack of data describing community exposure around Solvay has left the community in a precarious position, unable to appropriately steer their own health care and family choices. Carluccio also detailed PFAS exposure in communities adjacent to military bases in the state. She emphasized that company and agency recalcitrance to share information about legacy and novel PFAS use and contamination actively thwarts the needs of surrounding communities. She suggested that "ignorance is not bliss," as it may lead to misinformed health decisions; instead, informed community members gain

[4] Perfluorononanoic acid, a PFAS; see Chapter 1.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

agency and can best decide whether they want to avoid tap water, install additional drinking water treatment, move out of a contaminated area, or consider exposure in making reproductive and family decisions.

Loreen Hackett (PFOA Project New York)

Loreen Hackett provided insight about her experiences as an organizer from Hoosick Falls, New York. In 2015 the town was found to be severely contaminated with PFAS, specifically PFOA,[5] and has since been designated as the first PFOA site on the EPA Superfund national priorities list in the United States. The town is now home to three federal sites, as well as several additional state Superfund site declarations, with more currently being investigated in the small community.

Hackett detailed her intimate experiences with PFOA contamination by citing the highly elevated levels of PFOA found in her own blood and the blood of her grandchildren, comparing these staggering figures to national averages that are hundreds of times lower. Hackett commented that the alarming levels found in her family's blood required guidance from health care professionals, yet thus far her family and community health care needs have been poorly met in a clinical setting. As an example, Hackett described a situation shortly after the community learned about exposure. The New York Department of Health organized a community meeting with a pediatrician who lacked PFAS expertise. The pediatrician responded to community questions about health concerns by stating "I don't believe any of your illnesses are caused by PFOA." Hackett described feeling mortified and frustrated at this response, given the community was familiar with existing research that decisively indicated the opposite.

Hackett also described results from a community health study that supported the community's concerns, listing cases of kidney cancer, testicular cancer, thyroid disease, pregnancy-induced hypertension, and ulcerative colitis in the community. Hackett stated the people had to do research for themselves, which was arduous and confusing at times. This fact-finding process took up valuable time that could have helped mitigate exposure-related effects in the community. Hackett indicated that state and local regulatory agencies are now taking PFAS contamination more seriously, with the state setting more protective drinking water MCLs and continued community blood testing.

Hackett stated that too few doctors are trained in the ramifications of environmental toxins and associated care protocols. As a result, Hackett described her habit of bringing research studies to appointments with specialists or unfamiliar doctors to illustrate relationships between PFAS exposure and health effects. She indicated that few listen, and she is reluctant or unwilling to follow up with those who do not listen, therefore missing out on further treatment and testing options, as well as any associated benefits.

Hackett also mentioned that Hoosick Falls residents often rely on the closest hospital, which is in Bennington, Vermont, which is itself a PFAS-contaminated community. Yet even there, Hackett stated, many health care providers are unaware of PFAS and associated health implications. She provided an example in which a provider suggested her breast cancer was genetic despite family history and medical history suggesting otherwise. She articulated that health care practitioners unfamiliar with the issue often made her feel intellectually inferior because of her lack of formal medical credentials, rather than acknowledging and validating her significant health concerns. She stated this dynamic continues to occur even with health care providers directly situated in currently contaminated communities.

Hackett also provided an example depicting the benefit of informed health care, by stating that a local general practitioner took time to learn about the medical ramifications of PFAS exposure; this awareness has resulted in concerted follow-up on PFAS-related health issues in the immediate community to keep pace with the emergence of health effects. Hackett suggested the implementation of continuing education credits to incentivize continued training on environmental health issues for health care practitioners.

[5] Perfluorooctanoic acid, a PFAS; see Chapter 1.

KD2499

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Hackett also stressed the need to establish new health care paradigms and protocols specifically tailored to exposed communities. For example, she questioned whether blood donation is safe in highly exposed communities like Hoosick Falls. Additionally, she suggested that exposed women should be informed by obstetrical/gynecological care providers that PFAS will be passed to babies in utero and in breast milk. Health care mantras like "breast milk is best" need to be thoroughly reevaluated in exposed communities, given that breastfeeding may double or triple PFAS levels in infants in comparison with their mothers' levels. Families in exposed communities cannot make informed reproductive choices or other family decisions without information tailored to their situation. Hackett relayed concerns from community members now expressing guilt at unknowingly poisoning their child over the course of pregnancy and breastfeeding. Hackett also suggested that health care norms, such as visiting times, need to be adjusted to better fit environmental concerns because health care discussion about PFAS require more attention than a short office visit.

Hackett emphasized the need for health care professionals to trust their patients and their observations and knowledge on PFAS issues. By trusting local community members, practitioners and scientists can better use community data and experiences in building effective health care for people who have been exposed. Hackett described her participation on the Community Advisory Panel with University of Albany for their CDC-awarded multisite study, collecting and sharing published health studies related to PFAS for the study website. Working in this context, Hackett stated, the study design has shifted to include more tests beyond liver, kidney, and thyroid function, as immune suppression, endocrine disruption, neurological effects, reproductive issues, and breast cancer become increasingly salient community concerns.

Hackett also detailed ongoing contamination concerns in her community due to continued stack emissions and exposure to unregulated, short-chain compounds designed to replace PFOA that studies show to be as toxic as long-chain, legacy PFAAs.[6] As a result of regrettable substitution, Hackett advised that bioaccumulation and total body burden of numerous PFAS has to be considered for those requesting medical direction through continued blood testing beyond the limited number of PFAS currently under scrutiny.

Patrick Elder (Military Poisons)

Patrick Elder articulated concerns and insights about the understudied role of PFAS exposure from food. Elder stated that he believes there is too much emphasis on PFAS levels in drinking water, with too limited a focus on PFAS exposure from food, particularly seafood. Elder contextualized this position by detailing his experiences testing surface water and seafood items near his home in southern Maryland, adjacent to the Naval Air Station Patuxent River Webster Field Annex. Elder's efforts resulted in the detection of significant PFAS concentrations in surface water and seafood items. Elder published the results in the local press, leading to concern and outrage in the community. He indicated that a subsequent public meeting with Navy officials resulted in an unsatisfactory exchange of information with the local community, as Navy officials reiterated that the chemicals in question were no longer in use and there was no medical treatment to reduce PFAS in the human body. The community sought increased testing on seafood items and water, expressing disagreement with the Navy's assertion that not enough is known about PFAS in seafood and the human body to justify immediate intervention.

Elder further highlighted the untenable data gaps for PFAS in food in the United States through a comparison: the European Food Safety Authority recommendations suggest up to 86 percent of PFAS exposure stems from food intake while the U.S. Food and Drug Administration (FDA) issued a statement suggesting there is no evidence that dietary choices should consider PFAS contamination. Overall, Elder emphasized the importance of better limiting PFAS exposure from food and seafood items in the United States and incorporating this vector of exposure when considering health effects and health studies.

[6] Perfluoroalkyl acids, a class of PFAS; see Chapter 1.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Hope Grosse (Buxmont Coalition for Safer Water)

Hope Grosse described her experiences in Bucks and Montgomery counties (BuxMont), Pennsylvania. Grosse described a lifetime of exposure due to drinking water contaminated by AFFF use at Warminster Naval Base and Willow Grove Naval Air Station.

Grosse reported that people in the BuxMont community have voiced concern regarding their PFAS exposure and a number of diseases and health conditions including thyroid cancer, non-Hodgkin's lymphoma, kidney cancer, testicular cancer, breast cancer, liver cancer, brain tumors, ovarian cancer, lung cancer, bladder cancer, melanoma, bone cancer, altered metabolism and obesity, fertility issues, birth defects, diabetes, cholesterol, high blood pressure, preeclampsia in pregnant women, decreased infant birthweight, autoimmune diseases, chronic inflammation, immune response, and alterations in liver enzyme levels. The implications of exposure are not limited to physical ailments: the community has also collectively experienced serious experiences with fear, anxiety, grief, emotional and physical stress, and a feeling of being forgotten.

Grosse said she personally wrestles with an unbelievable lack of trust, fear, and emotional scars accumulated related to the premature death of her father, her own early cancer diagnosis, and deaths of multiple cherished community members. Grosse further revealed that she struggles with shame and fear due to the feeling that she inadvertently poisoned children because she was unaware of her exposure. Grosse also described the financial stress imposed on exposed communities to pay for bottled water, increased public water rates, home filtration, diagnostic testing, medical fees, and loss of wages due to health issues and related loss of productivity.

Grosse stressed the importance of increased awareness and resources to better educate health care practitioners about the health effects of PFAS. She indicated that communities need to be able to trust that their caregivers and practitioners are knowledgeable on the issue and capable of advising action to address their concerns. She stated that the community feels they have no local medical resources or health care providers to answer their questions or advocate for them in the health care system. During her own health struggles, she said she felt belittled and embarrassed for asking questions about environmental health and its relation to her health maladies. Grosse recommended considering practical measures to improve the patient experience for exposed people, such as requiring questions about exposure history or concerns in health questionnaires and forms or designing better collaborations between insurance companies and physicians so practitioners can readily issue scripts for bloodwork and diagnostics that are covered by insurance.

Grosse stressed that such clinical guidance must particularly provide proper direction detailing how to best protect and treat children, given the particular risks of PFAS exposure during critical developmental periods. Mothers need awareness and guidance to test for PFAS in blood and breast milk and make effective parenting choices based on exposure results to best safeguard children in utero or during breastfeeding. Grosse mentioned she lacked such information and agency raising her own children and would have greatly valued the knowledge and associated opportunity to switch to filtered water or bottle-feed her children to reduce their early-life exposures.

Grosse also emphasized that blood testing remains imperative to characterize exposure and changes in PFAS blood levels over time. Grosse posited that the value of blood testing is not predicated on how well the derived information can be explained or compared to thresholds. Rather, documentation of the exposure can retrospectively serve communities, as health science progresses to more fully understand the health ramifications of exposure. Grosse also asserted that blood testing facilitates appropriate health planning, as exposed individuals have a right to preventive health measures and testing tailored to their exposure reality, such as titer testing to deduce PFAS-altered vaccine responses or tests for PSA and liver enzymes.

"When I would go to the doctor's and tell them about some of the exposures of over 50 chemicals that I was exposed to, the doctors would laugh and say no. Clearly they didn't have any information about

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

environmental components [of disease]. They made me feel small, they made me feel stupid and embarrassed even just asking the question." *Hope Grosse*

Le'Meshia Whittington (North Carolina Black Alliance)

Le'Meshia Whittington discussed the perspectives and needs of Black and Brown communities in North Carolina. Whittington emphasized that Black and Brown communities face cumulative impacts in addition to environmental health concerns, resulting in disparate burdens and concerns for exposed minority communities well beyond drinking water. Whittington exemplified this reality as related to PFAS exposure in the Cape Fear River system in southeastern North Carolina. In 2017, the public learned about significant PFAS contamination in regional surface water and drinking water due to the industrial activities of Chemours in Fayetteville, North Carolina. Whittington highlighted that this news broke amid a history of climate-related disasters (e.g., hurricanes) that repeatedly damaged the regional water system over decades. As a result, with the occurrence of Hurricane Florence in 2018, regional communities were severely affected by floodwaters contaminated with coal ash, animal waste, and industrial wastes, as well as PFAS. However, the ramifications of PFAS-laden floodwaters were not addressed following Florence.

Whittington described the multifaceted and overlapping exposure vectors of concern for Black and Brown communities, highlighting that the interplay of these factors can cause undue cumulative exposure and subsequent harm. She highlighted that about 35 percent of North Carolinians are renters, leading to potential exposure from carpets, textiles, and building materials with no capacity to remove or replace these items. Whittington also pointed out 80 of the state's 100 counties are considered food deserts or contain food deserts, where residents face significant hurdles accessing fresh fruits, vegetables, and other sustainable foods. In these areas, people may unduly rely on packaged, processed, and fast foods prepared using PFAS-laden water, following storage or transport in food packaging materials that contain PFAS. This type of food sourcing leads to concentrated PFAS exposure. Whittington again highlighted the additive impact of many cumulative factors, noting many of these food desert areas in North Carolina are downstream from continued contamination from Chemours and are also routinely affected by climate-related flooding events.

Whittington also pointed out that occupational exposures require increased health monitoring, considering the cumulative risk imposed when different industrial activities collide in a given region. She stated that more information is needed describing how food service, essential, agricultural, and industrial workers may be exposed occupationally given inherent contact with potential PFAS sources in those jobs, as well as increased risk to those workers when their employment location is in a region rife with known contamination. For example, Whittington questioned how agricultural and abattoir workers who work in PFAS-contaminated zones may be routinely exposed through industrial air emissions and constant contact with PFAS-imbued agricultural products. Whittington suggested increased institutional study and support for workers through the Occupational Safety and Health Administration or other agencies, and the need for increased health care provisions for those closer in proximity and more consistently exposed to this group of chemicals.

Whittington also highlighted high-priority populations within wider Black and Brown communities. She identified pregnant women and children as two such priority populations given the demonstrated opportunity for maternal transmission of PFAS to their children. Whittington stressed the need for blood testing for expecting parents and children, and increased attention to fertility concerns. Whittington also highlighted veterans, people in law enforcement custody, people with disabilities, firefighters, residents of care and extended-stay facilities, and students as underserved priority populations. She stated that blood testing for PFAS should be made available and accessible to these and all demographic groups, with a critical need for exposure assessment over time.

Furthermore, Whittington stressed, it is important to have updated clinical guidance about PFAS blood testing, health concerns, and standards of care for health care professionals. This information must be disseminated among the wide range of practitioners, agencies, and institutions serving high-priority populations and wider Black and Brown communities. Whittington stressed that such guidance is also

Copyright National Academy of Sciences. All rights reserved.

urgently needed to ensure health insurance claims related to PFAS exposure are viable and compensable, increasing access to exposure-informed health care.

> "This is what we are asking: our communities are willing to undergo testing, they will participate in studies, it just needs to be designed for our communities, alongside our communities."
> *Le'Meshia Whittington*

Mike Watters (Gray's Creek Residents United Against PFAS in Our Wells and Rivers)

Mike Watters provided perspective as a resident of a community affected by the industrial activities of Chemours in Cumberland and Bladen counties in North Carolina. Watters described concerted efforts to engage his community to ensure awareness and engagement. One such effort included a community health survey of 100 people that highlighted shared community health concerns related to PFAS exposure, including thyroid function and hyperthyroidism, weight gain, arthritis, asthma, autoimmune disorders, skin cancer, chronic inflammatory conditions, vitamin D deficiency, type 2 diabetes, prediabetes, hair loss, high blood pressure, high cholesterol, high triglycerides, irritable bowel syndrome, and itchy scalp. Watters emphasized that continued measurements of PFAS in blood are urgent to associate these health concerns with PFAS concentrations and to allow health studies to catch up with the state of exposure. Watters also stressed the value to the community of baseline exposure assessment and the importance of tracking exposure over time through continued blood testing given evolving exposure scenarios. This work is currently being done through the North Carolina State University GenX (PFAS) Exposure Study with participation from people in the community, as well as pets from their homes.

Watters also discussed understudied vectors of exposure, such as fish, air, rain, locally grown vegetables, cooking water, cleaning water, clothing washed in contaminated water, and showers. The contribution of these sources to PFAS exposure and associated health outcomes are poorly characterized. These understudied exposure sources therefore stand as sustained concerns for community members. Watters suggested the continued need for more monitoring to keep pace with the unique exposure scenario in North Carolina and to address these understudied routes of exposure, given growing evidence that air emissions of novel PFAS continue to affect a growing number of residents across the region.

Emily Donovan (Clean Cape Fear)

Emily Donovan provided insight about the community experience of residents in southeastern North Carolina subject to high levels of PFAS exposure. Donovan explained that regional communities have been overexposed to hundreds of novel and legacy PFAS for decades because of regional industrial activities and that contamination is continuing. Donovan noted that existing health guidance does not adequately address the amount or types of ongoing PFAS exposure in the state. She also described the frustrating inability of state and federal agencies to halt ongoing discharge of the complex PFAS mixture impacting the region. She noted the prevalence of PFAS occurrence in regional wildlife, sediment, rainwater, and consumer products, pointing out that communities in the region are concerned about PFAS exposure from these and other sources given the excessive PFAS exposure from their drinking water. Donovan said that clinical guidance tailored to ongoing exposure in the state must consider this and protect community members from routes of exposures beyond drinking water.

Donovan noted the community's limited capacity to obtain blood testing for the suite of PFAS found in North Carolina as a major and exasperating challenge. Analytical methods that screen for all relevant PFAS are uncommon, and those that do exist are expensive or possess detection limits that are too high to be useful. Donovan mentioned that she has heard commentary that the exposure profile experienced in southeast North Carolina is "too unique" to warrant development of rigorous testing; she countered this idea by highlighting the use of PFAS produced by Chemours at manufacturing facilities across the nation.

KD2503

Copyright National Academy of Sciences. All rights reserved.

Donovan cited the GenX Exposure Study as an example of blood testing that occurred regionally, which found a range of novel and legacy PFAS in 400 local residents. However, she asserted that a larger proportion of the more than 300,000 people exposed should be included in further testing, citing the opportunity for the population to be used in larger health effects studies, given the long history of unique exposure across the area and documented health concerns shared across the population. She asserted this overexposed, large population is the "statistical power" required to identify understudied health effects so far missed by institutional investigation.

Donovan presented specific and heart-wrenching examples of personal contacts who are currently uncertain and worried about links between serious health conditions and their history of exposure. She detailed a litany of regional health concerns, including pediatric bone cancers, osteosarcoma and brain tumors, pediatric kidney cancers and diseases, bladder cancer, gallbladder dysfunction, testicular cancer, pancreatic cancer, liver cancer, nonalcoholic fatty liver disease, leukemia, blood cancers, colon cancer, thyroid cancer and dysfunction, autoimmune diseases, digestive issues, multiple sclerosis, skin disorders, infertility, premature births, developmental delays, learning disabilities, autism, breast cancer, and non-Hodgkin's lymphoma.

Donovan stated that the currently available data indicate increased risk of negative health effects, including birth defects, kidney disease, and increased cholesterol related to PFOA exposure. However, many PFAS found in southeast North Carolina were designed as replacements for PFOA, yet no such thresholds exist for these next-generation PFAS. Donovan stated that North Carolina communities and beyond need relevant clinical guidance that adequately identifies, protects, and monitors those who have high levels of diverse PFAS exposure, as current clinician guidance falls well short of these goals. Donovan specified that the regional community needs information about relationships between specific health outcomes and cumulative serum levels for total PFAS in their blood. Health care guidance must consider the complex mixture of exposures experienced by communities and go beyond clinical guidance for legacy PFAS. Donovan cited her current experience as an example, where she often finds herself informing her children's pediatrician about the most current research rather than vice versa; she described this as counterintuitive and discouraging.

Donovan exhorted the committee to investigate information gaps confounding or limiting health studies, suggesting that underreporting of relevant toxicity and health data by corporate producers contributes to damaging data gaps. Donovan stated the committee and the public should have full access to industry data related to production, toxicity, and health outcomes to fully explore the range of linkages between human health and complex PFAS exposures in this region.

> "Sadly, it feels like guinea pigs are treated better, because at least their exposures are thoroughly studied for the betterment of humanity."

> "At the moment I'm informing my pediatrician about the latest toxicity studies related to PFAS placental transfer and breast milk contamination. This is backwards and depressing." *Emily Donovan*

Cheryl Cail (South Carolina Indian Affairs Commission/SC Idle No More)

Cheryl Cail discussed her experiences as a Native American community member and a member of a PFAS-impacted community in Horry County, South Carolina.

The path to PFAS advocacy started for Cail when her 20-year-old son Trevor was diagnosed with testicular cancer. She shared a photo of her son's back showing bright red spots indicative of unknown but acute dermatitis. Cail explained they went to the doctor to identify a cause and solution; the local doctor was not aware of environmental health concerns and did not ask the right questions to quickly arrive at a diagnosis. As a result, Trevor's cancer progressed unchecked for 9 months.

Cail related that Trevor was working and attending school adjacent to Myrtle Beach Air Force Base, though at the time they did not realize the importance of this location and their regional exposure. Cail explained they then watched a movie entitled "The Devil We Know" about PFAS contamination in

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

West Virginia, and she started questioning whether PFAS were the cause of Trevor's testicular cancer given the demonstrated link between this type of cancer and PFOA exposure. The family also found a map detailing PFAS contaminated sites around the United States and realized their community's proximity to Myrtle Beach Air Force Base was problematic, as massive concentrations of PFAS had been found in the environment around the base despite remedial activities. Cail noted that right before the COVID-19 pandemic more state agencies began mobilizing to address the issue within her community and across the state, but this was only after years of inaction. She noted that she had seen this before, as institutions prioritize "wealth before health."

With more information about regional PFAS exposures, Cail and her family started trying to find answers from the medical community regarding how to get PFAS blood testing and how to get treatment for their exposure and related health effects. Cail mentioned that while her community is only beginning to understand the scope of PFAS contamination and related health effects, they have seen a concerning increase in cancers, autoimmune disorders, fertility issues, and birth-related defects. She stated that regional physicians were unaware of PFAS, its effects, and even the regional exposure event itself. Cail also described searching for PFAS blood testing options and the frustrating experience of trying to relay that information to a local physician. They found that regional testing was limited to people with occupational-related exposure, such as firefighters. Cail related that this left her son feeling defeated, but she saw a challenge that the committee and other PFAS-focused organizations could resolve.

Cail closed her statements by detailing specific asks from the committee, such as establishing PFAS as an environmental health issue and educating those working in the medical community. This education should involve establishing testing and treatment protocols for those in affected communities and those with diagnosed medical conditions linked to PFAS. She also petitioned the committee to seek expansive data collection to meaningfully assess the full scope of PFAS health effects in order to best design health-related services in exposed communities, including monitoring for children. Cail also relayed a statement from a local physician who has now treated thousands of exposed individuals in her community, who said that physicians need a protocol much like the protocol for lead poisoning; it is a nationwide issue, and so is PFAS poisoning.

Stel Bailey (Fight for Zero)

Stel Bailey offered perspectives as a cancer survivor and member of a military family from Florida's space coast. Bailey first recounted her personal journey with PFAS exposure to explain her path to advocacy. She explained that while her husband was deployed, multiple family members were diagnosed with various cancers in a span of a few months. Given this unusual frequency, she herself was told by multiple doctors that it was "impossible" for her to have cancer, and six different doctors provided care prior to reaching a cancer diagnosis despite continued breathing problems and swollen glands.

Within this harrowing process, Bailey was asked, "where did you grow up?" and subsequently made it her life's work to figure out how and why her background might be related to cancer outcomes. This endeavor took a major turn in 2018 with the release of a key report from the U.S. Department of Defense (DoD) explaining that the region around the facilities of the National Aeronautics and Space Administration, Cape Canaveral Air Force Base, and Patrick Air Force Base was highly contaminated with PFAS, with up to 4.3 million parts per trillion (ppt) of PFOS[7] and PFOA found in surrounding groundwater.

As a result of that report and prior community work investigating autoimmune and cancer cases in the surrounding population, Bailey connected with oncologist Julie Greenwalt. This physician went to high school near Patrick Air Force Base and was aware that dozens of high school classmates had since been diagnosed with cancer, starting at very young ages. Bailey stressed the importance of this advocate and resource for their community, stating "this support meant everything in our community." Bailey suggested that without Greenwalt's personal experience and concern, the surrounding community would

[7] Perfluorooctanesulfonic acid, a PFAS; see Chapter 1.

KD2505

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

still be woefully unaware of health issues related to their substantial PFAS exposure. Since 2018, Dr. Greenwalt has helped the community document 54 cases of various types of cancer in individuals under age 40, which served to bring awareness and resources to the issue. This community health information also helped frame relationships between health outcomes and PFAS levels in drinking water after it was discovered that regional drinking water was also grossly contaminated with PFAS. Bailey chronicled that a large group of people in the community helped crowdsource community health information and address this issue, yet many have been lost since the 2018 DoD report revealing the scope of contamination, including a girl who passed away from brain cancer just 3 days after her 17th birthday.

Community efforts have more recently focused on mapping autoimmune and cancer cases surrounding Patrick Air Force Base. Using this crowdsourced data, the community was able to push forward their own health assessment in the county. The assessment found an increased risk of certain cancers, including urinary, bladder, leukemia, liver, lymphoma, breast, and testicular cancer. Other concerns captured by the health assessment include liver damage, increased risk of thyroid disease, and birth defects. Bailey also described continued routes of exposure that concern the community, such as consumption of regional fish and wildlife and produce irrigated with contaminated water. Bailey mentioned that drinking water and groundwater contamination remain problematic, noting the emergence of short-chain, understudied compounds such as PFBA[8] in these sources.

Bailey emphasized that her primary message to the committee centers on the fact that early detection of cancer saves lives and reduces health care costs. Since learning about the PFAS problem in tandem with regional medical resources encouraging care, Bailey provided multiple examples of early interventions across the community that served to detect or treat cancer or other health problems before severe disease. Bailey concluded by outlining specific community needs from health care providers, including physician education, medical monitoring, PFAS blood testing, preventive health screening and assessments, documentation on medical records of PFAS exposure and environmental health attributes, and recognized guidance that ensures insurance coverage. Bailey particularly emphasized the need to normalize the inclusion of such questions as "Have you been exposed to any environmental toxins or chemicals in your home or workplace?" and "Where do you live?" on medical forms and records.

> "We are doing physicians a big disservice by not providing them the help or information. Lacking this guidance is only harming people. We need action to save lives now." *Stel Bailey*

Several other people at the Eastern Town Hall provided public testimony, which is available on YouTube[9]:

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

MIDDLE TOWN HALL

Andi Rich (Save Our Water [S.O.H2O])

Andi Rich offered insight as a community member from Marinette, Wisconsin, home to the JCI Fire Technology Center. This site is considered the third-largest PFAS contamination site in the United States. Rich described the extent of contamination around the site, stating that PFAS levels in groundwater around the site reach 400,000 ppt, and the contamination plume has spread for miles around the site. Rich mentioned community concern about discharge of PFAS-laden effluent into regional surface waters, application of contaminated biosolids on agricultural lands, and potential air contamination related to continued onsite outdoor testing involving unknown PFAS.

Rich also described an ongoing class action lawsuit focused on PFOA and PFOS levels in well water, noting that the suit does not consider people exposed through other, more complex exposure pathways that affect the community. Rich indicated this leaves residents poorly informed and inadequately prepared to make decisions in the lawsuit, which in turn affects the fairness of payout claims. She said that lawsuit participants and community members have repeatedly requested blood testing and medical monitoring to further understand their exposure. These requests have been met with sustained resistance. Rich indicated that the community has been told that PFAS exposure does not equate to illness, that blood testing would not be useful, and that blood testing is not recommended. Rich pointed out that blood testing would be highly useful to ensure lawsuit payouts are based on internal exposure, as payouts are currently slated to be distributed arbitrarily.

Rich shared some personal health history to further highlight the utility of PFAS blood testing and care guidelines for practitioners. She related that a physician recommended bloodwork to check thyroid function, which overwhelmed and frustrated Rich given her awareness of the association between PFAS exposure and thyroid health. The doctor tried to comfort Rich, but Rich found out the doctor was visiting from Nashville and had no knowledge of local exposure issues. Rich stated that practices such as traveling practitioners makes blood testing, medical monitoring, and results-based guidelines that much more imperative to ensure environmental health factors are comprehensively and continuously considered by transient health care providers. Rich also stated that she has not yet sought the recommended thyroid bloodwork, due to logistical constraints, though she said she would be far more likely to prioritize follow-up if blood testing indicated PFAS exposure. Rich compared the utility of PFAS blood testing to the breast cancer gene (*BRCA*) test that detects a person's genetic proclivity for the disease. Each test serves as an indication of the increased potential for illness that can inform preventive care routines.

Rich went on to state that Marinette is an impoverished community where few can afford the cost of PFAS blood testing. The majority of community members have been denied covered testing through state agencies and insurance providers. Rich said that the committee's recommendations have the potential to improve care and community health outcomes by making sought-after care accessible and affordable, and she urged the committee to recommend blood testing and medical monitoring for residents in exposed communities, ensuring those exposed through complex pathways are included. Rich also emphasized that the committee should actively avoid "not doing anything because of lack of data, and not collecting data because of a lack of evidence of harm."

"How can above average incidence of PFAS-related illness be identified in a community where the doctors aren't in town long enough to identify the trend?"

"We need help putting a stop to the contamination, as the corporate polluters are far more powerful than our voices." *Andi Rich*

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Laura Olah (Citizens for Safe Water Around Badger)

Laura Olah commented as a community member affected by the Badger Army Ammunition Plant in Wisconsin. Olah's remarks focused on the major lack of exposure information available to the public and the urgent need for medical monitoring. Olah stated that minimizing PFAS exposure leads to reduced health risks, but communities and physicians trying to accomplish this run into challenges trying to obtain PFAS exposure information in individuals and in the environment. She provided several examples illustrating the pervasive institutional secrecy that prevents transparency about exposure and risk.

She described a public meeting hosted by the U.S. Army to discuss groundwater contamination that has migrated offsite, contaminating rural drinking water wells and discharging into the Wisconsin River. Hydrogeological experts recommended testing drinking wells beyond the currently monitored area, including on the other side of the Wisconsin River. Army personnel argued against this, saying there would be no way to ensure PFAS in well water was derived from the base, and they were not certain which wells should be tested. Olah highlighted this as "ridiculous," pointing out that all wells should be tested given uncertainty about which wells are most at risk as there are no offsite groundwater data. Olah also described several frustrating experiences seeking existing information about PFAS in drinking water. For example, a request for information about PFAS in drinking water around Volk Air National Guard base required a formal Freedom of Information Act request, which has now been pending for 3 years. Another request for a written report describing PFAS contamination around a military base in Tennessee was also unmet, and is now 2 years old. Olah also highlighted that this lack of transparency was not limited to the military, as private corporations refer to PFAS products like AFFF formulations as proprietary mixtures or confidential business information and do not disclose PFAS content in their products. This lack of information makes it impossible to assess and prevent exposure and possible health risks.

Olah asserted that we cannot predict the potential implications and future benefits of medical testing today, but without these data, exposed communities face battles akin to Vietnam War veterans who are still fighting for presumptive care based on exposure to Agent Orange and other toxicants. PFAS blood testing helps baseline exposures and raises awareness so people can take steps in reducing exposures. Baseline testing could help answer health questions in the future and help secure health studies in communities at risk

> "Given all these barriers [to PFAS exposure information], the public and the medical community cannot identify which patients are at greatest risk to and harm from PFAS; therefore, our care must be presumptive."

> "Without medical monitoring data now, presumptive care will be out of reach for civilians and service members and children exposed to PFAS now and in 50 years from now." *Laura Olah*

Samraa Luqman (Concerned Residents for South Dearborn)

Samraa Luqman offered insights as an environmental advocate and a Yemeni-American community member from the South End in Dearborn, Michigan. Luqman framed her remarks by providing context about her community, describing the South End of Dearborn as a community that grew around Ford Motor Company. The continued need for cheap labor attracted immigrant populations over time, with a more recent influx of Middle Eastern immigrants. A high percentage of the population possess limited English skills, are considered low income, rely on some kind of food or government assistance, and rent their homes. The surrounding area is also home to various industrial activities, in addition to the Ford Motor Company, that use diverse types of environmental pollution. PFAS contamination has recently been identified in the area, resulting in the inclusion of the town on Michigan's PFAS Action Response Team website.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Luqman went on to highlight the importance of considering PFAS exposure beyond drinking water, including inhalation, dermal contact, and maternal offloading of PFAS from mother to child. These understudied exposure vectors are ongoing in the South End, along with continuous air quality issues, lead exposure, and other environmental health concerns. Luqman emphasized the importance of considering such cumulative multiple exposures, citing sustained community concern about deciphering causality or relationships between observed health effects and PFAS in what is clearly a complex exposure scenario. Luqman highlighted that PFAS blood testing can help clarify required follow-up care by identifying exposed individuals most prone to PFAS-related health effects. Luqman expressed particular concern about the relationship between PFAS exposure and immune impacts in the context of the ongoing COVID-19 pandemic. She stated that COVID-19 outcomes have been worse for her community compared with nonexposed communities. She also stated that a lack of PFAS exposure information for her community affects behavioral choices with real-world consequences. Luqman offered the example that someone from the South End exposed to PFAS may be more vulnerable to COVID-19 and require more diligent mask use compared with someone residing 10 miles away, but would never know this given the ongoing lack of exposure information.

Luqman also discussed the need for medical professionals to have awareness about environmental contamination and its potential implications, even decades after a person's leaving a contaminated area. She highlighted that health risks from environmental exposures must be assessed and considered by state agencies and health care practitioners; then this information must be provided to residents and patients to ensure full awareness of exposure. She provided an example of a community member who moved away from the South End area and is now dealing with cancer approximately 20 years later. Luqman stated that this person's doctor explained to them that despite moving away, the carcinogens and pollutants accrued while in the area do not go away. Luqman also underscored the need for health and exposure information to be communicated in culturally appropriate ways, acknowledging and overcoming language and sociocultural barriers.

Cathy Wusterbarth (Need Our Water)

Cathy Wusterbarth offered insights as a community member from Oscoda, Michigan. This community is adjacent to the Wurtsmith Air Force Base and is subject to major contamination of regional groundwater and surface water from AFFF use on the base. This widespread contamination has resulted in historical and ongoing PFAS exposure for service and community members, as well as the area's fish and wildlife.

Wusterbarth's remarks focused on several primary community needs: PFAS blood testing, improved guidance for health care practitioners, exposure assessment in the environment, and exposure mitigation. Wusterbarth highlighted the movie *No Defense* as a crucial example of the health effects of PFAS contamination. The film chronicles the serious lifelong health effects experienced by Mitchell Minor and his family, residents of Oscoda. Wusterbarth also introduced James Bussey, a service member in Oscoda. Wusterbarth explained that Bussey was too ill to present to the committee, but had asked her to provide his medical records for committee consideration. These records include a long list of ailments and physician recommendations based on his exposure to PFAS, which was documented through blood testing.

Wusterbarth emphasized that these real-world examples capture a crucial disconnect between exposure information and health outcomes, which can easily be rectified by improved access to PFAS blood testing. Wusterbarth declared testing should begin immediately to establish baseline exposure levels. Annual testing should occur thereafter, just as is done for other risk factor measurements, such as cholesterol. Wusterbath also identified that given the presence of PFAS in 98 percent of the U.S. population, everyone should have access to blood testing. However, priority should be given to communities and individuals with identified or hypothesized high-level PFAS exposure. Wusterbarth also suggested that testing should be implemented using simple, affordable labs, highlighting a recently opened laboratory in Oscoda as an example. Wusterbarth also recommended that all PFAS be included in

KD2509

Copyright National Academy of Sciences. All rights reserved.

blood testing, unless specific PFAS measurements are required to discern the role and liability of a specific polluter or product.

Wusterbarth further described a crisis of trust, stating that her community was experiencing the degradation of trust with the very institutions they believed would protect them, such as EPA, other government agencies, and the military. She detailed discouraging recent information from the DoD, noting that more than 700 military installations have now been recognized as PFAS hot spots, starting from just one in 2012. She also stated that health care providers have a duty to discern the causes of disease in their patients, but without guidance from the CDC or other medical authorities, practitioners are unaware of health risks associated with PFAS exposure to the detriment of patient care. Wusterbarth also emphasized the gravity of the committee's recommendations based on the town halls, stating that state agencies and communities are relying on the forthcoming guidance document to inform physicians and care. She shared a personal experience in which she provided PFAS information to her doctors, only to be told this information was too lengthy to review despite her history of cancer and immunological disease. Wusterbarth stressed the need for swift action by the committee to immediately curtail ongoing harm in exposed communities.

> "We've tested the fish; we've tested the deer; we've tested the groundwater, the waterways, and the foam. When are we going to test the people?"
>
> "The only risk [of testing] is to the polluters who do not want us to link them to our exposure."
> "This study is a result of the PFAS communities telling you changes are needed."
> *Cathy Wusterbarth*

Sandy Wynn-Stelt (Wolverine Community Advisory Committee, Michigan PFAS Action Response Team)

Sandy Wynn-Stelt lives in a PFAS-impacted community, Belmont, Michigan. Wynn-Stelt opened her remarks by sharing her own story of PFAS exposure. Wynn-Stelt and her husband moved to Belmont in 1992, seeking an idyllic and quiet home. They were not aware that the Christmas tree farm adjacent to the property was a dumping site for a major PFAS user, Wolverine Worldwide. In 2016 her husband's health rapidly deteriorated, and after only a few short weeks, he died of liver cancer, which Wynn-Stelt described as an unbelievable loss. Shortly thereafter, the Michigan Department of Environment, Great Lakes, and Energy tested her drinking water, and Wynn-Stelt learned the well water she and her husband had drank for more than 20 years was contaminated with PFAS at levels up to 80,000 ppt. On learning about her exposure, Wynn-Stelt sought blood testing. She described this process as challenging. She ultimately paid $800 for blood testing through a commercial laboratory in California. Her bloodwork indicated alarmingly high levels of PFHxS, PFOA, and PFOS, well above levels seen in blood studies as part of the National Health and Nutrition Examination Survey (NHANES) and in some other exposed communities.

Wynn-Stelt followed up with her community doctor regarding her bloodwork results; she described this physician as "very proactive and engaged." She stated that her doctor reviewed the ATSDR physician and patient guidance about PFAS that was available at the time. They concluded the guidance was not helpful and instead agreed on a plan to monitor those things listed as potential risks of PFAS exposure. As a result, when Wynn-Stelt experienced breathing problems several years later, this physician recommended thyroid testing based on their knowledge of Wynn-Stelt's PFAS exposure, although this diagnosis would normally be an unlikely candidate. This testing resulted in the identification of thyroid cancer. Wynn-Stelt credits this diagnosis and quick action to prior PFAS blood testing, adding this vital information to her medical history for consideration by her physician.

Wynn-Stelt provided an additional example of a neighbor exposed to PFAS from the same groundwater source. This neighbor's child received PFAS blood testing and was found to have elevated levels of PFOS. This information was provided to the child's pediatrician, who then monitored vaccine

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

response given the child's exposure history. The child was found to have reduced vaccine responses and required some boosters not normally required. Wynn-Stelt reported similar examples of adverse health effects across the community, with cases of thyroid disease, cancer, kidney disease, liver disease, and cholesterol issues in children and adults. Wynn-Stelt also highlighted the mental and emotional toll of exposure and the lack of discussion of this in exposed communities and in care guidelines.

Wynn-Stelt also took time to address often-cited statements used to deny community access to PFAS blood testing. Wynn-Stelt countered the assertion "that it is not ethical to test for something we can't treat" by explaining knowledge of environmental health and exposure is just as medically relevant as asking any patient for a history of diabetes or heart disease. All these pieces of information are required for patients and physicians to monitor potential problems and reduce risk. Wynn-Stelt also addressed the concern that patients may panic given hard-to-frame PFAS information: she countered that exposed patients are not fragile, and knowledge is power. Wynn-Stelt labeled the assertion that PFAS levels in blood cannot be definitively linked to health effects, and therefore should not be monitored as circular logic, stating if testing is not occurring at various scales, links cannot be identified, further and erroneously justifying a lack of testing.

Wynn-Stelt closed her remarks by stating explicitly her community's needs, including accessible PFAS blood testing for people in various exposed communities. She also urged expansive testing for the entire class of PFAS, rather than a few targeted chemicals. Wynn-Stelt also requested research about possible mechanisms to lower PFAS body burdens in exposed individuals and further research to better understand how PFAS levels may impact health care choices, such as blood or organ donation.

Tom Johnson (Clean Water Action)

Tom Johnson shared his perspectives with the committee as an environmental advocate and organizer working with exposed communities across Minnesota and beyond. Johnson explained that much of his work involves public education, seeking to inform people about toxic chemicals overall. When conducting educational activities in the East Metro region of Minnesota, Johnson indicated that PFAS are a central topic of interest, as this area is rife with PFAS producers and users whose activities have massively contaminated the regional environment. This contamination resulted in an $850 million legacy settlement. Johnson suggested that communities are increasingly aware that, although this settlement sum will cover long-term drinking water treatment for all area residents, there will be little or no money left for regional remediation.

Johnson attested to high levels of frustration from exposed communities in the region, with unanswered questions about the likelihood of current or future health effects for families and their children. Despite the lack of citable research, the community possesses large amounts of anecdotal and experiential evidence observed over decades that suggests links to health effects and informs the community concerns. Johnson described the experience of a mother of a low-birthweight baby, who is now concerned about a similar outcome with her second pregnancy. Her doctor has no ability to comment on the likelihood of this outcome given vast uncertainties surrounding her exposure and risk due to a lack of needed exposure assessment and health effects research. Johnson also discussed the importance of accessible and expansive biomonitoring for exposed communities and more broadly. In the case of the East Metro contaminated area, biomonitoring was available for some people in this community, but it is not available for all Minnesotans, leaving data gaps for those who have moved from the area and for other exposed communities. Johnson also highlighted the utility of testing to assess the efficacy of interventions over time and the ability of testing to illuminate links between exposure and understudied health effects.

Vicki Quint (Foam Exposure Committee)

Vicki Quint is a firefighter advocate through her work as a co-chair with the Foam Exposure Committee. Following a massive tire fire in Watertown, Wisconsin, and her husband's death due to cancer, Quint learned about significant exposure to PFAS in the fire service. Firefighters are exposed to

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

PFAS through AFFF use and the use of PFAS-containing protective gear. Quint provided further details about PFAS in AFFF and current activities, highlighting the current availability of fluorine-free alternatives to AFFF. She noted that there are several sites in Wisconsin contaminated with PFAS as a result of the use or product of AFFF.

Quint followed this information about firefighter exposure and AFFF use by describing the plight of exposed firefighters seeking PFAS blood testing. Military firefighters are now eligible for PFAS blood testing, but retired military firefighters and civilians are not. Quint related concerns from the fire service community regarding the ramifications of blood testing results and options to lower PFAS levels in blood. Quint emphasized the need for all fire departments to discontinue use of all fluorine-containing AFFFs, as there are no regulations requiring municipal fire departments to use AFFF.

Art Schaap (fourth-generation dairy farmer)

Art Schaap described his experience as a dairy farmer in New Mexico whose farm and family were unknowingly subjected to severe PFAS contamination due to military AFFF use.

Schaap stated he has been on his farm for more than 30 years and considered investments in his farm as his version of a 401(k). When he was approached about PFAS water testing, Schaap stated he readily agreed without prior knowledge about PFAS. Those tests revealed levels of PFAS up to 30,000 ppt in drinking well water from his property. These findings led Schaap to contact the New Mexico Department of Agriculture asking for PFAS testing in milk. The department informed Schaap that if PFAS were found in his milk, Schaap would need to dump the load. He insisted on the testing despite that risk, stating he did not want to distribute products with PFAS to customers around the nation. Schaap stated that PFAS testing in milk from his cows subsequently revealed PFAS concentrations ranging between approximately 800 and 2,500 ppt; this testing has been ongoing for more than 2.5 years.

The contamination has resulted in the devastation of his livelihood, as the cows can only be minorly rehabilitated, pose an economic burden, and reflect a major investment that will be devastating to lose without any possible profit. Schaap has limited options available to get rid of the contaminated animals in any profitable way. Dairy, beef, and rendering industries do not want PFAS-contaminated animals. Schaap described his efforts to filter water for his cows, only to find that it takes years for cows to eliminate PFAS from their body (also described by John Kern, below). PFAS have also been found in the soil on Schaap's farm, further exposing his herd beyond drinking water. This untenable situation has unfolded tragically for Schaap and has resulted in the stranding of at least 4,000 cows, the deaths of 1,200, and the dumping of 1,500 loads of milk.

Schaap enumerated a number of institutional failures that have left him with few resources to rectify his situation. He said that multiple government agencies continue to eschew responsibility for the situation and other PFAS exposure concerns, related to DoD pressure and the lack of actionable EPA standards. Schaap pointed out that if FDA provided standards for PFAS in food products, under the Comprehensive Environmental Response, Compensation, and Liability Act (Superfund), contamination on his farm would require action and remediation. He also mentioned the lack of discussion and accountability about this topic across the dairy industry at large.

Schaap concluded his remarks by recounting health effects he has observed over time in cattle, including decreased lactation, premature births, dwarf calves, reduced pregnancy rates, poor body condition, and increased mortality. He also described health concerns from his family, including high cholesterol, hypertension, kidney damage, kidney stones, diabetes concerns, and infertility.

John Kern (RuttenKern Policy Group)

John Kern offered comments to the committee from the perspective of a litigator and environmental advocate residing in New Mexico. Kern explained that in addition to concerns over drinking water, they also focus on PFAS exposure in the water relied on agriculture and a lack of

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

associated safety standards needed to protect the food chain. Kern's testimony dovetailed with the testimony of the previous presenter, Art Schaap.

Kern framed his perspectives by providing information about Cannon Air Force Base near the city of Clovis. AFFF contamination at the military based resulted in groundwater contamination spreading 5–6 miles from the base. The region is home to multiple dairies and cheese plants. Water from this source is provided to livestock, which are then the source for milk, cheese, and meat. This water is also used to cultivate silage vegetation and other crops. PFAS-contaminated groundwater has resulted in PFAS contamination of regional livestock, leading to sundry economic and health questions and concerns unrelated to drinking water exposure.

Kern displayed data from a regional dairy with high levels of PFAS in groundwater; these data show a decrease in lactation in dairy cows over time. Kern also described increasing mortality and birth defects over time in cattle from the same farm. Additionally, Kern presented data about PFAS in milk, stating that the FDA cites 400 ppt as an acceptable level of PFAS in milk. Measurements in milk from the Highland Dairy Farm varied between approximately 900 and 4,600 ppt from November 2018 to August 2020; the data show that dairy milk slowly reflected reduced PFAS exposure. A shorter-term study conducted by the Food Safety Inspection Service showed increased variability and a faster rate of PFAS elimination in dairy milk from exposed cattle compared with data from a longer-term study conducted on the same farm. Kern pointed out these rates have serious implications regarding how quickly cattle are considered rehabilitated from PFAS exposure and allowed for market purchase or dairy use. The slow elimination rates in the longer-term study also pose severe economic ramifications for farmers, given the average lifespan of cattle is around 6 years.

Kern concluded his remarks by describing a frustrating current impasse with the DoD regarding standards. Federal legislation compelled the DoD to clean up agricultural waters in 2018, yet the DoD responded that they would take no action until a federal agency tasked with ensuring food safety (e.g., the FDA or the U.S. Department of Agriculture) set standards for PFAS in food products. Kern emphasized the need for agencies to set standards to allow effective action on PFAS at multiple scales.

Two other people at the Middle Town Hall provided public testimony, which is available on YouTube[10]:

Pam Ladds, Don't Undermine Memphremagog's Purity
Beth Markesino, North Carolina Stop Genx in Our Water

WESTERN TOWN HALL

Liz Rosenbaum (Fountain Valley Clean Water Coalition)

Liz Rosenbaum provided testimony as an AFFF-exposed community member in El Paso County, Colorado. Rosenbaum described hearing about regional drinking water contamination in a group setting based on *The New York Times* reporting. Following the initial news of exposure, the community focused on learning about PFAS and government agencies that could assist in an appropriate response. The community response also entailed building partnerships with water districts and assuaging community anger toward these entities, who learned about the contamination at the same time as the community with no prior knowledge of the issue. Since 2018, Rosenbaum stated, the community has been focused on navigating the regulatory and legislative system to reap meaningful action as soon as possible, turning their anger into action through state legislation. This has involved building connections to EPA, state and county health departments, and elected officials at city and state levels. Rosenbaum reported that, as a result of these organizing efforts, legislation has been adopted increasing fines for polluting corporations.

[10] See https://www.youtube.com/watch?v=mGeABDDTCuI&list=PLGTMA6Qkejfg1GIgAPeqkMCDncdx04qHN&index=16.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Beyond detailing the exposure reality for her community, Rosenbaum described priority groups that require increased attention in further PFAS studies. She stated that military families move frequently and may be exposed at multiple sites; care must be provided to military families, as well as service members, from all branches. Rosenbaum also suggested that service members require assistance from the U.S. Department of Veterans Affairs (VA) like that provided to Vietnam veterans. Rosenbaum also indicated the need for equity in exposure assessment and mitigation for Black, Brown, and Indigenous families, as well as rural families, mentioning that rural families in her county are not being offered drinking water at the same nondetect level offered to households in PFAS-exposed municipalities. Rosenbaum stated that a recent ATSDR community-level exposure assessment revealed that this clean municipal water facilitated a decrease in PFHxS[11] levels in the blood of municipal residents.

Rosenbaum also pointed out the limited number of health care options in El Paso County, stating there are no hospitals in the southern half of the county. This lack of health care facilities exacerbates contamination issues because there is no capacity to monitor health outcomes, as families seek health care in the northern part of the county where doctors may not be able to identify localized health outcome patterns. Rosenbaum emphasized the immediate need for blood testing to establish a baseline that serves as evidence of contamination and an indicator of potential health effects. Rosenbaum concluded by emphasizing the need for continued patience and engagement between health care practitioners and researchers on this issue to find shared vocabulary. She explained that communities are living through frightening and unfamiliar exposures but may not have the appropriate technical vocabulary to describe their concerns or ailments.

> "Half the battle for the community has involved learning how to ask the right questions to get what we need to have clean and safe communities for our working families." *Liz Rosenbaum*

Martha Dina Argüello (Physicians for Social Responsibility)

Martha Dina Argüello provided perspectives as a Latina and an environmental advocate in California with experience connecting health care providers and communities. Argüello posited that guidance from the committee must include provisions for increased biomonitoring as many communities facing exposure are as yet unaware of the problem. She also discussed the distinct legacy of industrial contamination in Los Angeles. This history has resulted in community exposures to multiple pollutants, which means that approaches that focus on one chemical at a time do not address the lived reality of complex contamination. Argüello pointed out that these factors have led to distrust of water quality, particularly in the Latino community. She highlighted that Latino communities often pay more for water per capita than for fuel as a result of their reliance on bottled water. Comprehensive testing and proper health education for communities and practitioners is key to rebuild trust in water quality and address the comprehensive reality of complex environmental exposures.

Argüello also explained that communities often face the downplaying of anxieties and risks surrounding exposure; this reflects a lack of training that leads to an inability by clinicians to validate the lived experiences of exposed communities. This dynamic further compromises exposed communities. Argüello emphasized that it is essential for clinical guidance about PFAS exposure to include instruction about how to help concerned patients minimize exposure rather than brush off environmental health concerns.

Argüello cited the dynamics of PFAS regulation in California as an example illustrating how to avoid this paradigm of patient treatment. Argüello highlighted that helpful legislative efforts have been under way, yet early warning systems detecting PFAS in drinking water and through biomonitoring studies have not been appropriately heeded. She specifically flagged the response of a physician who is a member of the state legislature, who stated that exposure should not be quantified for patients as the worry is worse than the exposure. Argüello stated this exemplifies how physicians are trained to respond

[11] Perfluorohexanesulfonic acid, a PFAS; see Chapter 1.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

to environmental health concerns, and yet this lack of training and understanding of exposure often leads to minimizing people‘s experience with exposures.

Argüello also urged that clinical guidance should take an anticipatory approach to ensure health care practitioners are provided some education and literacy surrounding the PFAS issue and complex exposure scenarios: health care practitioners should be capable of some interpretation of water quality results and be able to comment on options for filtration. Argüello also specified that clinical guidance must provide intervention options accessible to different socioeconomic and cultural backgrounds. This stratification of intervention is critical to ensure appropriate guidance is provided for all types of exposed communities as many cannot "buy their way out of being exposed." Argüello also highlighted tools that allow tailored exposure assessment and risk reduction strategies, citing how doctors are now writing prescriptions for new carpeting or other household materials to aid rental tenants in substandard housing. Argüello also touted the use of a geospatial tool that allows physicians to assess cumulative exposure risk based on patient location overlaid with information about multiple ambient environmental health exposures.

"When scientists fear speaking truth to power, we know that truth dies."

"We need physicians to step forward because we have regulatory agencies that are actually not preventing exposure."

"We can't change this broken system without the partnership of science and physicians."
Martha Dina Argüello

Mark A. Favors (Fountain Valley Clean Water Coalition)

Mark A. Favors provided commentary as an Army veteran and community member from Colorado Springs, Colorado. Favors and his family learned of serious PFAS contamination affecting their region from activities at Peterson Air Force Base and other regional military bases, prompting Favors to assume an ardent advocacy role seeking safe water. Favors pointed out that while important state legislation regulating PFAS has been passed in Colorado (also discussed by Liz Rosenbaum, above), DoD is exempt from most state legislation. This exemption stands despite the fact the Air Force admitted to dumping AFFF into regional water resources three times per year for multiple decades.

Favors detailed that sustained contamination from AFFF exposure has led to high levels of PFHxS in the blood of people in the community: measured levels were the highest in the country except for individuals who directly manufactured the chemical. With this exposure in mind, Favors chronicled harrowing details about his family's struggle with health problems. For example, there have been many cases of kidney disease and cancer in family members of many ages in the contaminated zone, some requiring kidney transplants that were further complicated by development of cancer in the donated kidney. Favors stated that the abundance of serious kidney ailments in his family in Colorado Springs is particularly striking considering that no family members who live outside the contamination zone have encountered these issues.

Favors explained that these health issues assumed urgent relevance for his family in 2016 when the Air Force disclosed dumping PFAS into drinking water sources, given the known links between PFOA and kidney issues found at other locations. Favors reported that DoD also revealed the detection of PFAS in some community drinking water sources at concentrations up to 8,000 ppt, well above the EPA's health advisory limit of 70 ppt. Favors indicated that despite these levels, the state of Colorado has not provided expansive PFAS blood testing to all residents, even knowing the inherent value of blood testing as an indicator of exposure and potential health effects. Favors emphasized the particular importance of transparent information and access to testing when considering the transitory lifestyles of military members and other community residents. He pointed out that he did not find out about the contamination in his hometown until 2018 while visiting his mother in the region. Favors provided an additional

KD2515

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

example of a cousin who previously lived in the contaminated zone and has since moved, only to find unexplained liver tumors in one of their young children years later.

Favors also stressed the need for transparency and education in the health care community and shared his experience as a health professional in endoscopy. He stated that despite evidence linking PFAS to irritable bowel disease, gastroenterologists in his department were unaware of PFAS. Favors highlighted that such transparency and access to exposure information is key for both practitioners and community members, especially for exposed children and their families who are concerned about developing health problems in the future.

> "I have family members … buried at Fort Logan National Cemetery after surviving combat tours in Vietnam, Korea, and Afghanistan…. They're now buried in the National Cemetery from cancer after the military admitted dumping this toxic chemical into their water." *Mark A. Favors*

Andria Ventura (Clean Water Action)

Andria Ventura provided context about past and ongoing actions addressing PFAS in California from the vantage point of an environmental advocate. Ventura opened her remarks by describing her continued struggle engaging with the medical community about environmental health concerns as a long-time advocate, describing it as difficult for clinicians to make the connection between exposure and health outcomes. Ventura hypothesized that this stems from reluctance or avoidance by clinicians to assume an advocacy role. As a patient and a resident of a PFAS-affected city, she also stated she has never been asked about toxic exposure or environmental health background by her doctors or other medical caregivers, despite dealing with several chronic concerns over decades. She had to actively broach this topic with providers, likening this experience to the testimony of other presenters to the committee. However, it has been clear that doctors and nurses are not trained to take toxic exposure into consideration.

Ventura went on to provide abundant information about the PFAS problem overall. She highlighted the multifaceted ways humans can be exposed to PFAS, including through drinking water, surface waters, consumption of wildlife, or consumption of agricultural products exposed to PFAS in soil or water. She also reiterated the importance of considering PFAS as a class, stating thousands of PFAS have been identified and all are considered persistent, accumulative, mobile, and hazardous to some degree. Ventura also showed that multiple PFAAs have been linked to health effects that affect immunity, development and reproduction, fat and metabolism, liver function, endocrine function, and blood systems. She stressed the potential for additive and synergistic effects related to exposure to multiple PFAS, flagging this as a required point of awareness for health care practitioners. Ventura also emphasized that lack of research on novel PFAS should not hinder consideration of their health effects, stating that evidence is mounting that newer, short-chain PFAS have negative health effects. Ventura also stated that many novel PFAS degrade or transform into PFAAs.

Ventura went on to elaborate about specific actions and concerns in California, describing the recent position of the state to implement phased drinking water monitoring and site investigation. She added the caveat that this phased approach has failed to assess small water systems and private wells: this is a key data gap considering health care practitioners need detailed information about exposure to adequately consider environmental health concerns during care. Despite data collection limitations, data thus far indicate catastrophic PFAS contamination problems across the state that have so far not been addressed by sluggish regulatory efforts. Ventura also stressed key data gaps, such as uncertainties about PFAS levels in surface waters, PFAS in fish and wildlife consumed by humans, and implications for crops grown in PFAS-laden biosolids or irrigation water.

Ventura concluded her remarks by delineating key exposure assessment and health care needs in California. She emphasized the need for expanded understanding of the scope of the problem, including all PFAS in assessment efforts, as well as improved understanding about PFAS health effects. She suggested such fact-finding efforts should include expanded water monitoring; PFAS monitoring in

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

diverse environmental media; assessment of diverse exposure vectors; identification of those most at risk of harm from exposure; expanded health studies, including mixture exposure scenarios; and communication of health risks in culturally appropriate ways.

Linda Shosie (Mothers for Safe Air & Safe Water)

Linda Shosie provided perspective as a Latina and exposed community member in the South Side neighborhood of Tucson, Arizona. Shosie provided information to the committee collected as part of community-based exposure and health assessment efforts, highlighted egregious environmental justice issues, and explained her own path to advocacy. Shosie explained that her community is affected by PFAS contamination from military sites and airport activities, resulting in PFAS concentrations in drinking water up to 13,000 ppt. This high level of PFAS exposure is plaguing a majority-Latino community across a 3-mile contamination plume; Shosie provided a number of maps providing geospatial context about the extent of contamination. She described leading health assessments within the community, which revealed high rates of cancer and immune system disease around the Tucson International Airport and Morris Air Force Base. These community-derived results led the county health director to conduct a more in-depth epidemiological study in 2017. Shosie stated this study indicated "significant invasive cancer incidence rates" compared with people living in other areas around Tucson.

Shosie expressed frustration, sadness, and anger at the lack of action addressing PFAS contamination in her community and at other Superfund sites, saying, "environmental justice provisions continue to fail meanwhile thousands of contaminated sites remain unclean for more than 40 years." She also stated that those sites that have been remediated are in White or upper-class neighborhoods, while sites like the one in her low-income community remain unresolved to the detriment of community health and trust in governing institutions. Shosie also shared emotional details about losing her daughter, prompting her own path to find answers about environmental health issues in her community.

"We cannot rely on state, CDC, and other local government officials who continue to turn their backs on the people who are affected."

"Many people asked me why I got involved in the fight for … clean water, and demand government transparency and accountability. I got involved because I witnessed the death of my daughter out of this devastation I knew that I needed to find out why my daughter got so sick. *Linda Shosie*

Aaron Maruzzo (University of California, Berkeley, School of Public Health)

Aaron Maruzzo commented as a voice representing PFAS-contaminated communities in Western U.S. territories like Saipan in the Northern Mariana Islands. Maruzzo was born in Saipan and returned to work in the territory as a water quality analyst. Maruzzo framed the PFAS contamination problem in Saipan by leveraging data collected as part of the EPA's Third Unregulated Contaminant Monitoring Rule program. These program data capture PFAS concentrations in select public water systems from around the United States. Maruzzo comparison revealed major contamination in Saipan, with an average concentration of 1,700 ppt in territory drinking water, well above EPA health advisory limits and the levels observed in other U.S. states and territories. The highest detectable concentration of PFOS was also found in Saipan. Maruzzo said these data have been hiding in plain sight for many years and illustrate an ongoing environmental injustice.

Maruzzo went further to explain that PFAS contamination across the small island is unevenly distributed, with the highest levels found in water resources adjacent to the only airport found on the island, home to firefighting training facilities that used AFFF. Sixteen villages along the south and southwest margins of the island were disproportionally exposed to PFAS from this drinking water source, including the village where Maruzzo grew up. The southern portion of the island tends to include more non-White, noncitizens who may be easily missed in health data collection efforts as a result of frequent

KD2517

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

immigration and emigration. Health effects in this population may be also missed because of reluctance to seek medical care due to costs and accessibility. Despite these data collection challenges, preliminary reports suggest deep impacts on morbidity and mortality in the region, including heart disease, cancer, abnormal birth outcomes, hypertension, obesity, and cholesterol issues.

Maruzzo indicated that environmental justice issues are a key concern for his community, as "toxic exposures to hazardous chemicals continue to be disproportionately placed on communities of color and the poor working class." Maruzzo also stressed the continued systemic exclusion of U.S. territories like Saipan from continued dialogue about issues like PFAS.

With all this context, Maruzzo explained that the community needs further information about PFAS exposure routes specific to a small island setting. He indicated the need for further information about PFAS in the water of neighboring islands in the Northern Mariana Islands and the levels in private water systems, bottled water, and wastewater. Maruzzo flagged information gaps surrounding AFFF, questioning when AFFF was first used on the island and the composition of AFFFs over time. Maruzzo also questioned how military testing, imperialism, and globalization affect the contamination crisis today. Additionally, Maruzzo pointed out a lack of information describing PFAS in many consumer products, such as textiles and food packaging. Maruzzo indicated data gaps surrounding PFAS in fish and highlighted this as a problem, considering the cultural and economic importance of fishing on the island.

Following discussion of the unique exposure scenario ongoing in Saipan, Maruzzo offered comments, recommendations, and questions for the committee to consider while drafting clinical guidance. He explained that monitoring in humans can help answer questions about the importance of all these exposure gaps, while establishing an important baseline perspective. Maruzzo also argued for the importance of biomonitoring for optimal health care, as it allows families to make informed health care and lifestyle choices while empowering individuals to take action in their communities and environments. Biomonitoring studies also help constrain health effects, even as the candidate list of health effects explicitly related to PFAS requires further study. Maruzzo suggested that despite many unknowns plaguing our understanding of health effects related to PFAS, biomonitoring should be prioritized as it enables a precautionary approach to allow identification of unknown PFAS and health effects. Maruzzo mentioned the highly persistent nature of PFAS, pointing out that it is unadvisable to allow highly persistent chemicals to remain in our body only to find out about health effects later. Maruzzo also said this characteristic should be emphasized to physicians to help them understand the complexity of PFAS given typically low awareness about the issue in health care settings and in communities.

Maruzzo echoed other participants by pointing out that highly exposed and vulnerable populations should be prioritized for PFAS blood testing, using equity as a guide to design testing protocols. He further suggested that inclusion in these categories should be constrained by occupation, location, and biosocial vulnerabilities. Maruzzo stressed the importance of considering who is in the 95th or 99th percentile of exposure, while questioning who is missing from the dataset, to maximize understanding of the issue while minimizing exposure harms. Maruzzo raised the issue that there is also a moral component to blood testing that must be considered by the committee, asking how physicians will be prepared to educate exposed community members who do not already know about issues related to PFAS exposure. He asked whether an established protocol, cost considerations, or health care access would drive such decisions. Maruzzo also discussed the need to develop guidelines describing how to care for transient populations like migrants and military personnel. He asked the committee to consider how testing programs and rigorous exposure assessment should account for high loss of follow-up and discontinuity of care for these populations. Maruzzo also highlighted the value of culturally appropriate guidance and communication, stating that general scripts about risk reduction are "useful for a broad audience but there should be a mechanism to specify what's known into a local context."

"If there's one takeaway today, I think it's important to consider the implications of what happens when you don't listen to the voices at the margins."

"The absence of evidence or the absence of consensus doesn't mean a PFAS compound is safe."

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

"One of the most PFAS-polluted places in the United States is a U.S. territory, and this is a serious environmental injustice."

"Risk communication should prioritize not solely action but meaningful action which is guided through the lens of equity." *Aaron Maruzzo*

Pamela Miller (Alaska Community Action on Toxics)

Pamela Miller spoke as a community member and environmental health advocate in Alaska. Miller provided abundant context about the unique exposure and community dynamics present in Alaska, while offering clear recommendations to the committee about Alaskan health needs and concerns. Miller explained that Alaska's strategic military importance has resulted in the establishment of multiple military installations across Alaska that have used AFFF. Miller also explained that Alaska is a very aviation-dependent state, with AFFF-using airports situated directly adjacent to communities and their water resources. Miller stated that PFAS have been found in at least 100 different sites across 30 locations spanning the entirety of the state, with multiple communities exposed to unsafe amounts of numerous PFAS. A total of 11 current and former military installations are currently under investigation for PFAS contamination, with results to date indicating the environmental occurrence of PFAS above health advisory levels. Despite the abundance of known sites, and the likelihood of as-yet-unidentified sites, Miller explained that there is no cohesive state plan to measure PFAS in the environment, fish, and wildlife, or in people. Miller mentioned an overall failure of regulatory efforts to guide the state's response to PFAS contamination, despite the support of attempted legislative efforts by associations of health care professionals, such as the Alaska Nurses Association. Only a handful of the 33 communities relying on water likely contaminated by AFFF or other PFAS sources have been able to access drinking water testing, contributing to widespread unawareness of the problem across the state.

Miller stated that limited assessment of drinking water and other environmental factors is matched by a lack of health assessments probing the effects of PFAS in exposed communities; only two health assessments have been conducted. One of these studies found positive correlations between the PFAS found in drinking water and those compounds found in serum, indicating an influence of drinking water contamination on human body burdens. Miller highlighted the particular plight of Alaskan remote regions as a hemispheric sink for persistent organic pollutants like PFAS. Remote polar regions receive undue burdens of mobile pollutants as a result of global distillation processes that transport pollutants to remote areas, including PFAS. Marine mammals and fish from polar regions therefore contain some of the highest burdens of persistent organic contaminants in the world because of these transport mechanisms and the bioaccumulative nature of PFAS. She shared the results of a community-based study in an Indigenous community on the island of Sivuqaq (St. Lawrence Island) in the Northern Bering Sea. This study tested the blood of community members reliant on traditional diets incorporating polar fish and marine mammals. The assessment found 13 PFAS in the blood of 85 people, as well as correlated concentrations of select PFAS to thyroid disruption.

Miller urged the need for biomonitoring in Alaskan communities with known or suspected PFAS contamination, including remote communities exposed through water sources, traditional foods, firefighting workers, and other exposed workers. Miller stated that human biomonitoring should be paired with assessments investigating exposure from water, dust, produce, fish, and wild game. These data are vital to inform health care providers and the wider community about exposures, possible associations with adverse health effects, appropriate risk reduction interventions, and relevant health care options. These data are also vital to inform policy.

Miller provided examples that emphasized the need to ensure that clinical guidance about PFAS is made accessible to diverse health care providers through various communication and training avenues. She explained that in Alaska health care needs are often addressed by community health aides as many communities lack doctors or nurses. Health aides in Alaska require the same clinical guidance and education afforded physicians, given their central role in meeting community health needs. Current, clear

KD2519

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

synthesis of scientific information, as well as an ability to execute biomonitoring and medical monitoring, is needed for physicians, nurses, and community health aides to allow these health care providers to inform and protect their patients from PFAS. Miller suggested that provider education should occur through professional organizations, as well as continuing education credits offered through public health, medical, and community training programs tailored to different provider types, including the Indian Health Service and regional health care providers.

> "PFAS are contaminating groundwater, surface waters, fish, wild game, garden produce, and people throughout Alaska."

> "The burden of proof should not be on our communities, and this must change so that laws reflect current scientific understanding and are protective of public health."

> "Health care professionals must be informed to become even more effective advocates for their patients and for ending nonessential uses of PFAS." *Pamela Miller*

Randy Krause (Port of Seattle Fire Department)

Randy Krause, the port fire chief, provided commentary as a veteran firefighter and fire chief who previously used AFFF. Krause detailed his career as a firefighter, spanning experience with the DoD, private industry, and a public-serving fire department. Krause explained that fire training activities with the DoD involved regular training with military-grade AFFF or "mil-spec" foams. Training scenarios were enacted and AFFF was sprayed abundantly onto the training props and into the wider environment. Krause also related that, in 1985, these foams were used routinely to clean floors and wash trucks, and were thrown on other firefighters during training exercises.

When he moved to private industry, Krause found a similar approach to training, where an open pit was used to stage fire scenarios, and AFFF was thrown on training fires. Krause clarified that at the time firefighters were assured these mil-spec foams were safe, biodegradable, and did not pose a risk to the environment, which has seen been learned to be incorrect. Krause became fire chief at Seattle International Airport in 2010. While the department had at one time used a similar open pit training set-up with mil-spec foams for fire training activities, Krause indicated this approach was not in practice when he arrived. The department refrained from use of fluorine-containing AFFFs for training due to state bans.

Krause emphasized that the safety of his team is a top priority as fire chief and described an opportunity to contribute to the Firefighter Cancer Cohort Study. This study is a multicity, long-term national research effort focused on assessing cancer in firefighters across the nation. Participation in this study provided Krause and several other department members access to PFAS blood testing. Krause shared his blood testing data in graphical and chart format detailing concentrations of isomers of PFOA, isomers of PFOS, PFHxS,[12] PFDeA,[13] PFNA, PFUA,[14] and Me-PFOSA-AcOH.[15] His results varied in proximity to provided benchmarks, but showed levels of linear PFOS and PFHxS close to or surpassing the nationwide 95th percentile. Krause explained he does not know what these results mean at this time, but discussion with Dr. Jeff Burgess from the University of Arizona suggests high levels of PFOS and PFHxS are commonly elevated in other firefighters. Krause also highlighted that the reporting techniques used by the Firefighter Cancer Cohort Study were particularly helpful, providing his exposure data, average amounts in firefighters from his department, the 50th and 95th percentiles based on NHANES data, and the range of all amounts measured in the firefighters in his department.

[12] Perfluorohexanesulfonic acid or perfluorohexane sulfonic acid, PFAS; see Chapter 1.
[13] Perfluorodecanoic acid, a PFAS; see Chapter 1.
[14] Perfluoroundecanoic acid, a PFAS; see Chapter 1.
[15] 2-N-methyl-perfluorooctane sulfonamido acetate, a PFAS; see Chapter 1.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Jean Mendoza (Friends of Toppenish Creek)

Jean Mendoza spoke as a community member from the Lower Yakima Valley in Washington. Mendoza stated her community and organization have concerns about PFAS because of the prolific application of PFAS-imbued biosolids in agricultural fields across the area. Washington state statutes require biosolid application to the fullest extent possible. This raises concern as the area is highly reliant on agricultural activities and is home to large dairy cow populations; no information has yet investigated crop and livestock safety in response to biosolid-driven PFAS exposure in this area.

Mendoza conveyed discontent and frustration about blatant disregard of environmental health concerns in her community. Mendoza cited efforts by state agencies to measure PFAS in some areas across the state, but noted that PFAS measurements in central Washington and across the Yakima watershed seem to be intentionally omitted. Mendoza also pointed out that Yakima County ranks poorly in the state with respect to health outcomes and health factors, reflecting poor environmental health in an area home to tribal communities and majority Latino populations. In light of these findings, Mendoza stated that the state seems to be blatantly neglecting the exposure of people of the Yakima Valley.

Mendoza listed community health issues, including asthma, myocardial infarction, and low birthweights, noting the region is home to multiple complex exposures including PFAS, air pollution, nitrates, and pesticides that are associated with a number of adverse health outcomes. Mendoza raised the point that it is challenging for Yakima Valley residents to attribute health effects to any one pollutant, given the cumulative exposure to so many pollutants in the region. Mendoza also stated that concern about social maladies often trumps concern about PFAS in the region, given limited awareness of the problem in the community and inaction on the issue by the Yakima Health District. Mendoza moreover detailed that some elected officials take an "ignorance is bliss" approach and opt to avoid investigating the regional PFAS problem to avoid taking action on the issue.

Mendoza enumerated several challenges observed in her community that should be considered by the committee when formulating clinical guidance about PFAS for her community and beyond. She noted that many patients do not understand public health and risk assessment, and clinicians in the area receive no support from local health districts about PFAS. She also highlighted that many of the most exposed are poor households that live paycheck to paycheck, with limited capacity to worry or plan for long-term illness. She also cited the intangible nature of the PFAS problem, with no ability for folks to see, taste, or smell the issue. Mendoza offered recommendations as well, asking the committee to consider educating and informing clinicians about PFAS and other environmental health risks through professional organizations, to support biomonitoring studies, to recommend PFAS testing in fish, and to encourage a moratorium on biosolid application.

"We pay lip service to scientific evidence over here, but very often in Yakima Valley science is suppressed." *Jean Mendoza*

Rebecca Patterson (Vietnam Veterans of America)

Rebecca Patterson presented commentary as a Navy veteran and veteran advocate, highlighting the importance of PFAS blood testing for veteran's health care. Patterson explained that one of the largest sources of PFAS exposure for service members and military communities is the use of AFFF. These firefighting products have been used since 1970 to fight petroleum fires; legacy AFFFs contain PFAAs like PFOS and PFOA. While these are no longer in service, the DoD continues to use AFFF formulations containing PFAS despite the availability of fluorine-free alternatives. Patterson pointed out that use of these firefighting foams readily introduced PFAS into the environment and the water cycle and has led to widespread environmental contamination now documented at hundreds of military bases around the United States.

Patterson stated that her presentation was intended to educate the committee regarding how blood testing could help PFAS-exposed veterans gain access to VA health care. To accomplish this, Patterson

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

shared information about the Veterans Health Administration (VHA). The VHA is tasked with providing care to eligible veterans, though not all veterans access health care through the VHA. This means community health care practitioners may be serving veterans without knowledge of their service history and related exposure; this necessitates that health care providers ask patients about their service history. Patterson also explained that after basic eligibility criteria are met, service members qualify for VHA care based on several factors, including service-connected disability, income, and exposure to toxicants and environmental hazards.

Service-connected disability is of particular importance to the veteran community; this designation typically requires specific evidence substantiating the connection between the given disease or injury and military service. Since medical concerns can arise years after service, it can be difficult for a veteran to connect an ailment to military service or exposure incurred through service. Disability approval results in tiered compensation and priority access to VHA care. With this context, Patterson concluded that access to health care and disability compensation can have a tremendous impact on a veteran's quality of life. PFAS blood testing can provide evidence of exposure that enables veterans to access vital health care. Patterson also asserted that PFAS blood testing can lead to more informed health care, allowing service members and veterans to screen for and potentially prevent health conditions specifically associated with PFAS exposure.

Bucky Bailey (son of former DuPont Washington Works plant employee)

William "Bucky" Bailey III provided perspective as a community member from Parkersburg, West Virginia. Bailey was born with multiple birth defects, including only one nostril, a keyhole eyelid, a serrated eyelid, and breathing difficulties. The family had no idea what caused the defects, given the lack of similar issues in Bailey's siblings. However, Bailey's mother worked as a full-time employee at the DuPont Washington Works plant in Parkersburg, where she controlled the production of PFOA in a confined area. Upon returning to work from maternity leave, Bailey's mother found that other pregnant women were removed from the Teflon production process. She also discovered that studies had been previously conducted by 3M that showed the same birth defects in laboratory animals exposed to PFAS. Despite these lines of evidence, DuPont denied that Bailey's birth defects were a result of his mother's occupational exposure, and the Bailey family found litigation impossible to pursue given DuPont's stature in the community.

Years later, Bailey met Rob Bilott, the lawyer who uncovered DuPont's malfeasance and pursued settlements for exposed residents of Parkersburg. Bailey described feeling relief finding out about links between PFOA exposure and health effects, following years of surgeries and underlying uncertainty regarding the cause of his deformities. Yet Bailey explained that joy following these revelations was also met with disheartenment and discouragement, knowing that the contamination that likely caused his deformities was entirely out of his control and had caused other health problems and untimely deaths in his family and wider community.

Bailey indicated that the C-8 Health Project did not find concrete links between his specific deformities and PFOA exposure, despite admission by DuPont scientists that the compound can cause birth defects. Bailey was also told his children would have a 50 percent chance of inheriting his health issues, which Bailey described as a tough and deeply troubling finding considering his marriage and his love of children. Bailey stated he struggled deeply with the decision to have kids, not wishing to put his children through what he went through as a child. Bailey and his wife ultimately decided to have children after wrestling with the question for over 10 years, and he reported he is the happy father to a healthy son and daughter. Bailey pointed out that knowledge of his contamination and related health risks delayed their family's decision to have children, which ultimately occurred after his father passed away. This timing deprived his children a relationship with their grandfather and deprived Bailey's father the opportunity to meet his grandkids. Bailey stated that his concerns now center on potential health effects like kidney and testicular cancer that he may encounter in the future given his significant PFOA contamination.

Appendix D

Evidence Review: Methods and Approach

This appendix describes the approach and methods that the committee used to address the portions of the Statement of Task that asked for "an objective and authoritative review of current evidence regarding human health effects of those PFAS [per- and polyfluoroalkyl substances] being monitored in the CDC's [Centers for Disease Control and Prevention's] National Report on Human Exposure to Environmental Chemicals" (see Box 1-3 in Chapter 1). The Statement of Task specifically asked the committee to:

> Assess the strength of evidence for the spectrum of putative health effects suggested by human studies (including immune response, lipid metabolism, kidney function, thyroid disease, liver disease, glycemic parameters and diabetes, cancer, and fetal and child development) to establish a basis for prioritized clinical surveillance or monitoring of PFAS health effects. This assessment should characterize the likelihood of those health effects occurring (qualitative probability) given real world human exposures and identify the human populations at most risk (consider life stage, health status, exposure level). Data/evidence gaps that contribute to uncertainty about health effects of most concern should be annotated.

The committee decided that this portion of the Statement of Task required three different determinations:

- qualitative categories that describe the strength of evidence of PFAS putative health effects that can be used to prioritize clinical surveillance or monitoring,
- identification of the human populations at most risk (considering life stage, health status, exposure level) from PFAS exposure, and
- a scoping review that maps the data or evidence gaps that contribute to uncertainty about health effects of most concern.

To produce these outputs, the committee developed a multistage process. The first stage was to catalog what is known about PFAS and their health effects. The committee identified all authoritative reviews of the PFAS identified by the CDC (see Table 1-1 in Chapter 1) and all human health outcomes. The second stage was to identify any recent, high-quality systematic reviews between PFAS and any human health outcome; as noted below, the results of this stage were uninformative for the committee's goals. The third stage was to review the published research articles describing the association between exposure to PFAS and human health outcomes, based on the authoritative and systematic reviews. The committee's review approach improved efficiency while minimizing the risk of excluding scientific findings that would inform the committee's recommendations.

The committee was charged with assessing

> the strength of evidence for the spectrum of putative health effects suggested by human studies (including immune response, lipid metabolism, kidney function, thyroid disease, liver disease, glycemic parameters and diabetes, cancer, and fetal and

KD2532

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

child development) to establish a basis for prioritized clinical surveillance or monitoring of PFAS health effects.

However, the committee did not restrict its evaluation to only the listed putative health effects.

The next section of the appendix covers the committee's analysis of the authoritative reviews; the following section covers its original literature review, and the final section covers the committee strength-of-evidence determination.

AUTHORITATIVE REVIEWS

The committee defined authoritative reviews to be reviews produced by government agencies or other bodies that publish strength-of-evidence determinations through a process that includes peer review. The committee focused on national or international organizations or agencies that influence other organizations. The following organizations met these criteria for authoritative reviews:

- C-8 Science Panel Reports
- European Food Safety Authority (EFSA)
- International Agency for Research on Cancer (IARC)
- Organisation for Economic Co-operation and Development (OECD)
- National Toxicology Program (NTP)
- Agency for Toxic Substances and Disease Registry (ATSDR)
- U.S. Environmental Protection Agency (EPA)

Table D-1 summarizes the authoritative reviews found by the committee. Among the authoritative reviews, the ATSDR's *Toxicological Profile for Perfluoroalkyls* included the greatest number of PFAS included in the committee's Statement of Task (MeFOSAA not included) and was the most recent (literature search conducted in September 2018). The other authoritative reviews were older and included chemicals that were also included in the ATSDR's *Toxicological Profile for Perfluoroalkyls.* Therefore, the ATSDR's *Toxicological Profile for Perfluoroalkyls* was used by the committee as the basis for the next stages of the review process.

TABLE D-1 Authoritative Reviews Found by the Committee

Review	PFAS Chemicals Covered in Review	Health Endpoints Covered in Review	Date of Last Literature Search by the Organization
ATSDR *Toxicological Profile for Perfluoroalkyls*	PFBA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnA, PFDoDA, PFBS, PFHxS, PFOS, FOSA	Not limited	September 2018
EFSA *Risk to Human Health Related to the Presence of Perfluoroalkyl Substances in Food*	PFOA, PFNA, PFHxS, PFOS	Fertility and pregnancy outcomes, development effects, neurotoxic outcomes, immune outcomes, endocrine effects, metabolic effects, kidney function, cardiovascular disease and mortality, bone mineral density	March 2013
EPA Health Effects Document (PFOA)	PFOA	Serum lipids, cardiovascular disease, liver disease, kidney disease, diabetes, developmental toxicity, thyroid effects, immunotoxicity, cancer: kidney and testicular cancer, neurotoxicity, steroid hormones	2015
EPA Health Effects Document (PFOS)	PFOS	Serum lipids, cardiovascular disease, liver disease, kidney disease, diabetes,	2015

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

		developmental toxicity, thyroid effects, immunotoxicity, cancer: testicular and kidney, neurotoxicity, steroid hormones	
IARC Monograph	PFOA	Cancer	June 2014
NTP Monograph	PFOA, PFOS	Immunotoxicity	May 2016
OECD Synthesis Paper	PFOA, PFOS, PFHxS, PFNA, PFDA, PFBS, PFBA, PFHxA, PTFE, PVDF, PFBE	Developmental toxicity, hypocholesteremia, ulcerative colitis, thyroid diseases, testicular cancer, kidney cancer, preeclampsia	Not presented, published 2013
C-8 Science Panel Probable Link Reports[a]	PFOA	Heart disease, kidney disease, liver disease, osteoarthritis, Parkinson's disease, autoimmune disease, infectious disease, neurodevelopmental disorders in children, respiratory disease, evaluation of stroke, thyroid disease, cancer, diabetes, birth defects, pregnancy-induced hypertension, miscarriage and stillbirth, preterm birth and low birthweight	Last report published in 2012

[a] See http://www.c8sciencepanel.org/prob_link.html (accessed July 1, 2022).
NOTE: ATSDR = Agency for Toxic Substances and Disease Registry; EFSA = European Food Safety Authority; EPA = U.S. Environmental Protection Agency; IARC = International Agency for Research on Cancer; NTP = National Toxicology Program; OECD = Organisation for Economic Co-operation and Development.

The committee's review did not assess the quality of the authoritative reviews, but it notes several areas where the ATSDR's *Toxicological Profile for Perfluoroalkyls* could be strengthened. First, the toxicological profile does not provide a detailed description of the evidence identification methods and does not document decisions as to why specific studies may have been excluded. Second, the study quality assessment does not appear to follow a standard approach, and in some cases it is difficult to identify the study designs that were included in the review. Third, the process to assess the strength of the evidence is not always clear.

REVIEW OF SYSTEMATIC REVIEWS

The committee's review of systematic reviews consisted of the following steps: literature search, screening of abstracts, full text review of studies identified in the abstract screening, evaluation of a final set of relevant studies, evidence assessment, and synthesis.

Literature Search

Systematic reviews were identified through searches of the medical and scientific literature on three databases: Embase Update, Medline, and Scopus. These three searchable databases index biological, chemical, medical, and toxicological publications. Search terms included full and abbreviated chemical names, common and manufacturer trade names, Chemical Abstracts Service (CAS) numbers, and MeSH[1] descriptors for each of the PFAS species of interest. Systematic reviews were included regardless of when they were published or where they were conducted. Systematic reviews were considered if they reviewed human studies, were classified as review papers, and were published in English. The databases were searched on June 28, 2021.

[1] MeSH descriptors are sets of terms naming descriptors in a hierarchical structure that permits searching at various levels of specificity.

Screening of Abstracts

The literature search identified 639 potentially relevant systematic reviews. The publications were imported into PICO Portal, a web-based tool for collaborative citation screening for systematic reviews.[2] After importing to PICO Portal, 119 articles were identified as duplicates, leaving 520 for title and abstract screening. The review used the following population exposure comparison and outcome (PECO) statement:

> **Population:** Systematic reviews of health effects of PFAS in humans
> **Exposure:** PFAS species measured in the CDC's *National Report on Human Exposure to Environmental Chemicals* (see Chapter 1, Table 1-3)
> **Comparison:** Any comparison groups, including internal controls
> **Outcome:** Any human health outcome

The inclusion and exclusion criteria related to the PECO statement were as follows:

> **Inclusion Criteria:** Includes human evidence; includes the PFAS species measured in the CDC's *National Report on Human Exposure to Environmental Chemicals*; assesses the evidence for an association of PFAS and a health outcome in humans; and has a methods section
> **Exclusion Criteria:** Did not review health effects of PFAS; reviewed only animal or mechanistic studies; reviewed chemicals other than the PFAS included in the Statement of Task; reviewed generic classes of chemicals such as "endocrine disruptors" or "persistent organic pollutants;" or reviewed the ecological effects of PFAS or PFAS exposure pathways

Title and abstract screening was completed by two screeners. Disagreements were resolved by an adjudicator who helped facilitate a consensus decision. Fifty-four articles were included for full-text review.

Full Text Review

For the full text review, articles were excluded because they did not include human studies (n = 2), did not include relevant PFAS (n = 5), did not have a methods section (n = 18), or did not evaluate the association of PFAS exposure with a human health outcome (n = 3) (see Figure D-1). Thus, the full text review covered 26 articles.

FIGURE D-1 Preferred reporting items for systematic reviews and meta-analyses (PRISMA) diagram for the committee's review of reviews on health effects of PFAS.

Evaluation and Evidence Assessment

The quality of the 26 included systematic reviews was evaluated using the AMSTAR-2 (A MeaSurement Tool to Assess systematic Reviews) (Shea et al., 2017), which has been used by several other committees of the National Academies of Sciences, Engineering, and Medicine (NASEM, 2019, 2021). AMSTAR-2 includes several critical appraisal domains (see Box D-1). The quality assessment was conducted by a staff member and was confirmed by a committee member. The committee conducted a critical appraisal of the systematic reviews because systematic reviews can be subject to a range of biases.

KD2537

Copyright National Academy of Sciences. All rights reserved.

BOX D-1
AMSTAR-2 Critical Domains and Overall Confidence in the Results

Critical Domains

- Protocol registered before commencement of the review (item 2)
- Adequacy of the literature search (item 4)
- Justification for excluding individual studies (item 7)
- Risk of bias from individual studies being included in the review (item 9)
- Appropriateness of meta-analytical methods (item 11)
- Consideration of risk of bias when interpreting the results of the review (item 13)
- Assessment of presence and likely impact of publication bias (item 15)

Rating: Overall Confidence in the Results of the Review

- *High:* No or one noncritical weakness: the systematic review provides an accurate and comprehensive summary of the results of the available studies that address the question of interest.
- *Moderate:* More than one noncritical weakness: the systematic review has more than one weakness but no critical flaws. It may provide an accurate summary of the results of the available studies that were included in the review.
- *Low:* One critical flaw with or without noncritical weaknesses: the review has a critical flaw and may not provide an accurate and comprehensive summary of the available studies that address the question of interest.
- *Critically Low:* More than one critical flaw with or without noncritical weaknesses: the review has more than one critical flaw and should not be relied on to provide an accurate and comprehensive summary of the available studies.

Synthesis: Results

Of the 26 systematic reviews identified by the committee, 9 included studies published after the ATSDR's *Toxicological Profile for Perfluoroalkyls* (Bartell and Vieira, 2021; Boesen et al., 2020; Deji et al., 2021; Dzierlenga et al., 2020; Ferrari et al., 2019; Luo et al., 2020; Petersen et al., 2020; Steenland and Winquist, 2020; Xie et al., 2020; Zare Jeddi et al., 2021). Although all were of moderate quality, some reviews covered the same original data and papers, and the committee found it challenging to synthesize across them. As a result, the systematic reviews were used as sources for reference in the committee's determination of the biologic plausibility between PFAS and a health effect, but they were not formally included as part of the final strength-of-evidence determination.

ORIGINAL LITERATURE REVIEW

The original literature review consisted of the following steps: literature search, screening of abstracts, full text review of studies identified in the abstract screening, evidence mapping and evaluation, and data abstraction.

Literature Search

As was done for the review of reviews, the literature for the original literature review was identified through searches of the medical and scientific literature on three databases: Ovid Embase, Ovid Medline, and Scopus. These three searchable databases index biological, chemical, medical, and toxicological publications. Search terms included full and abbreviated chemical names, common and

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

manufacturer trade names, the CAS numbers, and MeSH[3] descriptors for each of the PFAS species of interest. There were no time constraints or geographic constraints included in the search. The only constraints were human studies and English language only. The databases were searched on March 30–31, 2021.

Abstract Screening

The literature search identified 5,172 potentially relevant studies. The studies were imported into PICO Portal, a web-based tool for collaborative citation screening for systematic reviews.[6] After importing the studies to PICO Portal, 112 articles were identified as duplicates, leaving 5,060 articles to be screened. The titles and abstracts were screened for relevance to the research questions for the review. The review used the following PECO statement:

> **Population:** Studies of health effects of PFAS in humans
> **Exposure:** PFAS species measured in the CDC's *National Report on Human Exposure to Environmental Chemicals*
> **Comparison:** Any comparison groups, including internal comparisons
> **Outcome:** Any health outcome measured in humans

The inclusion and exclusion criteria related to the PECO statement were as follows:

> **Inclusion Criteria:** Is an epidemiologic or human study; includes a quantitative measure of the PFAS species measured in the CDC's *National Report on Human Exposure to Environmental Chemicals*; assesses the evidence for an association of PFAS and a health outcome in humans; and English language only

[6] See https://picoportal.net (accessed July 1, 2022).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Exclusion Criteria: Did not review health effects of PFAS; reviewed only animal or mechanistic studies; was about chemicals other than the PFAS included in the Statement of Task; did not include a quantitative measure; or was on the ecological effects of PFAS or PFAS exposure pathways

The literature search identified 5,172 potentially relevant studies. After removal of duplicates (112 articles), 5,060 articles were subject to title and abstract screening by two independent reviewers.

Full Text Review

For the full text review, 4,434 of the articles identified in the literature search were excluded because the titles and abstracts did not meet the inclusion criteria, so 626 articles were subject to full text review. During that review, additional articles were excluded if they were published before 2018 or listed in the references to the ATSDR's *Toxicological Profile for Perfluoroalkyls* (n = 320); were cross-sectional in design (n = 160); were not published in English (n = 1); did not provide risk estimates associated with PFAS exposure (n = 3); or were not studies in humans (n = 3) (see Figure D-2). Cross-sectional studies were largely excluded because this study design measures exposure and disease at the same time so cannot determine cause and effect. Thus, the full text review covered 139 articles.

Evidence Mapping and Evaluation

The committee then categorized the 139 articles according to the human health outcomes studied. The committee mapped the evidence with the goal of determining evidence gaps and to inform strategies for the evidence evaluation and evidence synthesis (see Figure D-3).

The committee focused on those endpoints for which additional review might change the committee's understanding of the association between PFAS exposure and health outcomes.

The committee conducted a narrative evaluation of the study quality and considered factors that may contribute to the study's risk of bias (see Box D-2) using a tool adapted from the Navigation Guide (Woodruff and Sutton, 2014). Bias is a systematic error that leads to study results that differ from the actual results. Bias can lead to an observed effect when one does not exist or to no observed effect when there is a true effect. Risk of bias is the appropriate term, as a study may be unbiased despite a methodological flaw (Higgins et al., 2019). The risk-of-bias assessment in a systematic review is based on the quality of the individual component studies (Eick et al., 2020).

A trained reviewer from ICF International, the EPA, the National Academies, or Johns Hopkins University abstracted the critical domain information from each study that the committee used to support its judgment determinations regarding a study's risk of bias, and the committee made the final risk of bias judgments for each study.[7] Each paper was given an overall assessment of its risk of bias (low, probably low, probably high, or high risk of bias).

[7] For some studies included in the committee's review, the data had been previously abstracted by ICF or the EPA to support the EPA's ongoing assessments of PFAS; newer evidence was abstracted by ICF or consultants at Johns Hopkins.

BOX D-2
Critical Domains Used by the Committee to Assess Risk of Bias

Exposure Measures: Assay information, quality control measures, repeat measures, validation studies

Outcome Measures: Sources of the effect measure, blinding to exposure status or level, methods of measurement or classification, incident versus prevalent disease, evidence from validation studies

Participant Selection: Study design, where and when was the study conducted, and who was included? Recruitment process, exclusion and inclusion criteria, type of controls, total eligible, comparison between participants and nonparticipants (or followed and not followed), final analysis group. Does the study include potential vulnerable/susceptible groups or life stages?

Potential Confounding: Potential confounders and outcome; degree of exposure to the confounder in the population

Analysis: Extent (and, if applicable, treatment) of missing data for exposure, outcome, and confounders, approach to modeling, classification of exposure and outcome variables (continuous versus categorical), testing of assumptions, sample size for specific analyses, and relevant sensitivity analyses

Selective Reporting: Are results presented with adequate detail for all of the endpoints of interest? Are results presented for the full sample as well as for specified subgroups? Were stratified analyses (effect modification) motivated by a specific hypothesis?

Sensitivity: What exposure range is spanned in this study? What are the ages of participants (e.g., not too young in studies of pubertal development)? What is the length of follow-up (for outcomes with long latency periods)? Choice of referent group and the level of exposure contrast between groups (i.e., the extent to which the "unexposed group" is truly unexposed, and the prevalence of exposure in the group designated as "exposed")

Source of Funding: Description of the disclosed sources of funding for the paper

Data Abstraction

Data abstraction was completed by a trained scientist from ICF, the EPA, the National Academies, or Johns Hopkins.[8] The data abstraction form included the following:

Reference: Author year and DOI number if relevant
Chemical: Acronym of specific PFAS
Endpoint: Name of the specific outcome for the risk estimate
Subpopulation: Description of the specific subpopulation for the risk estimate
N: Sample size that informs risk estimate
Exposure Levels: That apply to the risk estimate
Comparison: Description of type of risk estimate, such as "SMR for bladder cancer in the high exposure group compared to no workplace exposure" or "change in ln (TSH) per standard unit increase in serum PFOA."
Risk/Effect Estimate: Reported number
Lower Confidence Interval: Reported number
Upper Confidence Interval: Reported number

[8] For some studies included in the committee's review, the data had been previously abstracted by ICF or the EPA to support the EPA's ongoing assessments of PFAS; newer evidence was abstracted by ICF or consultants at Johns Hopkins University.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Effect estimates from the individual studies included in the review were extracted into a database and uploaded to a public website (Tableau Public) to allow for visualizations, such as evidence maps and forest plots.[9] The effect estimates in the Tableau represent those from the model most adjusted for confounders.

STRENGTH-OF-EVIDENCE DETERMINATION

To assess the strength of evidence regarding the potential for PFAS to cause a particular health effect, the committee then integrated the evidence reviewed in the ATSDR's *Toxicological Profile for Perfluoroalkyls* and other authoritative reviews with the evidence from the original literature review from the epidemiologic studies.

The synthesis of available data was guided by a framework based on the Hill considerations (Hill, 1965), which help to determine whether associations are causal (see Box D-3). The committee did not consider the Hill considerations to be a heuristic for assessing causation in isolation, that is, as a checklist where each item must be met to establish causality. Rather, the committee considered them as a list of possible considerations meant to generate thoughtful discourse by the committee to help inform its determinations for the strength of evidence (Fedak, 2015; NASEM, 2018).

BOX D-3
Bradford Hill Considerations

Strength: A small association does not mean that there is not a causal effect, though the larger the association, the more likely that it is causal.

Consistency: Consistent findings observed by different people in different places with different samples strengthens the likelihood of an effect.

Specificity: Causation is likely if there is a very specific population, at a specific site, with a specific disease with no other likely explanation.

Temporality: The effect has to occur after the cause.

Biological Gradient: Greater exposure should generally lead to greater incidence of the effect. In other cases, greater exposure leads to lower incidence.

Plausibility: A plausible mechanism between cause and effect is helpful.

Coherence: Coherence between epidemiological and laboratory findings increases the likelihood of an effect but "lack of such [laboratory] evidence cannot nullify the epidemiological effect on associations" (Hill, 1965, p. 298).

Experiment: Occasionally it is possible to appeal to experimental evidence.

Analogy: The effect of similar factors may be considered.

SOURCE: Hill, 1965.

[9] The committee's public Tableau is available at https://public.tableau.com/app/profile/nationalacademies/viz/NASEMPFASEvidenceMaps/PFASEvidenceMap (accessed July 1, 2022). The information may be viewed as an evidence map or as a forest plot. Within forest plots, filters can be accessed using the "toggle filters" function in order to restrict the view to data on specific health effect categories and other factors (such as reference, chemical, study design, study population).

Animal and Mechanistic Studies

The Statement of Task called for the committee to "assess the strength of evidence for the spectrum of putative health effects suggested by human studies." The committee focused on more recent epidemiological literature in line with its Statement of Task. However, the committee recognizes the importance of toxicologic evidence in making strength-of-evidence conclusions and relied on the toxicological data included in the ATSDR's *Toxicological Profile for Perfluoroalkyls*, other authoritative reviews, and systematic reviews that provide integrative conclusions based on multiple lines of evidence. In synthesizing evidence in this manner, the committee acknowledges that animal evidence greatly improves the interpretation of the human studies.

An observed association between PFAS exposure and a health effect does not necessarily mean that the exposure is the cause of that outcome. Toxicologic evidence, whether it supports or conflicts with evidence from epidemiologic studies, provides insights about biologic processes and informs how an observed association might be interpreted. The degree of biologic plausibility itself influences whether the committee perceives positive findings to be indicative of a pattern or the product of statistical fluctuations. Ultimately, the results of the toxicology studies should be consistent with what is known about the human disease process if they are to support a conclusion that the development of the disease was influenced by an exposure (NASEM, 2018).

Categories of Association

Sufficient Evidence of an Association

For effects in this category, a positive association between PFAS and the outcome must be observed in studies in which chance, bias, and confounding can be ruled out with reasonable confidence. For example, the committee might regard as sufficient evidence of an association evidence from several small studies that is unlikely to be due to confounding or to otherwise be biased and that shows an association that is consistent in magnitude and direction. Experimental data supporting biologic plausibility strengthen the evidence of an association but are not a prerequisite, nor are they sufficient to establish an association without corresponding epidemiologic findings.

Limited or Suggestive Evidence of an Association

In this category, the evidence must suggest an association between exposure to PFAS and the outcome in studies of humans, but the evidence can be limited by an inability to rule out chance, bias, or confounding with confidence. One high-quality study may indicate a positive association, but the results of other studies of lower quality may be inconsistent.

Inadequate or Insufficient Evidence to Determine an Association

If there was not enough reliable scientific data to categorize the potential association with a health effect as "sufficient evidence of an association," "limited or suggestive evidence of an association," or on the other end of the spectrum, "limited or suggestive evidence of no association," the health outcome was placed in the category of "inadequate or insufficient evidence to determine an association" by default. In this category, the available human studies may have inconsistent findings or be of insufficient quality, validity, consistency, or statistical power to support a conclusion regarding the presence of an association. Such studies may have failed to control for confounding factors or may have had inadequate assessment of exposure.

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Limited or Suggestive Evidence of No Association

A conclusion of "no association" is inevitably limited to the conditions, exposures, and observation periods covered by the available studies, and the possibility of a small increase in risk related to the magnitude of exposure studied can never be excluded. However, a change in classification from inadequate or insufficient evidence of an association to limited or suggestive evidence of *no* association would require new studies that corrected for the methodologic problems of previous studies and that had samples large enough to limit the possible study results attributable to chance.

Abstract

This white paper provides an overview of the published literature on whether personal behavior modifications can demonstrably reduce exposure to per- and polyfluoroalkyl substances (PFAS) (e.g., by showing decreases in serum levels). The reviewed studies are presented by exposure source. The preponderance of the identified literature relates to diet and drinking water. Literature on interventions for other exposure sources, such as dust and consumer products, is more limited. Breastfeeding is an important potential source of exposure for infants; the effect of lactation on mothers' PFAS levels is unclear. For communities with high levels of PFAS in drinking water, interventions related to tap water filtration showed some efficacy in reducing PFAS levels in the water. It is possible that an intervention may reduce PFAS levels in a particular medium, but if this medium is not a major source of overall exposure, then that intervention may not contribute significantly to reduction in human exposures. Overall, the intervention literature is sparse and has many limitations. Thus, the committee may have to rely on assumptions and other bodies of evidence to make recommendations to individuals and communities about exposure reduction.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

E-1

Introduction

Per- and polyfluoroalkyl substances (PFAS) are anthropogenic chemicals that have been produced and utilized globally since the 1940s.[1] PFAS have garnered attention for several reasons, including their ubiquitous presence in the environment (Ahrens and Bundschuh, 2014; von der Trenck et al., 2018) and in humans (Calafat et al., 2019; Göckener et al., 2020; Health Canada, 2019; Kannan et al., 2004), and because—as their epithet "forever chemicals" suggests—many of these chemicals are persistent both in the environment and in humans, with half-lives estimated to be several years (Li et al., 2018; Myers et al., 2012). Exposure to PFAS has been linked with such health endpoints as reduced immune response, lipid metabolism, and kidney function; thyroid disease; liver disease; glycemic parameters and diabetes; cancer; and impaired fetal and child development (ATSDR, 2020).

Activities to limit the production and use of exposure to PFAS compounds include regulatory limits, voluntary reductions in manufacture (Butenhoff et al., 2006) and use in products, cleanup of contaminated sites, and modifications to publicly owned treatment works (POTWs) to reduce PFAS in drinking water. However, as evidenced by studies of measurements of PFAS in serum from nationally representative populations in the United States (Calafat et al., 2019), as well as serum measurements in communities near sites with known contamination (Herrick et al., 2017), exposure to PFAS is ongoing. It has been well documented that PFAS are present in numerous media and products, including drinking water; breast milk; other foods and food packaging material; cosmetics; and household products, including carpets, stain- and water-repellent fabrics, nonstick products, polishes, waxes, paints, and cleaning products (D'Hollander et al., 2010; EFSA, 2020; Eichler and Little, 2020; Fromme et al., 2009; Sajid and Ilyas, 2017; Sunderland et al., 2019).[2]

Communities impacted by PFAS exposure would like advice on how they can prevent its potential health effects. To help clinicians respond to patient concerns about PFAS exposure, the Agency for Toxic Substances and Disease Registry (ATSDR) has published *PFAS: An Overview of the Science and Guidance for Clinicians on Per- and Polyfluoroalkyl Substances* (referred to hereafter as the ATSDR PFAS Clinical Guidance) (ATSDR, 2019). This guidance summarizes general information about PFAS and PFAS health studies and suggests answers to example patient questions. Some people living in PFAS-impacted communities have voiced frustration that the clinical guidance lacks clear recommendations to their physicians about what people can do to protect their health, which prompted the ATSDR and the National Institute of Environmental Health Sciences (NIEHS) to request that the National Academies of Sciences, Engineering, and Medicine convene a committee to provide advice for clinicians about PFAS testing, such as when to test, whom to test, how to test, what to test for, and the risks of testing. The committee is also charged with developing principles clinicians can use to advise patients on exposure reduction.[3] The committee commissioned this white paper to determine whether evidence exists that supports the effectiveness of these types of behavior changes. The literature review in this white paper is intended to help the National Academies committee evaluate possible evidence-based recommendations for improving the ATSDR's PFAS Clinical Guidance. This white paper is not intended to be a comprehensive review of human exposure to PFAS; the National Academies have other sources for that information.

Various organizations have provided suggestions for personal actions to lower individual PFAS exposure. These include avoiding contaminated water or fish and selecting personal care products that do

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

not contain PFAS and related compounds (ATSDR, 2020; EWG, 2016; Loria, 2019; ODH, 2020). Reducing intake of PFAS should reduce exposure, but people may not necessarily know whether their foods, beverages, or products contain PFAS. This review addresses the following question: Based on current research, are there interventions or *personal* changes that individuals can make to *effectively* reduce their PFAS exposure? This question includes two key concepts. First, "personal" indicates that the focus is on research related to media and products that people may be able to control partly or wholly (see Figure E-1) as opposed to activities that occur on a larger scale, such as contaminated site cleanup, changes in occupational exposures, or modifications to publicly owned water treatment plants. Second, "effectively" refers to changes in personal behavior that can result in measurable or substantial reductions in exposures.

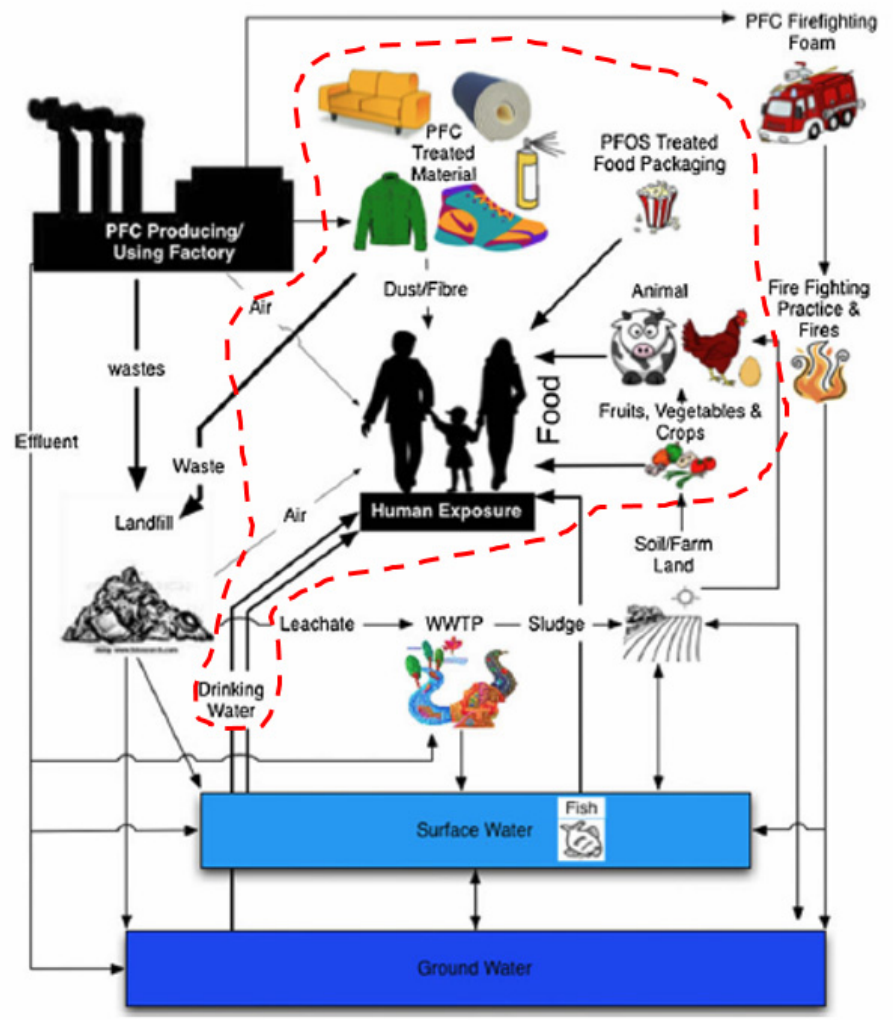

FIGURE E-1 Human PFAS exposure pathways. The area inside the dashed red line denotes pathways for which individual actions may lower PFAS exposures.
NOTE: PFC = per-/polyfluorinated chemical; WWTP = wastewater treatment plant.
SOURCE: Adapted from Oliaei et al., 2013. CC BY 4.0.

To answer the above question, it is important to consider several factors related to reducing human PFAS exposure. First, PFAS must be present in the media or products of interest. While this seems like a straightforward notion, information on PFAS concentrations in local media (e.g., local

KD2555

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

drinking water) and specific products (e.g., cookware) may in fact be sparse or unavailable. Second, there must be a complete exposure pathway between the medium or product and humans. In other words, if PFAS are present in a medium or product but there is no human contact, then exposure will not occur. Third, an exposure pathway may be complete but not contribute substantially to overall human exposure. In this case, a reduction in the PFAS source may not result in a meaningful reduction in human PFAS exposure. Fourth, actions to reduce PFAS exposure from one pathway may result in exposure to PFAS or other chemicals from a new pathway (e.g., an action to remove exposure to one food item with known PFAS levels may result in exposure to another food item that has not yet been analyzed for PFAS or other chemicals). Finally, PFAS tend to have long physiological half-lives; thus, interventions or changes in behavior may not produce near-term changes in internal PFAS levels (i.e., serum levels).

Taking these issues into consideration, this white paper explores the following three questions:

1. *Is there research that links specific interventions or changes to reductions in human exposures?* This paper focuses on studies seeking to establish that an intervention or behavioral change produces a quantifiable reduction in human exposure as evidenced by measurements of PFAS in the media of interest or directly in humans. As noted above, studies relying on biomonitoring to assess the efficacy of an intervention must consider the long half-lives of many PFAS and must be of appropriate duration to enable observation of postintervention decreases in serum levels.
2. *Can information from exposure assessments that estimate human intakes from multiple pathways of exposure and exposure routes be used as the basis for individual or community recommendations?* In this type of study, measurements of PFAS in various media are used to model human PFAS intake (i.e., nanograms [ng] per day or ng/kilogram [kg] per day). If sufficient measurement data are available, it may be possible to estimate the relative importance of various pathways of exposure.
3. *Is the available research sufficiently robust such that recommendations for modifications to behavior can be made?* Studies differ in terms of their quality and generalizability (i.e., how well the results translate from the studied population and conditions to other populations and conditions). They therefore also differ in terms of the confidence one can place in the results. Factors impacting confidence in studies can include sample size, quality assurance, inter- and intrastudy consistency in results, and completeness of reporting. In addition, for recommendations applicable to the United States, it is important to consider whether the studies reflect conditions that apply to behaviors and exposures in this country.

The remainder of this paper first describes our approach to identifying and reviewing the literature. We then provide results by medium. Next, we discuss efforts to model relative contributions of media and products to overall PFAS intakes in the United States.

We note that there are more than 9,000 PFAS compounds (NASEM, 2021), and any given study generally examines only a very small subset of these. We focus here on the 16 PFAS[4] chemicals included in the Centers for Disease Control and Prevention's (CDC's) *National Report on Human Exposure to Environmental Chemicals* (CDC, 2009).

[4] PFBS: perfluorobutane sulfonic acid; PFDA: perfluorodecanoic acid; PFDoA: perfluorododecanoic acid; PFHpA: perfluoroheptanoic acid; PFHxS: perfluorohexane sulfonic acid; PFNA: perfluorononanoic acid; PFOA: perfluorooctanoic acid; n-PFOA: n-perfluorooctanoic acid; Sb-PFOA: branched perfluorooctanoic acid; PFOS: perfluorooctane sulfonic acid; n-PFOS: n-perfluorooctane sulfonic acid; Sm-PFOS: perfluoromethylheptane sulfonic acid; PFOSA or FOSA: perfluorooctane sulfonamide; EtFOSAA: 2-(n-ethyl-perfluorooctane sulfonamido) acetic acid; MeFOSAA: 2-(n-methyl-perfluorooctane sulfonamido) acetic acid; PFUnDA: perfluoroundecanoic acid. The various PFAS abbreviations used in this paper are defined in the listing at the beginning of the paper. For brevity, these abbreviations are not spelled out further in the text of this paper.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

E-2

Methods

This review is a scoping review that aims to (1) "identify the types of available evidence in a given field," (2) "report on the types of evidence that address and inform practice in the field and the way the research has been conducted," (3) "examine how research is conducted on a certain topic," and (4) "identify and analyze gaps in the knowledge base" (Munn et al., 2018).

LITERATURE IDENTIFICATION

Online data sources, including PubMed, EMBASE, and Google Scholar, were used to conduct the initial literature searches. We used such keywords as "(PFBS OR PFDA OR PFDoA OR PFHpA OR PFHxS OR PFNA OR PFOA OR n-PFOA OR sb-PFOA OR PFOS OR n-PFOS OR Sm-PFOS OR PFOSA OR FOSA OR EtFOSAA OR MeFOSAA OR PFUnDA OR PFAS)," "PFAS," "perfluoroalkyl," "human," "exposure," "cooking," "dust," "fish," "shellfish," "water," "nail polish," "cleaning," "consumer products," "filter," "water filter," "filtration," "intervention," "determinant," "reduction," "diet," "vacuum," "popcorn," "biomonitor," "breast milk," "breastfeeding," "infant formula," "milk powder," "carpeting," "packaging," "indoor," "bottled water," "air conditioning," "fabrics," "well water," "water treatment," "apparel," "inhalation," "ventilation," "cosmetics," "dental floss," and "personal care products," as well as various combinations of these and related keywords. We selected articles describing interventions designed to reduce human exposure to PFAS, specifically interventions that could be carried out by individuals (e.g., excluding site cleanups, modifications of publicly owned treatments works [POTWs]). Secondary references of retrieved articles were reviewed to identify publications not identified by the electronic search. Additional literature searches were conducted to identify reviews that contained estimates of human PFAS intakes using the following keywords in different combinations: "(PFBS OR PFDA OR PFDoA OR PFHpA OR PFHxS OR PFNA OR PFOA OR n-PFOA OR sb-PFOA OR PFOS OR n-PFOS OR Sm-PFOS OR PFOSA OR FOSA OR EtFOSAA OR MeFOSAA OR PFUnDA)," "PFAS," "exposure," "review," "biomonitor," "PFOA," and "human." The final search date was March 5, 2021.

The criteria for inclusion in the review were as follows: studies of interventions related to personal modifiable behavior and English-language publications. Exclusion criteria included the following: occupational studies and those interventions requiring professional activities, such as modifications to POTWs. For publications on modeled intake estimates, we were interested primarily in PFAS intakes in the United States. Research focused on clinical interventions is outside the scope of this review (e.g., Ducatman et al., 2021; Genuis et al., 2014).

LITERATURE REVIEW AND DATA EXTRACTION

Each study that met the above inclusion criteria was examined by both authors. The data from each intervention study were tabulated. Information extracted from each study included (where available[5]) the following:

- description of the study population: size, composition, source, and location;
- study design: laboratory and population;
- type of specimen and number of samples;

[5] Because of the disparate nature of the identified studies, it was often possible to include only a portion of the elements.

Copyright National Academy of Sciences. All rights reserved.

- PFAS and concentrations or changes in concentrations; and
- results: percent decrease/increase, concentration decrease/increase, and a measure of precision (e.g., 95% confidence interval [CI], standard deviation [SD]). (For publications with results reported qualitatively, the text was extracted and reproduced verbatim.)

ASSESSMENT OF EVIDENCE

We evaluated the overall strength of evidence for each medium, considering such elements as overall study design, participant selection, sample size, and exposure assessment (LaKind et al., 2014; Vandenbroucke et al., 2007). For studies using biomonitoring data to assess the efficacy of an intervention, we considered whether sampling intervals were designed to capture potential effects of the intervention. To assess the utility of the available evidence for providing recommendations for behavior modifications to reduce PFAS exposures, we examined such factors as (1) the number of available studies for each medium/PFAS chemical/intervention type combination, (2) the quality of the individual studies, (3) the intra- and interstudy consistency in results, and (4) the generalizability of the information to U.S. populations.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

E-3

Results

Studies with the potential to provide information on methods that could be used by individuals for reducing exposure to PFAS were identified. The intervention areas include preparation of fish and other foods, reduction of exposure to PFAS in drinking water either via water filtration at point of entry (POE) or point of use (POU) or via consumption of bottled water, selection of cookware, minimization of indoor dust exposure through modification of indoor products, and use of personal care products or dietary fiber. Literature on breast milk/infant formula and both mother and infant PFAS exposure reduction is discussed. Finally, studies on source contributions to overall PFAS intake in the United States were identified. Each of these bodies of literature is described in the following sections.

FOOD PREPARATION: FISH, SHELLFISH, AND MOLLUSKS

Fish, shellfish, and mollusks have been studied for their potential as a source of PFAS exposure in humans. Nine studies examining the effect of various fish and seafood preparation methods on PFAS levels were identified. The studies included different species, cooking practices, and PFAS. We briefly summarize these studies here.

Alves and colleagues (2017) measured PFOS and PFUnA levels in mackerel and flounder purchased in markets in Spain, Italy, and the Netherlands (25 samples per species/location). PFAS were measured in raw samples and from samples steamed at 105°C for 15 minutes. No significant differences in concentrations were found between the steamed and raw samples. Mean concentrations of PFOS in flounder for raw and steamed samples were 24±1.5 nanograms per gram (ng/g) wet weight (ww) and 22±1.5 ng/g ww, respectively. Mean concentrations of PFUnA in mackerel for raw and steamed samples were 3.1±0.2 ng/g ww and 2.9±0.1 ng/g ww, respectively.

The 16 PFAS compounds identified previously (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDcA, PFUnA, PFDoA, PFTrA, PFTeA, PFBS, PFHxS, PFHpS, PFOS, and PFDS) were measured in raw and steamed tuna, hake, plaice (n = 25 each; fillets), and mussels (n = 50) purchased in European markets (Barbosa et al., 2018). Steaming was performed at 105°C for 15 minutes (fish) or 5 minutes (mussels). The effects of steaming varied considerably by both species and compound. Selected results shown in Figure E-2 illustrate these differences.

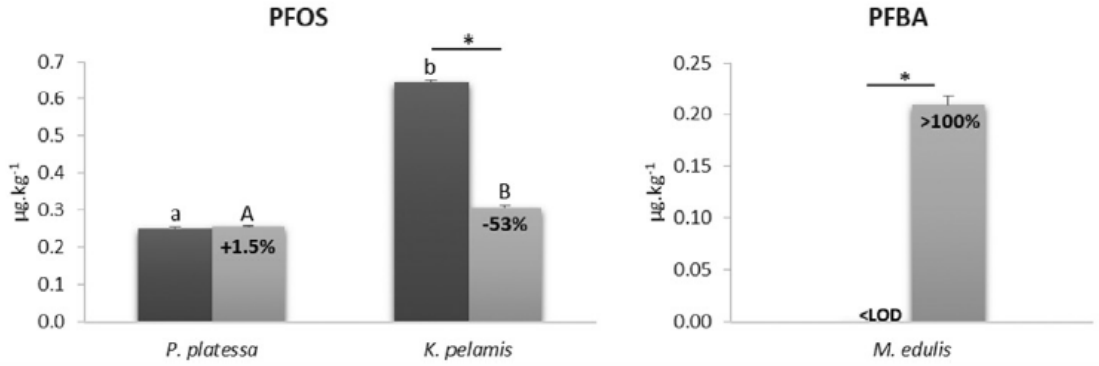

FIGURE E-2 Examples of PFAS content (micrograms per kilogram [μg/kg] wet weight [ww]) in raw and steamed seafood samples and percentages of PFAS content increase (+) and decrease (−) after steaming (mean ± standard deviation [SD]).

Bhavsar and colleagues (2014) measured various PFAS (including perfluoroalkyl carboxylic acids, perfluoroalkane sulfonic acids, perfluoroalkyl phosphonic acids, perfluoroalkyl phosphinic acids, and polyfluoroalkyl phosphoric acid diesters) in fresh-caught Chinook salmon, lake trout, common carp, and walleye obtained in Ontario, Canada (fillets from four or five fish per species). PFAS levels in the cooking oil were below the limit of detection (LOD). Fillet samples were placed on a layer of canola oil and fried, baked, or broiled for 10–15 minutes. PFOS was by far the dominant PFAS in each species; thus, the results were focused on the effects of cooking methods on PFOS fish concentrations. All cooking methods resulted in mostly statistically significant increases in concentrations of PFOS in salmon, trout, and walleye (the increase in walleye after frying did not appear to be statistically significant). For example, PFOS concentrations in raw, baked, broiled, and fried chinook salmon (mean ± standard deviation [SD]) were, respectively, 12.70±12.61 ng/g ww, 16.56±18.00 ng/g ww, 16.45±15.63 ng/g ww, and 16.03±15.19 ng/g ww. For carp, broiling and frying resulted in no significant changes. The authors also assessed the change in amount of PFOS (in contrast with the concentration change) to account for loss in mass due to cooking. With this approach, results were mixed in directionality and mostly nonsignificant.

Del Gobbo and colleagues (2008) analyzed fish and shellfish species purchased in Canadian markets for PFOA, PFNA, PFDA, PFUA, PFDoDA, PFTeDA, and PFOS. Species included catfish, cuttlefish, grey mullet, grouper, monkfish, octopus, red snapper, sea squirt, skate, whiting, and yellow croaker. Composites from each species were comprised of at least three individuals from three different sources or markets (total of nine). The fillets (sometimes with skin) were baked, boiled, or fried in water, sesame oil, rice wine, or vegetable oil. PFAS levels in the cooking oil were below the LOD. Baking and frying times were 15 minutes at 163°C or 325°C. All cooking interventions were found to decrease PFAS concentrations, with boiling and frying reducing total PFAS concentrations by an average of 79 percent and 54 percent, respectively. Baking reduced all measured PFAS to below the LOD (0.03–10 ng/g ww). Boiling appeared to increase concentrations of PFOS in octopus (from nondetect to 0.23 ng/g ww) but not in red snapper, skate, or yellow croaker. The authors hypothesize that large loss of mass in the boiled octopus (87 percent) may have resulted in an increase in levels above the LOD.

Hu and colleagues (2020) measured 13 PFAS compounds (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnDA, PFDoDA, PFBS, PFHxS, PFOS, and FOSA) in grass carp taken from Tangxun Lake, China (n = 5). The fillets were either steamed, boiled, fried, or grilled, with cooking temperatures for the various processes ranging from 100°C to 210°C. The authors note that in the "cooking blank juice samples all PFAS were below the MLQs [Method Quantitation Limit] except PFBS and PFOS. The concentrations of PFBS and PFOS in cooking blank samples were 1.31–2.43 ng/g and 0.131–0.169 ng/g, respectively" (Hu et al., 2020, p. 4). The effects of the cooking methods on concentrations of various PFAS compounds were found to be inconsistent. For example, median PFOS concentrations increased from 71.3 ng/g ww in uncooked fish to 146 ng/g ww in fried fillets. In contrast, median PFBS concentrations decreased from 20.3 ng/g ww in raw fish to 8.08 ng/g ww after grilling. These results exemplify the difficulty in characterizing the directionality and magnitude of the effectiveness of cooking fish as a proposed type of intervention.

Kim and colleagues (2020) measured 19 PFAS (PFOS, PFDS, PFHxS, PFTeDA, PFTrDA, PFDoA, PFUnDA, PFBS, PFDA, PFNA, PFOA, PFHpA, PFHxA, PFPeA, PFOSA, N-EtPFOSAA, N-MePFOSAA, L-PFHpS, and PFBA) in mackerel bought from a market in Korea (n = 10). Composited fillets from three mackerels each were prepared with various washing, soaking, and cooking (grill, braise, steam, or fry) methods (two composites each). The fish were cooked between 6 and 25 minutes with various ingredients including oil, water, potato, soy sauce, pepper paste, sugar, garlic, and ginger. Preparation methods included such traditional Korean practices as soaking the fillets in sake or rice-washed solutions. These soaking practices reduced PFAS levels by 51 to 80 percent. Washing the mackerel with water resulted in a reduction in PFAS of 74 percent. Similarly, all cooking methods reduced total PFAS content compared with the raw samples: grilling—91 percent, steaming—75 percent, frying—58 percent, and braising—47 percent. While cooking with potatoes further reduced PFAS levels in the mackerel, it also increased the levels in the potatoes.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Luo and colleagues (2019) assessed the effect of pretreatments and cooking on levels of 19 PFAS (PFOA, PFOS, PFBA, PFPeA, PFHxA, PFHpA, PFNA, PFDA, PFUnDA, PFDoDA, PFTrDA, PFTeDA, PFBS, PFHxS, L-PFHpS, PFDS, PFOSA, N-MePFOSAA, and N-EtPFOSAA) in fish cakes (n = 4 brands) and swimming crabs (n = 100) purchased in markets in Korea. The effects of a wide range of cooking methods were evaluated. Additional foods used in the cooking processes included soybean oil, two types of soy sauce, and Korean radish. Blanching, commonly used as a pretreatment before cooking fish cakes, did not yield significant changes in PFAS levels. Significant reductions in total PFAS were observed after boiling, frying, and stir-frying fish cakes (total PFAS in control, boiled, fried, and stir-fried fish cakes, respectively, were as follows: 2.96 ± 0.6 ng/g, 1.60 ± 0.16 ng/g, 1.93 ± 0.19 ng/g, and 1.94 ± 0.07 ng/g). For the crabs, presoaking reduced PFAS levels. PFAS in the crabs were significantly decreased after steaming and stewing.

Taylor and colleagues (2019) collected school prawn, blue swimmer crab, and dusky flathead from contaminated or reference estuaries in New South Wales and analyzed them for 20 PFAS compounds (PFAS above the limit of quantitation [LOQ] were PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnDA, PFDoDA, PFBS, PFHxS, PFOS, PFDS, FOSA, and NEtFOSE) before and after cooking. Dusky flathead fillets were baked or pan-fried in olive oil, while the crab and prawn were boiled in salted water. PFAS were below LODs in the cooking water and oil. Five or six replicates were used for each species and each cooking treatment (for prawns, each replicate was comprised of a composite of 10 individuals). The effect on PFAS concentrations varied with species, cooking method, and chemical. For instance, PFOS concentrations showed no change in crab following boiling, whereas PFHxS and PFOA concentrations were reduced. However, PFOS, PFHxS, and PFOA concentrations increased in prawns after cooking. For the dusky flathead, PFOS levels did not change significantly after frying, but baking resulted in a small but significant increase. The authors conclude that "cooking does not consistently reduce PFAS concentrations, and cannot mitigate dietary exposure" (Taylor et al., 2019, p. 280).

Vassiliadou and colleagues (2015) obtained several species of fish (anchovy, bogue, hake, picarel, sardine, sand smelt, and striped mullet) and shellfish (Mediterranean mussel, shrimp, and squid) from local markets in Greece and mussels from a mariculture farm. Twelve PFAS compounds (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnDA, PFDoA, PFBS, PFHxS, and PFOS) were measured in raw or washed samples that were then fried (in virgin olive oil at 170°C) or grilled (at 180°C). Total PFAS concentrations were found to be mostly higher after grilling and after frying, but changes in individual PFAS were inconsistent.

In general, there appear to be numerous factors related to preparation of fish, shellfish, and mollusks that can impact changes (increases or decreases) in concentrations of PFAS. Taylor and colleagues (2019) observe that whether cooking reduces PFAS concentrations in fish depends on the physicochemical properties of the chemical, the cooking method used, and the species. They note several processes that could impact changes in PFAS levels in fish from food preparation: losses to the cooking medium (e.g., cooking oil), moisture loss during cooking, PFAS precursors in fish tissues transforming during cooking to PFAAs, protein loss, or protein increase. Additional factors possibly affecting changes in concentration are the size, shape, and thickness of fish fillets (Hu et al., 2020).

Overall, robust recommendations for fish preparation interventions would ideally be based on consistent intra- and interstudy results; use of fish species and preparation methods common to the United States; and well-powered, replicated studies. The results from the studies reviewed here indicate that the effects of preparation of fish and shellfish on PFAS levels are inconsistent (examples are shown in Figure E-3). It is therefore difficult to use this information to inform recommendations regarding the efficacy of fish and shellfish preparation for reducing PFAS intake.

Furthermore, some of the fish species and preparation methods included in this body of research are not common to the United States, limiting the generalizability of results for U.S. communities. Additionally, because very few of these studies used the same cooking methods and species, it is difficult to corroborate even the instances in which a particular intervention appears to have been effective (within this small group of studies, various cooking preparation approaches included soaking followed by stewing, steaming, boiling, frying, or stir-frying; grilling, steaming, baking, boiling, or frying without presoaking; and baking in rice wine or vegetable oil). Furthermore, several of the studies included very small sample sizes. Finally, while some studies considered the effect of moisture or mass variations on PFAS concentration changes, others reported only concentration data. A more relevant metric in terms of human exposure would be the mass of PFAS remaining in the samples after preparation.

FOOD PREPARATION: OTHER

Two studies were identified that examined the effect of preparation on PFAS levels in foods other than fish (Binnington et al., 2017; Jogsten et al., 2009). Jogsten and colleagues (2009) measured several PFAS in various uncooked and cooked foods (see Table E-1).[6] Specifically, composite samples (n = 2) of beef, pork, or chicken were cooked in an oil mixture using nonstick cookware. Only PFHxS, PFOS, PFHxA, and PFOA were detected in at least one of two composite samples. PFOS levels increased in grilled pork, grilled chicken, and fried chicken compared with the raw samples. In contrast, levels did not increase in cooked veal or fried pork. The results from this study are not directly relevant for intervention recommendations. First, foods were purchased outside of the United States, and it is not known whether PFAS in these foods are similar to those in foods found in the United States. Second, only two samples per food type were included; there was no information on brands and limited information on cooking procedures; and results were inconsistent regarding the efficacy of cooking in reducing PFAS concentrations. Finally, it is not clear whether the effects of cooking can be disentangled from those of the Teflon-coated cookware used in this study.

[6] Jogsten and colleagues (2009) also measured PFAS in foods wrapped in different types of packaging. The foods were purchased in Spain, and the brands were not identified, so the relevance to the U.S. population is unclear. Egeghy and Lorber (2011) note that while fluorochemical-treated food packaging can be a source of PFAS in food, it appears that PFAS levels in packaging such as fast-food wrappers have decreased over time.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Binnington and colleagues (2017) studied the effects of preparation of beluga whale blubber on nutrients and environmental chemicals, including PFAS. They collected samples from two male whales (aged 24 and 37 years) from the Northwest Territories and prepared them using traditional approaches. Measured PFAS (detected in ≥50 percent of the samples) were PFNA, PFDA, PFUnDA, PFDoDA, and PFOS. PFAS were measured in raw and prepared (boiled, roasted, and aged) samples. Roasting increased concentrations of some of the PFAS compared with certain other treatments (e.g., air-drying, hang-drying, and boil pot), but were reduced in oil (Table E-1 includes concentration results for PFOS). According to the authors, issues with sample preparation may prevent these results from being considered representative of the overall mixture.

TABLE E-1 Summary of Results of Studies Examining the Effect of Food Preparation on PFAS Levels

Source	PFAS	Study Location	Food Type	Number	Concentration
Jogsten et al., 2009	PFBuS PFHxS PFOS PFHxA PFHpA PFOA PFNA PFDA PFUnDA PFDoDA	Spain	Beef, pork, chicken	Two composite samples from at least six subsamples for each food type from each of two sampling locations	PFOS, ng/g fresh weight (standard deviation) *Veal* raw: <0.015 grilled: <0.008 fried: <0.018 *Pork* raw: <0.008 grilled: 0.011 (0.009) fried: <0.008 *Chicken* raw: <0.008 grilled: 0.012 (0.01) fried: 0.010 (0.007)
Binnington et al., 2017	PFNA PFDA PFUnDA PFDoDA PFOS	Canadian Arctic	Male beluga whale blubber	Blubber sample divided into portions for different preparation processes	nanograms per gram wet weight (ng/g ww)[a] PFOS: nondetect (ND) to <1 PFNA: ND to <4 PFDA: ND to <4 PFUnDA: ND to <4 PFDoDA: ND to <4

[a] Estimated from publication figures.

In summary, only two studies of changes in PFAS levels associated with cooking foods were identified. These studies included small sample sizes and yielded inconsistent results.

LOCAL FOOD CONSUMPTION ADVISORIES

State advisories for guidance on consumption of locally grown foods could be a source of information to inform exposure reduction decisions. Eleven states have advisory guidelines for consumption of fish, wildlife, and other foods (California [seafood], Connecticut, Hawaii [in process], Maine [fish, beef, and milk], Michigan [fish and deer], Minnesota, New Hampshire, New Jersey, New York, Washington [in process], Wisconsin [fish and deer]) to protect human health from exposure to PFAS.[7] These advisories offer guidance on limiting the quantity of these foods consumed. Depending on the state-specific PFAS and concentrations, different consumption levels are indicated, ranging from do not eat (e.g., fish or deer in Michigan with PFOS concentrations of more than 300 parts per billion [ppb])

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

to unlimited consumption (e.g., fish in New Jersey with 0.56 ng/g PFOS). While fish consumption has a role in a healthy diet (Mozaffarian and Rimm, 2006), weighing the risks of PFAS exposure from fish consumption against the benefits of fish consumption is a complex process, and no intervention studies were identified that evaluated the impact of reduced consumption of fish on PFAS levels in blood and urine.

DRINKING WATER

Ingestion of drinking water is thought to be a major pathway for PFAS exposure (Domingo and Nadal, 2019). Research on two types of drinking water interventions is described in this section. The first addresses whether—and the extent to which—the use of water filters at POE into the home, under the sink (POU), or in water pitchers reduces PFAS exposure. The second addresses whether the use of purchased bottled water results in lower PFAS exposure compared with the use of tap water. Because PFAS levels in water can vary widely, we focus on studies that measured PFAS in tap and bottled water obtained from the same geographic area.

Six publications and one agency report evaluating possible drinking water interventions were identified. Four (Ao et al., 2019; Iwabuchi and Sato, 2021; MDH, 2008; Patterson et al., 2019) evaluated use of POE, POU, and water pitcher filtration devices; and three (Ao et al., 2019; Gellrich et al., 2013; Heo et al., 2014) evaluated differences in PFAS concentrations between tap water and bottled water. These studies are summarized here. Also discussed is one association paper assessing the relationship between drinking water source and serum levels in a highly contaminated area (Emmett et al., 2006).

POE, POU, and Water Pitcher Filtration

Ao and colleagues (2019) (also discussed in the next section) measured six PFAS compounds (PFOA, PFOS, PFNA, PFBS, PFHpA, and PFHxS) in tap (n = 9), filtered (n = 9), and bottled (n = 9) water in Shanghai, China. Paired tap and filtered water samples were collected from each of nine homes served by three different water sources. The filtered water samples were collected from the effluent of the home's water purification device. No further information on sampling or quality control in the field was given, nor was information on the type or brand of filter provided. ΣPFAS median concentrations in tap water and filtered water were 4.44 nanograms per Liter (ng/L) and 3.13 ng/L, respectively, but the differences were not statistically significant.

Herkert and colleagues (2020) tested municipal, well, and filtered (n = 89) and unfiltered (n = 87) tap water in residences (n = 73) in North Carolina for 11 PFAS compounds (GenX, PFBS, PFBA, PFHxS, PFOS, PFPA, PFHxA, PFHpA, PFOA, PFNA, and PFDA). The 89 POE and POU filters tested varied in both type (e.g., pitcher, under sink, faucet, whole house) and filtration method (reverse osmosis [RO], granular activated carbon [GAC], single-stage, two-stage). Notably, RO filters and dual-stage filters were found to consistently remove most measured compounds (except PFNA and GenX) at an average of ≥90 percent efficiency. On the other hand, GAC filters had more variable performance and were far less effective in removing short-chain PFAS compounds, with an average removal efficiency of just 41 percent for those chemicals. Whole-house activated carbon POE systems resulted in increased levels of PFAS in half of the tests (n = 4). The authors did not observe any correlations between removal efficiency and brand, source water, loading, or filter age.

Iwabuchi and Sato (2021) tested pitcher-type water filters for their ability to reduce concentrations of six PFAS compounds (PFOA, PFOS, PFHxA, PFDA, PFDoA, and PFHxS). Four different models from four manufacturers were evaluated—two with a carbon, ceramic, and hollow fiber membrane design; and two with an activated carbon (AC) and ion exchange design (brand names not given). One liter of the test water was applied to the water filters 200 times, with filtrate analyzed after 10 L, 100 L, and 200 L had been passed through the filters. For each model, filtration effectiveness decreased with prolonged use, but three of the four models were effective in removing the majority of all PFAS compounds. Removal efficiency did not appear to be related to filter material type. Removal

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

efficiency varied by carbon-chain length (i.e., more efficient removal was observed for longer-carbon-chain PFAS) and the PFAS functional group (PFOS >PFOA, and PFHxS >PFHxA). All tests were performed with initial PFAS concentrations of 50 ng/L. It is possible that filter effectiveness may vary with initial concentration levels. Iwabuchi and Sato (2021) conclude that household water purifiers are effective at reducing PFAS levels in drinking water.

Patterson and colleagues (2019) tested five commercially available POU/POE water treatment systems for six PFAS (PFOS, PFOA, PFHpA, PFHxS, PFBS, and PFNA). These included three RO systems (iSpring RCS5T, HydroLogic Evolution RO1000, and Flexeon LP-700) and two GAC systems (Calgon Filtrasorb 600 AR+ and Evoqua 1230CX). The filters were tested at various flow rates. The authors found that both RO and GAC systems had the potential to remove PFAS to below the LOD under their experimental water quality and operational conditions. They note, though, that performance was variable and that the long-term performance of the systems was not tested.

In addition to the publications described above, the Minnesota Department of Health (MDH, 2008) conducted a survey of POU water filtration devices for PFAS. Fourteen filters were lab-tested, and 11 of these that passed initial testing were field-tested using water from municipal wells. The brands were AC (n = 8)—Aquion Rainsoft Hydrefiner P-12 9878, Kinetico MACguard 7500, and Sears Kenmore Elite 625.385010; and RO (n = 6)—GE Smartwater GXRM10GBL and Watts Premier WP-4V. The four AC devices removed PFAS compounds to below the analytical reporting level (0.2 micrograms [µg]/L). The RO devices also removed PFAS to below the reporting limit. In terms of use by consumers, MDH notes, AC filters, RO membranes, and other filter elements have a limited service life and must be periodically replaced. Manufacturer recommendations vary, but many suggest replacing filters after 500 gallons of treatment or every 6 months (MDH, 2008).

MDH also tested a small, inexpensive, faucet-mounted carbon filter (PUR models FM-2000B, FM-3333B) using chlorinated and unchlorinated water with levels of PFAS that exceeded the U.S. Environmental Protection Agency (EPA) Lifetime Health Advisory Levels. The filter removed all PFAS from the unchlorinated water to below the LODs (which ranged from 5 to 10 ng/L). Some breakthrough of PFBA occurred for the chlorinated water test, but even at the filter capacity recommended by the manufacturer (100 gal), the filter was still removing 73 percent of the PFBA.[8]

In the course of their work sampling private well water in Washington County, Minnesota, MDH staff collected incidental samples of water treated by homeowner-installed carbon and RO systems. While many of these systems performed quite well, others achieved only partial removal of PFAS or none at all. MDH did not have the capacity to investigate further regarding the reasons for poor performance, but suspected that inadequate system maintenance may have been the main cause. When conveying the results of such tests, whether the system was performing well or not, MDH cautions homeowners that no guarantee can be made regarding long-term effectiveness of the system and recommends that they work with a qualified water treatment company to ensure proper maintenance of their system (Virginia Yingling, personal communication, July 14, 2021).

For those homes that exceed the state's drinking water guidance values, the Minnesota Pollution Control Agency installs and maintains whole-house GAC filter systems consisting of two 90 lb carbon canisters in series. As there are currently more than 1,000 of these systems in place, the state does not manage them individually, but changes the carbon out annually (which is more frequent than needed for the levels of PFAS present in the groundwater). Testing shows that the state's GAC systems remove all PFAS below reporting limits (4.4 ng/L). However, some trace levels, especially of PFBA, have been detected above the method detection limits (which range from 0.5 to 1.0 ng/L). In a few instances, the filter systems were found not to be working, but these cases were related to the homeowners having accidentally switched the bypass valve or altered the plumbing in a way that bypassed the filter. As a result, the state's contractor now inspects every system and plumbing at the annual filter changeout (Virginia Yingling, personal communication, July 14, 2021).

A study of residents living in an area served by the Little Hocking water system in Ohio—with water PFOA levels in the low ppb range at the time of the study—examined whether a community relying on highly contaminated public water could significantly reduce exposure through the use of a carbon water filter (Emmett et al., 2006). Serum PFOA was measured in a random sample of study participants (n = 324), who also provided information on their drinking water habits. Those who used only water from the Little Hocking water system in their homes were categorized as using a home carbon water filtration system (n = 64) versus no home water filtration system, a system not known to remove PFOA, or a system of unknown type (n = 209). Participants with home carbon water filters were shown to have statistically significantly (p = 0.008) lower median serum PFOA levels compared with those who did not (318 nanograms per milliliter [ng/ml] versus 421 ng/ml, respectively). The difference in serum PFOA levels in these two groups of participants was not as large as that seen for individuals using bottled, spring, or cistern water (see the next section for more information). The authors ascribe this finding to the limited effectiveness of water filters, as well as reliability issues associated with filter maintenance. They do not recommend use of home filtration systems that were available at the time.

All but one of the studies reviewed here found that various filtration methods showed evidence of their potential effectiveness. These studies suggest that pitcher-type, POE, and POU filtration systems can reduce PFAS levels in drinking water under the conditions tested. It is worth noting that optimal filtration depends on the user's actively maintaining these devices, and no study has yet looked at the effectiveness of these interventions in real-world circumstances.[9]

Bottled Water (Versus Tap Water)

Here we summarize three studies that included measurements of PFAS in bottled, tap, or filtered water from the same area in order to compare levels across drinking water sources. This research was conducted in China, Germany, and Korea.

Ao and colleagues (2019) measured six PFAS compounds (PFOA, PFOS, PFNA, PFBS, PFHpA, and PFHxS) in tap (n = 9), filtered (n = 9), and bottled (n = 9) water in Shanghai, China. Tap and filtered water samples were collected from each of nine families served by three different water sources. Paired tap and filtered water samples were taken from each home. The filtered water samples were collected from the effluent of the home's water purification device. Bottled water was purchased from local markets and represented nine best-selling brands. No further information on sampling or quality control in the field was given. ΣPFAS median concentrations in tap water, filtered water, and bottled water were 4.44 ng/L, 3.13 ng/L, and 2.36 ng/L, respectively; the differences were not statistically significant.

Mineral water (n = 119), tap water (n = 26), and spring water (n = 18) samples were measured for 10 or 19 (tap water only) PFAS compounds (PFBA, PFBS, PFPeA, PFHxA, PFHxS, HPFHpA, PFHpA, PFOA, H4PFOS, PFOS, FOSA, PFNA, H2PFDA, PFDA, PFDS, H4PFUnDA, PFUnDA, PFDoDA, and PFTeDA) (Gellrich et al., 2013). The mineral water samples were from Germany; spring water samples from Switzerland, the Czech Republic, and Germany; and tap water samples from homes in unidentified locations. No further information on water sampling was given. The highest ΣPFAS concentration was in tap water (42.7 ng/L). The proportions of individual PFAS differed across water type. For example, PFOS was below the LOD in all of the spring water samples but was detected in 9 percent of all of the mineral water samples. The authors note that the PFAS concentrations in the three water types were similar and described the concentrations as "low." For example, the median PFOA levels in mineral, spring, and tap water samples were 1.6 ng/L, 1.4 ng/L, and 2.6 ng/L, respectively.

Heo and colleagues (2014) measured 16 PFAS compounds (PFBA, PFPeA, PFHxA, PFHpA, PFOA, PFNA, PFDA, PFUnDA, PFDoDA, PFTrDA, PFTeDA, PFBS, PFHxS, PFHpS, PFOS, and

[9] Information on certified water filters can be found at the following website: https://www.nsf.org/knowledge-library/perfluorooctanoic-acid-and-perfluorooctanesulfonic-acid-in-drinking-water (accessed May 12, 2021). Note that the certification applies only to PFOA and PFOS, and the water filter must be able to reduce these chemicals to under 70 parts per trillion (ppt).

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

PFDS) in tap (n = 34) and bottled (n = 8) water from Busan, Korea. The bottled water samples were purchased in markets, and the tap water samples were collected from 16 districts in Busan (no further information on types of bottled water or sampling methods for tap water was provided). PFAS concentrations and detection frequencies were higher in the tap water than in the bottled water samples. For example, mean ΣPFAS levels in bottled and tap water were 0.48 ng/L and 41.3 ng/L, respectively. The authors do not provide information on whether the observed differences were statistically significant.

A study of residents living in an area served by the Little Hocking water system in Ohio suggests that a community relying on highly contaminated public water could significantly reduce exposure through the use of bottled water (Emmett et al., 2006). Serum PFOA was measured in a random sample of study participants (n = 324), who also provided information on their drinking water habits. Residents who reported drinking primarily bottled/spring/cistern water had a median serum PFOA level of 71 ng/mL, compared with a statistically significantly higher level of 374 ng/mL for those who drank only Little Hocking system water. Overall, the authors observed a strong relationship between serum PFOA levels and PFOA concentrations in the drinking water source.

For communities with highly contaminated water supplies, the use of alternative drinking water sources has been shown to be associated with significantly reduced exposures. However, none of the intervention studies reviewed here provide robust evidence for the effectiveness of replacing tap water with bottled water for U.S. locations with background levels of PFAS. The studies reviewed here were conducted in Europe and Asia, and the water PFAS concentrations there may not be generalizable to the United States. Lack of brand information and small sample sizes present additional challenges for evaluating this intervention.

Use of bottled water as a replacement for tap water can be expensive and inconvenient. To be confident that the use of bottled water will result in a reduction in PFAS exposure, an understanding of local water conditions in comparison with PFAS levels in specific types of bottled water is needed. As described above, while PFAS levels in bottled water tend to be approximately between <LOD to <100 ng/L, it cannot be assumed that levels in bottled water are always lower than those in tap water. Outside of highly contaminated areas, the degree of spatial granularity for concentration data required to ensure that replacing tap water with bottled water will reduce PFAS exposure is not well understood. However, based on public data POTWs (EPA, 2017), PFAS levels in treated water can vary widely within regions or states (e.g., PFOS water concentrations in Delaware ranged from <MRL [Minimum Reporting Level] of 0.04 to 1.8 µg/L, while PFOA water concentrations in Pennsylvania ranged from <MRL of 0.02 to 0.349 µg/L).

The EPA's Third Unregulated Contaminant Monitoring Rule (UCMR) (EPA, 2017) includes monitoring data for PFOS, PFOA, PFNA, PFHxS, PFHpA, and PFBS (data from 2013 to 2015 from a representative sample of public water systems serving ≤10,000 people). Figure E-4 shows varying concentrations of these six PFAS across the United States for PFAS levels above the method reporting limits. Levels in drinking water can vary across the United States by at least an order of magnitude. The concentrations are in the low ng/L range, similar to reported levels in bottled water. Also note that for much of the United States, PFAS levels in drinking water are below the method reporting limit (see Figure E-5, green symbols) and so would possibly be similar to those in bottled water.

BREAST MILK AND INFANT FORMULA

In considering the idea of "intervention" as it pertains to breast milk, there are two underlying concepts. The first is whether there are interventions that could reduce exposure to the breastfeeding infant, and the second is whether lactating can be an effective method for reducing the mother's levels of PFAS compounds. We discuss each of these concepts in this section.

The Infant's Exposure: Does Formula Feeding in Place of Breastfeeding Reduce Exposure?

Many mothers choose to breastfeed rather than use infant formula. Breastfeeding confers various health advantages to the infant and mother (AAP, 2012; WHO, 2020). At the same time, breast milk includes environmental chemicals (LaKind et al., 2001, 2018; Lehmann et al., 2018) that derive from the mother's body and are transferred to the infant via breastfeeding. Thus, concern has been expressed about the possible health effects on the infant from those environmental chemical exposures. This concern raises the question of whether formula feeding would serve as a method for "intervening," or reducing infant exposure to PFAS.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

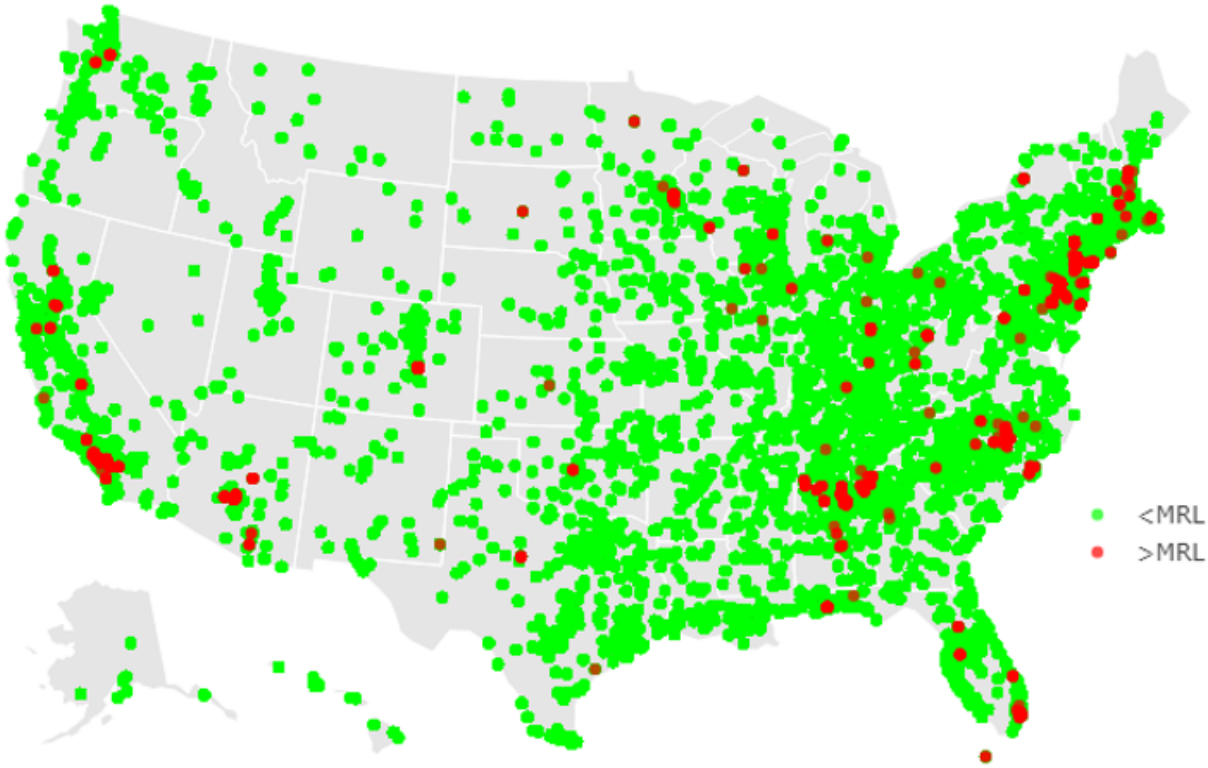

FIGURE E-5 PFAS levels above (red) and below (green) the method reporting limit in drinking water in the United States.
NOTES: The symbols represent a total of 215,963 measurements from the U.S. Environmental Protection Agency's (EPA's) Third Unregulated Contaminant Monitoring Rule (UCMR 3) for PFOA, PFOS, PFHxS, PFBS, PFHpA, and PFNA. MRL = Minimum Reporting Level.
SOURCE: Data were extracted from the EPA's UCMR 3 (2013–2015) database (EPA, 2017).

At least two factors need to be taken into consideration. The first is that infants' exposures begin in utero. Some studies suggest that despite environmental chemical exposures associated with breastfeeding, infants who are breastfed may do better in a number of health-related aspects compared with formula-fed infants (LaKind et al., 2008). The World Health Organization has stated, "in studies of infants, breastfeeding was associated with beneficial effects, in spite of the contaminants present. The subtle effects noted in the studies were found to be associated with transplacental, rather than lactational, exposure" (WHO, 2000, p. 237). These conclusions are drawn from research on persistent chemicals, such as dioxins; to our knowledge, there is no PFAS-specific literature on health effects of breastfed versus formula-fed infants. At present, there does not appear to be sufficient PFAS-related research that would allow for a definitive conclusion regarding infant health and the choice between breastfeeding and use of infant formula. Thus, it is not clear that formula feeding is a scientifically supported "intervention" that would prevent adverse health outcomes.

The second factor is that in choosing formula feeding to reduce infant exposure to PFAS, the assumption is being made that infant formulas do not themselves contain PFAS compounds. While studies have reported on detectable levels of PFAS in infant formula in other countries (e.g., Llorca et al., 2010; Macheka et al., 2021), it is instructive to review available data on levels of PFAS in breast milk versus infant formula in the United States to assess whether levels in formula are lower than those found in breast milk. As an additional complication, it is not uncommon to purchase powdered formula and reconstitute it with drinking water. Therefore, we provide here a synopsis of U.S. levels of PFAS in breast milk, formula, and drinking water.

PFAS in Breast Milk in the United States

Reviews of PFAS in breast milk (Lehmann et al., 2018; Liu et al., 2020) identify three studies reporting measurements of PFAS levels in breast milk in the United States. One of these studies (Kuklenyik et al., 2004) is an analytical methods study. No information on either the milk donors or the sampling procedures is reported; the information from this study is not relevant to this discussion. In a second study, von Ehrenstein and colleagues (2009) collected milk samples from 34 breastfeeding women in North Carolina at 2–7 weeks and 3–4 months postpartum. Nine PFAS were measured (PFOS, PFOA, PFNA, PFHxS, PFOSA, MeFOSAA, EtFOSAA, PFBS, and PFDA). Measurements below the LOD were assigned a value of LOD/sqrt2. PFAS levels were below the LOQ in most of the 34 milk samples collected at both sample times (note that the LOQs for PFAS in milk ranged from 0.15 to 0.60 ng/ml, or ppb). Specifically, PFAS were detected in samples from only 4 of the 34 women, and of these only three PFAS were above the LOQ: Et-PFOSA-AcOH (1.0 ng/ml) and Me-PFOSA-AcOH (0.7 ng/ml) in one woman, and PFOSA in three women (0.3 ng/ml, 0.5 ng/ml, and 0.6 ng/ml). The remainder of the milk samples from both collections were found to have concentrations <LOQ.

In contrast, Tao and colleagues (2008a) measured PFAS (PFOS, PFOA, PFHxS, PFNA, PFHpA, PFDA, PFUnDA, and PFDoDA) in milk samples collected from 45 primiparous and multiparous women in Massachusetts. Levels that were below the detection limit were assigned a value of zero, while those detected but below the LOQ were assigned a value of one-half the LOQ. Mean levels of PFOS and PFOA were 131±103 parts per trillion (ppt) (mean±SD) and 43.8±33.1 ppt, respectively. Mean PFHxS and PFNA levels were 14.5±13.7 ppt and 7.26±4.70 ppt, respectively. The remainder of the PFAS were detected in only ≤4 samples (<24 ppt).

PFAS in Infant Formula in the United States

In a 2018 review of environmental chemicals in breast milk and infant formulas (Lehmann et al., 2018), only one publication is identified with measurements of PFAS in infant formula in the United States (Tao et al., 2008b). Tao and colleagues (2008b) measured PFAS in 21 formula samples purchased in Washington, DC, and Boston, Massachusetts. The brands represented >99 percent of the U.S. market. Most of the samples were organic or nonorganic milk- or soy-based powders and ready-to-use or concentrated liquids. PFOS was detected in one sample (11.3 ppt; LOQ = 11.0 ppt). PFHxS was detected in two samples (1.36 ppt and 3.59 ppt; LOQ = 1.35 ppt). No other PFAS (PFOA, PFNA, PFBS, PFHpA, PFDA, PFUnDA, and PFDoDA) were detected in any samples.

PFAS in Drinking Water in the United States

An assessment of infant exposure to environmental chemicals would not be complete without considering exposures via drinking water used to reconstitute infant formula (LaKind et al., 2005). ATSDR (2019) has noted that a source of PFAS exposure to infants and toddlers is "formula mixed with PFAS contaminated water." It is important to be able to provide information on what is meant by "contaminated," as PFAS levels in tap water vary widely. For example, Andrews and Naidenko (2020), using national and state databases, estimated that 18−80 million people in the United States use tap water containing at least 10 ng/L (ppt) PFOA and PFOS combined, and more than 200 million people may have water with a combined PFOA and PFOS level of at least 1 ng/L.

Formula may also be reconstituted with bottled water. There is a paucity of data on PFAS levels in bottled water in the United States. Akhbarizadeh and colleagues (2020) reviewed the international literature on PFAS levels in bottled water (with none from the United States) and report levels of various PFAS in the low ng/L range, with some levels as high as the low 100s ng/L depending on the type and number of PFAS included in the reporting. They note that researchers have attributed the PFAS in bottled water to several possible sources, including PFAS from the plastic bottles themselves; introduction of PFAS to the water before bottling or during bottle closure; or contamination of contact materials during

Copyright National Academy of Sciences. All rights reserved.

bottling, handling, and storage of the bottles. In a study of tap, spring, and mineral water from Germany, Gellrich and colleagues (2013) found PFAS levels to be generally in the low ng/L range.

Looking beyond the peer-reviewed literature, *Consumer Reports* (Felton, 2020) conducted a study on PFAS levels in bottled water purchased in stores in the United States and from online retailers. The noncarbonated water levels in 31 brands were less than 1 ppt, and two other brands had levels of 1.21 ppt and 4.64 ppt. These results derive from the averages of two to four samples of each product, but it is not clear whether these were replicates from the same bottle or different bottles. The report does not include information on detection limits or specific PFAS compounds detected, but merely describes "total PFAS as the sum of average concentrations of all PFAS detected in the samples tested of a product."

The U.S. Food and Drug Administration (FDA) measured PFOA and PFOS in carbonated and noncarbonated bottled water (n = 30; brands not identified) and found that levels were below the lower LOQ in all samples (0.004 µg/L).[10]

Studies have also detected PFAS in bottled water from other countries (see, e.g., Le Coadou et al., 2017). As brand names are not provided by these authors, it is not clear how this information could be used for intervention recommendations for the United States.

Based on these very limited data, it is possible that ready-to-use formulas may have lower PFAS levels than formulas reconstituted with tap or bottled water (see Figure E-6). However, the following caveats must be noted: data comparisons across studies are complicated by differences in total PFAS included; measurements may include more legacy PFAS compounds and not include PFAS compounds used to replace the older chemistries; studies use varying detection limits and approaches for assigning values to measurements below the LOD; and sampling in these studies is not representative of regions within the United States.

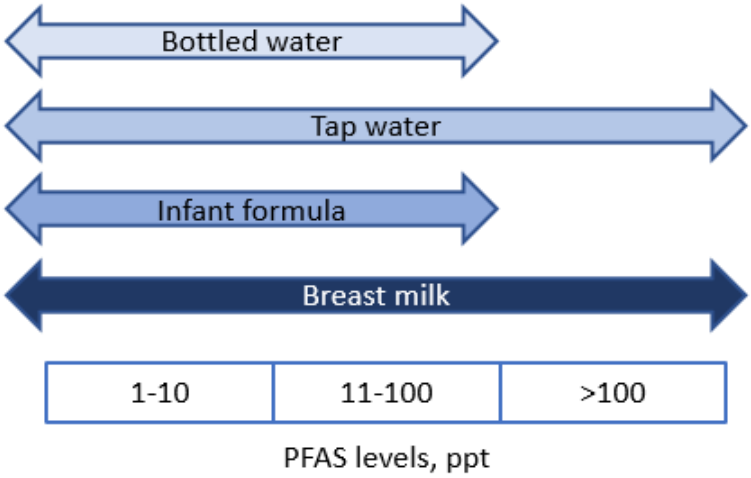

FIGURE E-6 Limited data on PFAS levels in breast milk and infant formula in the United States show general overlapping concentrations, which also overlap with PFAS concentrations in drinking water that could be used to reconstitute formula.
NOTES: Double-headed arrows indicate that these bars could extend in either direction as new data are obtained. ppt = parts per trillion.

The Mother's Exposure: Does Lactation Reduce Internal Exposure?

There are two likely sources of persistent chemicals in breast milk: legacy stores in the mother from her lifetime exposure, and current sources of exposure, such as diet (LaKind, 2007). So the question arises: If a mother lactates, can she lower the stores of chemicals in her body, thus reducing her internal exposures? (If she disposes of her milk rather than breastfeeding, a process referred to as pumping-and-dumping, can she similarly reduce her exposure?) The reduction in chemical levels in the body via lactation, referred to as depuration, has been studied for such persistent chemicals as dioxins, polychlorinated biphenyls (PCBs), polybrominated diphenyl ethers (PBDEs), and chlorinated organic compounds (LaKind, 2007). Those studies have yielded mixed results (reviewed by LaKind et al., 2001), with some showing substantial declines in breast milk levels over time (Klein et al., 1986; Yakushiji et al., 1978) and others showing either minimal declines, no changes, or increasing levels over the course of lactation (Hooper et al., 2007; LaKind et al., 2009).

If lactation is an effective process for reducing the legacy stores of PFAS in the mother, one would expect to see levels of PFAS in serum and breast milk decline as lactation progressed and the mother's stores were depleted. We review here the literature on this topic.

In a review of the literature on breastfeeding and serum levels in mothers, VanNoy and colleagues (2018) conclude that the published studies support an association between breastfeeding and serum PFAS concentrations among women. However, they also observe that key aspects of breastfeeding, including duration, exclusivity, and timing of sample collection, should influence the breastfeeding–serum relationship, yet only one study in their review included all three exposure variables. They further describe the importance of parity for predicting maternal serum PFAS levels and note that most of the studies reviewed were unable to disentangle the effects of breastfeeding versus those of parity on PFAS exposure. The ability to fully assess the impact of breastfeeding on maternal PFAS levels is therefore limited.

Another approach to assessing the impact of breastfeeding on maternal PFAS exposure is to examine changes in PFAS levels in breast milk over the course of lactation. If stores of PFAS predominate over current exposures via diet and other sources, and if lactation resulted in mobilization and excretion of those stores, then lactation (with either breastfeeding or "pump-and-dump") could result in lower internal exposures for the mother. Three studies were identified that followed individual women over the course of lactation and collected multiple breast milk samples, which were analyzed for PFAS.

Lee and colleagues (2018) collected breast milk samples (n = 293) from 127 mothers at four different times postpartum (<7, 15, 30, and 90 days) as part of the Children's Health and Environmental Chemicals in Korea Cohort study. Samples were measured for 16 PFAS. Of the 127 women, only 15 provided samples across the lactation period, and samples from these women were pooled by sampling time. The concentrations of PFOS, PFOA, PFNA, and ΣPFAS 30 days postpartum were statistically significantly higher than in milk from sampling at <7 days postpartum.

In a study in Norway with nine women (Thomsen et al., 2010), milk samples were collected monthly from approximately 2 weeks postpartum up to 1 year postpartum (n = 3–10 per woman). The authors found a consistent decrease in concentrations of PFOS and PFOA, except for PFOS in one woman (these were the only PFAS >LOQ). The modeled depuration rates were reported as 7.7 percent and 3.1 percent reduction per month for PFOA and PFOS, respectively. Regarding generalizing these results, the authors note that because they did not have information on changes in the mothers' body weight or diet during the sampling timeframe, they could not evaluate the influence of these factors on depuration rates.

Fromme and colleagues (2010) also measured PFAS in breast milk samples collected monthly over 5 months from seven women. No significant differences in PFOS levels over the 5 months were observed.

In summary, our understanding of PFAS depuration based on breast milk measurements rests on three studies with between 7 and 15 women that yielded conflicting results. This is not necessarily surprising as depuration rates likely depend on numerous factors, such as current exposures, volume of

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

breast milk excreted, and initial levels of PFAS in the body. Thus, the value of lactation as an intervention is unknown and requires additional study.

Would "Real-Time" Testing of Milk Help Guide Decision Making Regarding Infant Feeding?

It is unclear whether "real-time" testing of breast milk is an advantageous approach to guiding new mothers in decision making regarding infant feeding. First, testing requires sampling, shipping to laboratories, and conducting the analyses, which comes with a monetary cost. But even with unlimited resources, the time component is a critical consideration, as results may not be available until well into the infant's first few weeks or months. Second, a single measurement may not capture the infant's actual exposure as PFAS levels in milk may change over the duration of lactation, and the direction and rate of change are not well understood.

INDOOR DUST

Dust is a potential exposure pathway for PFAS compounds (Trudel et al., 2008). One dust-related PFAS intervention study was identified (Young et al., 2021). Dust samples were collected from floors by vacuum in "PFAS-free" refurbished rooms (7 with a full intervention and 28 with a partial intervention) and 12 control rooms at a university in the northeastern United States. Fifteen PFAS compounds were measured (PFOS, PFOA, PFHxA, PFHxS, FOSA, PFHpA, PFPeA, PFNA, PFBS, PFDS, PFBA, PFDA, PFUnDA, PFDoDA, and N-MeFOSAA), with detection limits ranging from 0.06 to 1.5 ng/g. PFAS levels in field blanks were either below the LOD or substantially lower than levels in the samples.

The geometric mean ΣPFAS levels were 481 ng/g (225–1,140 ng/g) in rooms with no intervention, 252 ng/g (18.1–8,310 ng/g) in rooms with partial interventions, and 108 ng/g (43.6–243 ng/g) in rooms with full interventions. Use of PFAS-free furnishing resulted in a statistically significant (78%, 95% CI: 38–92) ΣPFAS reduction in dust compared with control rooms. The results from this study suggest a possible intervention for reducing exposure to PFAS in dust.

While not an intervention study, research conducted by Scher and colleagues (2019) examined associations between PFAS-contaminated soil outside of homes and dust concentrations inside of the homes. The authors collected dust samples from the interior of the house and entryways to determine whether entryway dust levels indicate that "track-in" is an important contributor to house dust PFAS levels. They observed higher PFAS levels in the interior of the homes compared with soil levels, and suggest that soil track-in was not an important source of PFAS in interior dust.

Interpretation of PFAS dust studies is complicated by the lack of standardized sampling techniques for dust collection; the impact of use of different sampling methods on PFAS concentrations is unknown (Scher et al., 2019). Furthermore, for interventions that reduce PFAS in dust, the extent to which overall human intakes of PFAS would be reduced is not known. Estimates of the PFAS intake via dust have varied considerably (Nadal and Domingo, 2014).

OTHER POTENTIAL INTERVENTIONS

Other possible actions that could be considered interventions include limiting the use of PFAS-containing household goods and personal care products and introducing substances to the diet specifically intended to remove PFAS from the body. No intervention studies for these behavioral changes were identified, but here we describe one study on nonstick cookware, one study related to use of dental floss, and one dietary modification approach in the context of future exploration.

Nonstick Cookware

Nonstick cookware has been studied as a source of PFAS exposure. In terms of interventions, at issue is whether replacing nonstick cookware with items that do not contain PFAS would result in a

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

measurable decrease in human PFAS exposures. While no intervention studies were identified, we briefly describe one study conducted in the United States that compared the release of PFAS into air and water from nonstick versus stainless steel frying pans. Sinclair and colleagues (2007) purchased four brands of domestic and imported nonstick frying pans and one brand of stainless steel frying pan (three to five of each brand) in New York. The pan brand names are not identified. All pans were precleaned with hot, soapy water; rinsed with Milli-Q water; and dried with a towel. The stainless steel pans were used as controls. The authors report that under normal cooking conditions (179°C to 233°C surface temperature), PFOA in the gas phase was measured at 11–503 picograms per square centimeter (pg/cm^2) from the nonstick frying pans. (Fluorotelemer alcohols were also detected, but these are not chemicals of focus in this paper and are not discussed further.) Gas-phase PFOA decreased after repeated use of one brand of pan but not the others (n = 1 for each brand). The authors also measured PFOA in Milli-Q water boiled for 10 minutes in selected pans and found inconsistent results (certain pans resulted in measurable levels of PFOA in the water, while others did not).

Since brand names are not included in the publication, this information cannot be used as the basis for specific intervention recommendations. Even if brand names were included, given the small sample size and the lack of study replication, it would be difficult to use this information as the basis for general recommendations. Finally, as neither air nor water concentrations are provided, the extent to which this exposure source contributes to overall intake is unclear.

Dental Floss

One study examined the association between use of dental floss and serum PFAS (PFOA, PFNA, PFDeA, PFHxS, PFOS, and Me-PFOSA-AcOH) levels (Boronow et al., 2019). Serum PFAS levels were measured in 178 middle-aged women. An administered questionnaire included one question on use of dental floss: "In the last month, how often did you use Oral-B Glide dental floss?" Response choices were as follows: "Never or almost never, Several times a month, 2 or more times a week, Every day." Only "ever" and "never" were used in the regression analysis. While five of the PFAS compounds did not show significant associations, a 24.9 percent (95% CI: 0.2–55.7) higher level of PFHxS was found in subjects who used Oral-B Glide floss. It is worth noting that the questionnaires were administered several years after blood sample collection.

The authors also analyzed 18 dental floss products (only one or two samples per brand were analyzed, except the Oral-B Glide brand [five samples]) for total fluorine (as an indicator for polytetrafluoroethylene or PTFE), 6 of which yielded detectable levels. Given the lag in time between blood collection and questionnaire administration, the small number of floss samples analyzed, and the mostly nonsignificant results, it is not clear whether dental floss is an important route of human exposure to PFAS.

Fiber Intake

Studies have observed relationships between higher fiber intake and lower serum PFAS levels (e.g., PFOA, PFOS, and PFNA [Dzierlenga et al., 2021]; PFOS and PFOA [Halldorsson et al., 2008]; PFOS, PFOA, PFHxS, EtFOSAA, MeFOSAA, and PFNA [Lin et al., 2020]). This finding is based on studies examining associations between dietary recall information and serum levels in cross-sectional study designs. Thus, it is unknown whether other factors (e.g., whether diets with high fiber generally have lower levels of PFAS) influence this relationship.

MODELED INTAKES AS THE BASIS FOR RECOMMENDATIONS FOR REDUCING EXPOSURE TO PFAS

Well-conducted and generalizable intervention studies can be considered the gold standard for recommending approaches to reductions in personal exposure to PFAS. In the absence of such studies, it

Copyright National Academy of Sciences. All rights reserved.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

may be informative to use results from studies designed to model the relative contributions of exposure pathways to overall PFAS exposure. This approach would focus attention and intervention strategies on the most important exposure pathways. In this section, we discuss results from studies using concentration data from several media and products (e.g., soil, water, and food concentration data) in combination with generic intake factors (e.g., g intake/kg body weight per day) to model human intakes of PFAS. We explore whether any common, generalizable themes emerge from such modeling studies regarding dominant intake pathways.

Because of geographic differences in both environmental media and product concentrations, the emphasis here is on studies conducted for the U.S. population. First, however, we provide a brief synopsis of reviews on studies conducted for populations outside of the United States. Although some of the modeling efforts included less well-studied PFAS (e.g., PFHxS), the most commonly assessed PFAS were PFOA and PFOS. Sunderland and colleagues (2019) recently compiled data from the literature on percent source contribution in adults. The results are summarized in Figures E-7 and E-8. The modeling approaches represented by the underlying papers included different concentration data and intake assumptions. Regardless of the approach used, diet appears to be the major pathway of exposure to PFOS, with the percent contribution ranging from 65 to 96 percent. For PFOA, the range of percentages for dietary contributions is wider (6–86 percent). While these results point to the importance of diet, the location of a study and the presence or absence of point sources will influence the relative contributions of various pathways to overall PFAS intake. Behavioral differences across countries can also impact the results and their generalizability to communities in the United States. We therefore focus on two studies that modeled source contributions for PFOA (Lorber and Egeghy, 2011) and PFOS (Egeghy and Lorber, 2011) in the United States.

For PFOA intake modeling, Lorber and Egeghy (2011) used the following data, assumptions, and approach. Their intakes were developed for adults and 2-year-old children. PFOA concentrations in various media from the published literature were used in combination with EPA exposure contact rates. The authors generated intake distributions by inputting different exposure media concentrations into the model. They assumed that PFOA concentrations in indoor air were 20 times higher than those in outdoor air, with outdoor air data being derived from a study in Albany, New York. Whether these air concentrations represent more general U.S. exposures is not discussed. The authors also used dietary data from the Canadian Total Dietary Survey (Tittlemier et al., 2007); thus, it is not known whether this aspect of the model is representative of exposures to PFOA in the United States. PFOA levels in drinking water were estimated from surface water concentrations in various parts of the United States (New York, North Carolina, New Jersey [drinking water], Great Lakes, Tennessee, and Florida). Dust concentration data were obtained from dust samples from homes and day care centers in Ohio and North Carolina.

Lorber and Egeghy (2011)[11] discuss numerous limitations around their estimates of intakes, including the following: no estimates of intake via direct contact with consumer products (e.g., treated carpets or cosmetics), no inclusion of PFOA precursors, and a lack of PFOA data for food in the United States. However, Lorber and Egeghy (2011) also used a simple one-compartment, first-order pharmacokinetic model in combination with National Health and Nutrition Examination Survey (NHANES) 2003–2004 data and back-calculated intakes. Their central tendency intake estimates for adults and children (70 ng/day and 26 ng/day, respectively) are not dissimilar to the intakes back-calculated from the NHANES data (56 ng/day and 37 ng/day for males and females, respectively). These models would benefit from the use of improved measurement data in food and other media specific to—and representative of—the United States (or at least areas or regions of interest within the United States) and the use of more recent NHANES data.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

Egeghy and Lorber (2011) used a similar approach to model intakes of PFOS and its precursors. In addition to modeling of precursors, this effort differs from the PFOA models described above in that the models were developed for both "typical" and "contaminated" scenarios. (The contaminated scenario was similar to the background scenario except that much higher water concentrations were used.) In terms of available data on environmental concentrations of PFOS and precursors, the authors note that "measurement of PFCs in exposure media in North America was relatively sparse for all media compared with European data with the possible exception of dust. Food data are sparse for both continents. No measurements of PFOS in uncontaminated soil could be found" (Egeghy and Lorber, 2011, p. 158). The authors found that diet was the main route of exposure in the general population, while for children, dust ingestion was almost as important a contributor to intake as diet. Perhaps most important in the context of using modeled uptakes as the basis for recommendations for modifying behaviors to reduce exposure, Egeghy and Lorber (2011) found that the pathway-specific contributions spanned several orders of magnitude and overlapped substantially.[12]

Use of model estimates of dominant pathways of PFAS exposure for making recommendations to individuals regarding exposure reduction faces a number of challenges. First, while diet appears to be a major pathway of exposure, there is little information on PFAS in commercial foods commonly consumed in the United States. The FDA has released PFAS data for certain foods, which could be used in future studies involving modeling of source contributions to PFAS intake.[13] However, the FDA observed that its data for produce, meat, dairy, and grain products are based on a small sample size, and the results "cannot be used to draw definitive conclusions about the levels of PFAS in the general food supply" (para. 3). It is not currently well understood whether the data on commercial foods from other countries used in the intake models are representative of levels in the United States. Wu and colleagues (2015) state, "Information on dietary predictors in U.S. is still limited" and "more data are needed to determine the relative contributions of food and dust to serum PFCs for both adult and child populations" (p. 265). A review of PFAS in foods by Domingo and Nadal (2017) identifies only two recent studies for the United States: one focused on PFAS uptake by lettuce and strawberries irrigated with reclaimed water (Blaine et al., 2014) and the other on concentrations of PFAS in freshwater fish samples from urban rivers and the Great Lakes (Stahl et al., 2014).

Furthermore, the relative importance of different sources varies by study (see Figures E-7 and E-8) and by demographic group and population (Sunderland et al., 2019). In describing the findings of their recent review on nonoccupational intakes via background exposures, De Silva and colleagues (2021) observe that the inconsistency in the relative importance of different exposure sources from one study to the next may be due to differing concentrations of PFAS in media, as well as the assignment of different values for exposure intake factors (e.g., exposure frequency and duration). They conclude, "Without rigorously conducted exposure studies it is challenging to rank order the most important human exposure pathways and without these data, our ability to design evidence-based exposure intervention strategies will be limited" (De Silva, 2021, p. 644).

Within even a small geographic area, one could envision varying exposure characteristics that could, in turn, affect sources of PFAS intakes. Vestergren and Cousins (2009) explored this possibility by estimating relative intakes for those with exposure to background PFAS levels, exposure to higher levels in drinking water or drinking water impacted by a PFAS point source, or occupational exposures; they found substantial differences in the relative contributions to overall intakes (see Figure E-9).

Another factor related to modeling principal sources of exposure is the changes in production and use of individual PFAS over time. Sunderland and colleagues (2019) describe the changes in serum PFAS levels following the phase-out of production of PFOS and its precursors, with PFOS declining, but other PFAS, such as PFHxS, increasing. They observe that while exposures to PFOS and PFOA "have been successfully reduced by product phase-outs for many populations, exposures to C-9-C-11 PFCAs have not followed the same trends" (Sunderland et al., 2019, p. 138). Thus, it is important to use recent environmental and consumer product and dietary data to develop robust estimates of current dominant pathways of exposure.

Guidance on PFAS Exposure, Testing, and Clinical Follow-Up

E-4

Discussion

In this review, we have sought to address the following question: Based on current research, are there interventions or *personal* modifiable behavioral changes that individuals can make to *effectively* reduce their PFAS exposure? We have described research on potential ways in which an individual could reduce exposure to PFAS. It is important to acknowledge that communities across the United States have received guidance from state and federal agencies regarding PFAS exposure reduction, including advisories around consumption of drinking water and fish. While it may seem obvious that avoiding exposure to sources of PFAS would result in reduced intake of PFAS and, in turn, lower internal PFAS levels, some caution in assuming that exposure and risk reduction would ensue is warranted. For example, if one is advised to avoid locally caught fish because of known PFAS contamination in that fish, such avoidance could result in reduced exposure. However, if dietary fish is replaced by another food that is also high in PFAS, avoiding the fish may not result in lower PFAS exposure. Another issue to consider is that avoiding one group of chemicals by changing diet or other behaviors can result in increased exposures to other chemicals. Finally, if a certain PFAS source is related to a small portion of overall exposure, then avoidance of that source may not result in appreciable reductions in internal levels of PFAS. Thus, while avoiding known sources of PFAS exposure may be a useful approach to lowering overall exposure, these other considerations should be taken into account; research on the efficacy of various interventions could help shed light on these complexities.

The number of intervention studies available to address the question of whether there are interventions or *personal* modifiable behavioral changes that individuals can make to *effectively* reduce their PFAS exposure ranged from 1 to 11, depending on the source of exposure; for some pathways, no studies were found (see Figure E-10). Overall, only the water filtration studies provided relatively consistent evidence of an effective reduction in PFAS levels. No studies were identified that confirmed reduction in human exposure via biomonitoring. To fully demonstrate the efficacy of an intervention, a study would need to be conducted over a timeframe sufficient to account for the long half-lives of PFAS.

Demonstration that PFAS exposures are reduced in a meaningful way through biomonitoring confirmation is an important step. It is possible that an intervention may reduce PFAS levels in a particular medium, but if this medium is not a major source of overall exposure, then that intervention may not contribute significantly to reduction in human exposures. Overall, the intervention literature is sparse and has many limitations. Thus, the committee may have to rely on assumptions and other bodies of evidence to make recommendations to individuals and communities about exposure reduction.

We also considered whether intake models could assess with some degree of confidence the relative source contributions to overall intake and whether this approach could be used to inform decisions regarding community recommendations. While diet appears to be a major contributor to overall intake, dietary data from the United States were not used in these models. It is not known whether the Canadian data used are representative of levels in the United States. As observed by Macheka-Tendenguwo and colleagues (2018), “numerous investigations have attempted to establish the main exposure pathway of PFAS in humans, but differing viewpoints make the results inconclusive” (p. 36066).

In conclusion, other than using certified POE or POU water filters, the available intervention studies generally do not appear to be sufficiently robust to support recommendations for personal behavioral modifications for communities in the United States. The studies reviewed here were limited by small sample sizes, generally inconsistent study designs and results, and a possible lack of generalizability to the United States. It is also important to consider additional factors when developing recommendations for changes in personal behavior, such as the ease and cost of an intervention, associated trade-offs (i.e., If an intervention lowers concentrations of PFAS, does it increase exposures to other chemicals, including

KD2579

Copyright National Academy of Sciences. All rights reserved.

other PFAS?), and whether enough is known about varying PFAS levels in the environment and consumer products to understand the necessary scale of an intervention recommendation (e.g., individual, local, or regional). Information will be needed on local levels of PFAS in drinking water, as well as levels in breast milk, for any recommendations regarding infant nutrition to be well supported.

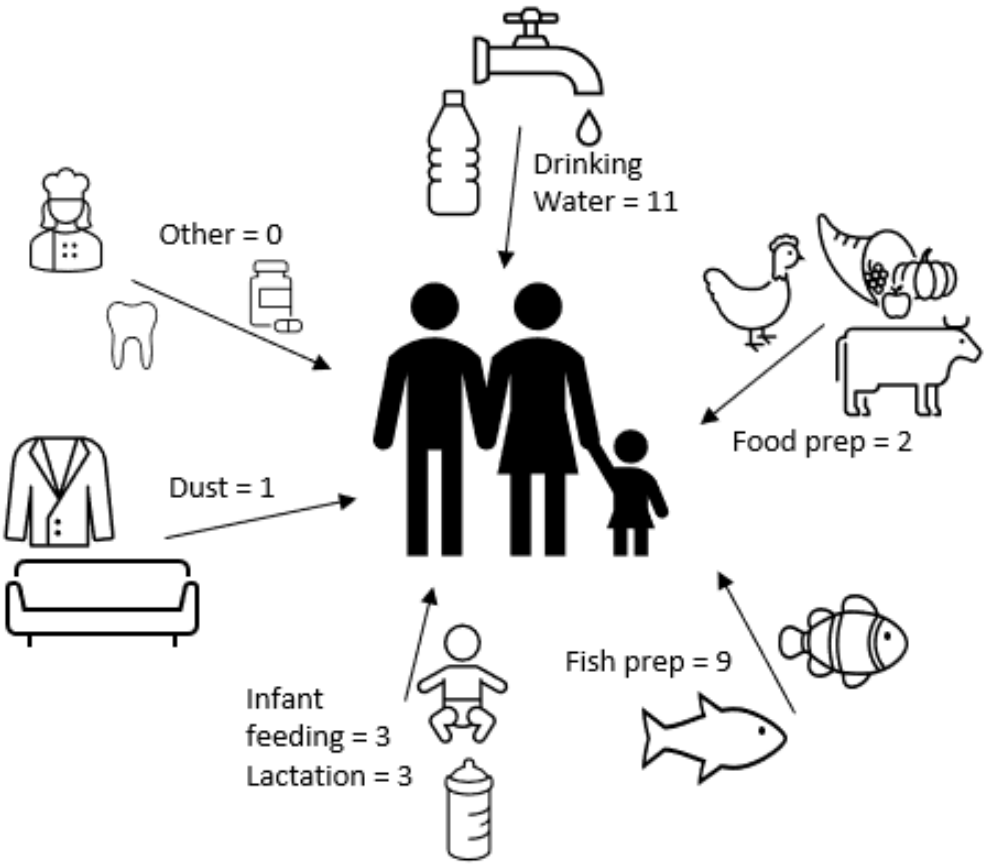

FIGURE E-10 Summary of numbers of studies identified for each PFAS exposure source.
NOTE: "Other" includes nonstick cookware, dental floss, and fiber intake, which these sources are described in the text but for which no intervention studies were identified.

Air emissions during destruction of PFAS-containing materials

Abstract

Per- and polyfluoroalkyl substances (PFASs) are synthetic chemicals used across numerous industrial and consumer applications. Their persistence and toxicological impacts necessitate their removal from the environment and their complete destruction; however, many PFAS destruction technologies release gas-phase and aerosol-phase fluorinated products of incomplete destruction (PIDs). In this Review, we discuss the PIDs released by PFAS destruction methods and approaches to categorize and measure them. Existing and emerging technologies use thermal, chemical, electrical or biological approaches to degrade PFASs, with varying degrees of success. Although many technologies achieve destruction and removal efficiencies of more than 99.99%, this metric does not account for the formation of airborne PIDs. Methods are being developed to measure PIDs in air emissions to protect exposed communities and facilitate the closure of fluorine mass balances. The choice of sampling and analytical methods depends on the polarity and volatility of the PIDs. Closing the mass balance is important because PIDs such as CF_4 can have unintended global impacts, and potential localized risks from exposure to PIDs remain uncertain. Therefore, diverse analytical methods are needed to comprehensively characterize PIDs; such characterization is important to identify PFAS destruction technologies that minimize atmospheric emissions and their associated environmental and human health risks.

Introduction

Per- and polyfluoroalkyl substances (PFASs) are a large class of synthetic organic chemicals that have been widely used in industrial processes and consumer products such as textile protectants and aqueous film-forming foams (AFFFs) since the 1940s[1–3]. The high chemical and thermal stability that makes PFASs suitable for these applications also enables them to persist in the environment[4,5] (Box 1). PFASs are released into the environment during PFAS manufacturing, their incorporation into products, and during and at the end of product life cycles[6–8]. The environmental and human health impacts of many PFASs are the subject of much study; for example, exposure to some PFASs such as perfluorooctanoate (PFOA) can lead to an increased risk of certain cancers[9,10]. Therefore, treatment approaches are required to reduce ongoing releases of PFASs and to clean up contaminated sites.

Non-destructive technologies are frequently used to remove PFASs from contaminated water or soil. However, these approaches produce PFAS-laden residuals that pose a substantial risk of secondary pollution if not managed properly. Current management approaches are problematic: the residuals are either sent to landfills where PFASs persist or transform into other PFASs, or are thermally treated, in which case incomplete degradation can lead to the release of products of incomplete destruction (PIDs)[11–15] (Fig. 1). PIDs are formed when conditions are insufficient to completely mineralize PFASs: that is, convert them to inorganic fluorine such as hydrogen fluoride (HF) and fluoride salts, and other inorganic species such as carbon dioxide (CO_2). PIDs can be present in solid and liquid residuals as well as in airborne emissions; they can include carbon tetrafluoride (CF_4), perfluoroethane (C_2F_6), other fluorinated and mixed halogenated organics, and PFASs with well understood toxicity, such as PFOA[16–33].

Numerous treatment technologies are being developed to destroy PFAS-containing wastes such as AFFFs, water, soil, biosolids, pavements, and residuals produced by non-destructive technologies. It is important to assess the performance of destruction technologies not solely based on the disappearance of the parent PFASs, but also with respect to the minimization of PID formation in atmospheric emissions and other residuals. Destruction and removal efficiency (DRE) calculations, which simply account for the loss of individual PFASs by comparing the mass feed rate to the mass emissions rate through the stack exhaust[34], fail to account for the potential release of fluorinated PIDs to the air and for the potential presence of the parent compound or PIDs in residual solids and liquids[35,36]. This definition does not apply to destructive technologies without stacks, for which the DRE concept can be extended to refer to the loss of individual PFASs in the aqueous phase. Therefore, aiming to close the fluorine mass balance, instead of solely relying on DRE measurements, is a critical goal when evaluating the performance of PFAS destruction technologies[12]. The fluorine mass balance and the degree of PFAS mineralization can be calculated from measurements of organic and inorganic fluorine. However, accounting for the fate of every fluorine atom to achieve a complete fluorine mass balance is difficult at all scales and improbable at large scales. This difficulty arises because fluorine reacts with reactor surfaces and matrix constituents, but also because quantitative analytical methods are still being developed for many PIDs.

Despite being neglected by the DRE metric, it is important to characterize air emissions for potential PIDs from PFAS destruction technologies. Gas-phase and aerosol-phase PIDs can represent a substantial portion of fluorine in the fluorine mass balance of destruction processes[37,38]. Once these PIDs are discharged to the atmosphere, they can be transported over large distances and returned to terrestrial and aquatic ecosystems via dry and wet deposition[39–41] (Fig. 1). This atmospheric transport broadens the environmental impacts and the risk of human exposure through inhalation or ingestion of contaminated air, water, and food. Comprehensive characterization of PFAS-derived PIDs is important even when they are produced in trace amounts because some compounds might exhibit high risk even at low concentrations.

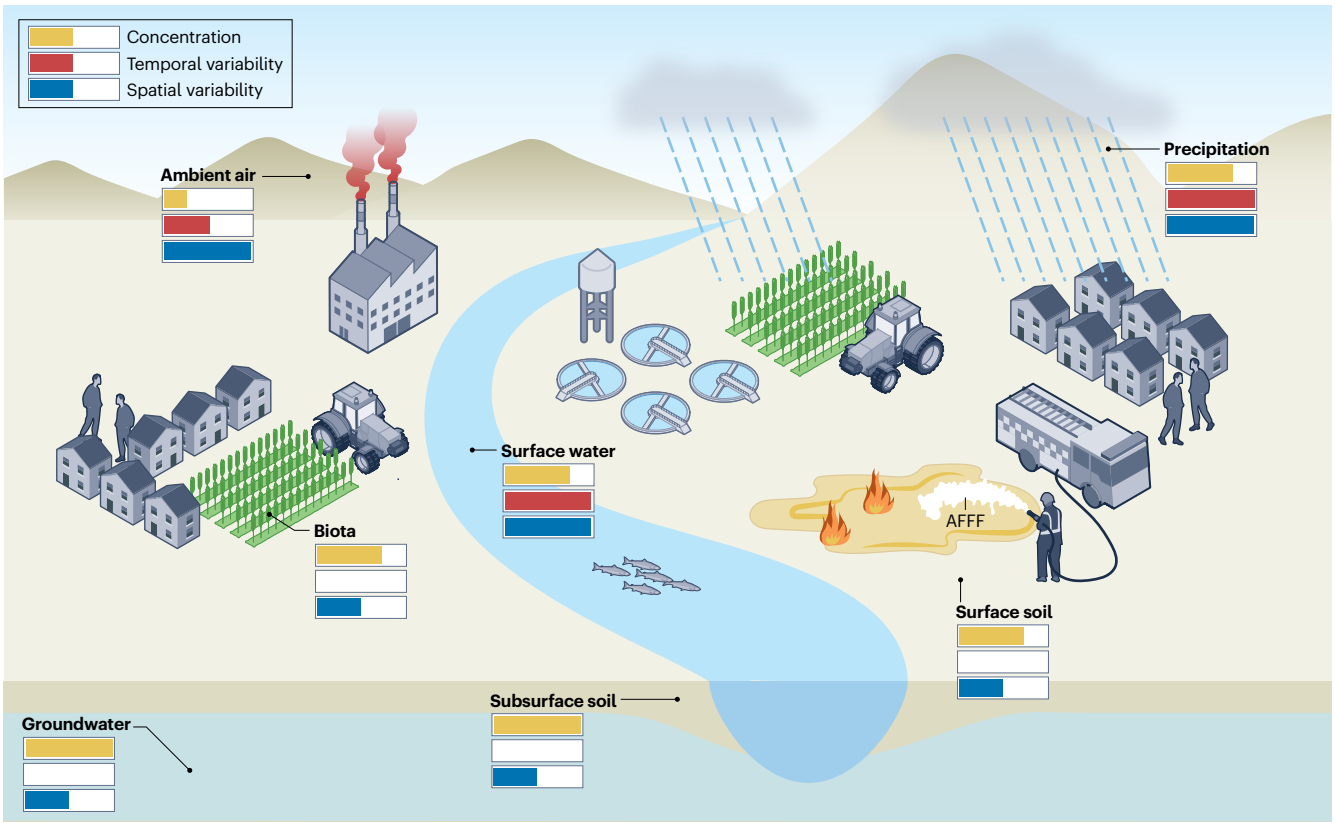
In this Review, we evaluate methods to characterize PIDs produced by PFAS destruction technologies, with a particular focus on characterization of gas-phase and aerosol-phase PIDs. First, we introduce existing non-destructive technologies for PFASs. We then discuss potential PIDs generated during PFAS destruction processes and outline existing destructive technologies as well as some emerging destructive technologies. Next, we review the analytical methods available for identifying and quantifying PIDs. Finally, we outline priority research needs to address the knowledge gaps that currently limit understanding of PID formation during PFAS destruction.

Non-destructive treatment

In many remediation strategies, PFAS-containing media are first treated by non-destructive separation processes that concentrate PFASs. Although these methods do not destroy PFASs, they have a critical role in interim containment and exposure reduction. However, they inevitably generate PFAS-laden residuals that require PFAS destruction to achieve long-term environmental protection. In this section, we briefly outline common separation processes used to remove PFASs from soil, water, and air. More detailed information on these non-destructive technologies is available elsewhere[29,42–46].

Separation technologies such as granular activated carbon (GAC) adsorption[47–49], ion exchange[49,50], reverse osmosis[45,51], and foam fractionation[52] are commonly used to treat PFAS-contaminated water. These approaches can economically remove PFASs from the large volumes of water that require treatment (typically 1,000s to 10,000s of cubic metres per day) and concentrate PFASs in residual streams of lower volume[53,54]. Activated carbon is used to remove a wide range of PFASs and many other organic contaminants from water, whereas ion-exchange resins are generally more selective[43,55]. Membrane technologies, such as reverse osmosis, can remove a broad spectrum of PFASs and other constituents via size exclusion and electrostatic interactions, generating a concentrated brine waste[45,51]. After treatment, the spent adsorbents and brines are either landfilled or sent to a destructive process. Foam fractionation exploits the surfactant properties of PFASs, particularly long-chain species, by concentrating them in a collectible foam layer[52,54]. Emerging non-destructive PFAS removal methods, such as electrosorption and adsorbents including metal–organic frameworks and supramolecular macrocycles, show promise but remain at early development stages[56–58].

For soils and sediments, non-destructive approaches aim to immobilize or extract PFASs. Stabilization, solidification, and in situ sorptive amendments (that is, using sorbents such as activated carbon, biochar and organoclays) can substantially reduce PFAS leaching[59,60]. However, the long-term performance of these approaches under field conditions, where pH and/or redox conditions might change, remains uncertain[44]. Ex situ soil washing can remove PFASs from coarse-grained soils[42,61,62] but is often less effective for fine-grained or organic-rich matrices, and it generates PFAS-laden wash water[61], which must be treated.



Box 1 | Understanding PFASs

Definition

Per- and polyfluoroalkyl substances (PFASs) are a family of synthetic fluorinated substances that contain at least one perfluorinated methyl ($-CF_3$) or methylene ($-CF_2-$) group, without any H, Cl, Br or I atom attached to the carbon atom, as defined by the Organisation for Economic Co-operation and Development (OECD)[182]. PFASs include polymers (such as polytetrafluoroethylene, PTFE) and non-polymers (such as perfluorooctane sulfonate, PFOS), with non-polymeric PFASs currently drawing the most regulatory and research attention. Subclasses of PFASs are typically categorized by head groups, such as perfluorocarboxylates (PFCAs) and perfluorosulfonates (PFSAs), as well as fluorine saturation levels, with perfluorinated compounds containing no C–H bonds and polyfluorinated compounds containing at least one bond between C and H, Cl, Br or I. PFASs can also be classified as long-chain ($C \geq 8$ for PFCAs and $C \geq 6$ for PFSAs), short-chain and ultrashort-chain ($C \leq 3$) structures depending on their number of C atoms[183].

Persistence, environmental relevance and toxicity

PFASs are highly resistant to degradation or transformation in natural and engineered systems. This persistence arises from the strength of the carbon–fluorine (C–F) bond, which has a bond dissociation energy of ~500 kJ mol^{-1} (refs. 184,185). Consequently, released PFASs can persist in environmental matrices for long periods. Media-specific environmental concentrations of PFASs are highly interrelated, show substantial temporal and spatial variability, and can exceed reference concentrations by several orders of magnitude near release sites, such as fluorochemical manufacturing facilities and sites contaminated with aqueous film-forming foam (AFFF) (see the figure: with partially to fully filled bars indicating an exceedance of 1 to 4 orders of magnitude for the media-specific concentrations relative to reference values (empty bar) of 4–10 ng l^{-1} for water, 0.07 µg m^{-3} for air, and <1 µg kg^{-1} for soil, representing typical background concentrations[186], and the full, half-full and empty bars indicating high, medium, and low spatial and temporal variability, respectively). High concentrations of PFASs can lead to ubiquitous human exposure through contaminated water, food, and air[187–193]. Although risk-based toxicity factors for non-cancer effects and cancer risk are available for some PFASs[118], further examination of the effects of exposure to PFAS mixtures[194] and intermediates[195] and an analysis of toxicological interactions[196] are needed.

Destructive treatment and PID formation

PFAS-impacted waste generated from non-destructive treatment technologies should be subjected to effective destructive treatments to prevent secondary pollution (Fig. 2a). Currently, these materials are often managed by landfilling and, in the case of biosolids and water treatment residuals, land application, but

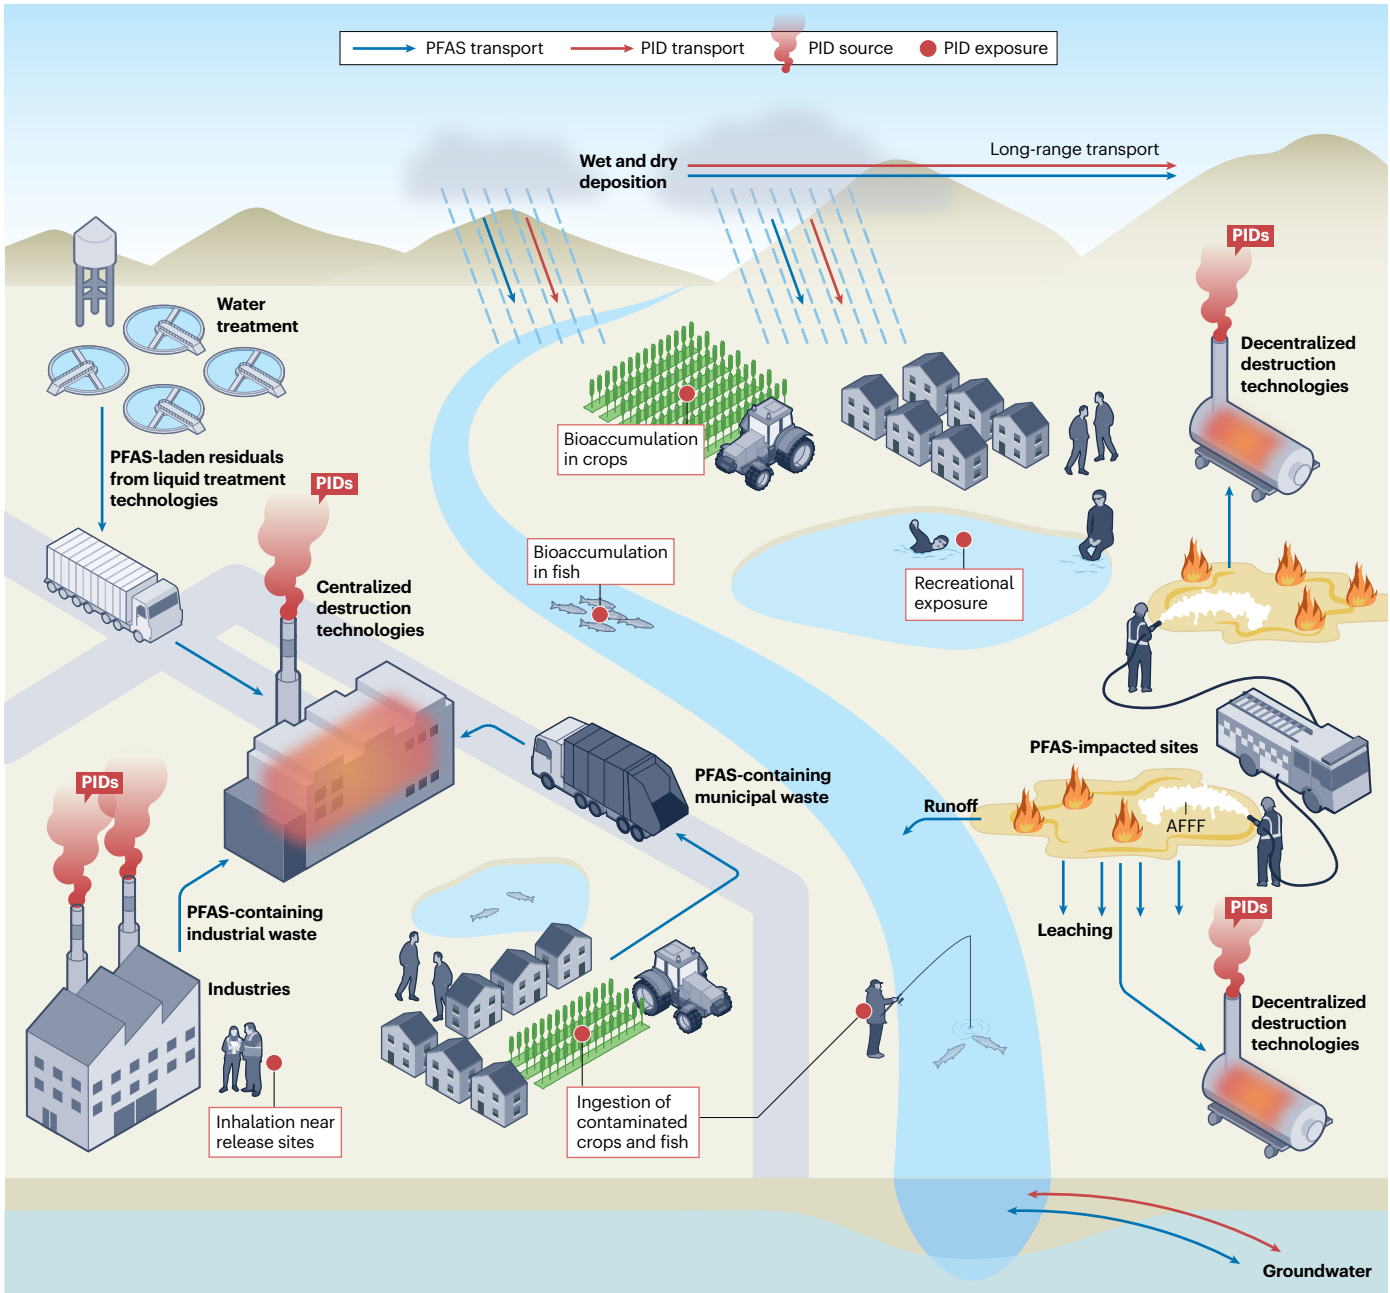


Fig. 1 | Sources, transport and exposure points of PFAS-derived PIDs. Products of incomplete destruction (PIDs) are generated from the destruction of wastes that contain per- and polyfluoroalkyl substances (PFASs). Such wastes include residuals from water treatment technologies, municipal solid waste, industrial waste, and soil contaminated with aqueous film-forming foam (AFFF). These PFAS-containing materials can be transported to centralized or decentralized destruction technologies for processing. The gas-phase and aerosol-phase PIDs from these technologies can be transported across large areas in the atmosphere and through dry or wet deposition. Consequently, people might be exposed through multiple pathways: inhalation near facilities that manufacture, use or treat PFASs; ingestion of contaminated food and water; and through recreation activities such as swimming. The definition for PFAS-derived PIDs is inclusive of PFASs.

such management approaches lead to PFAS cycling in the environment. Various destruction technologies have been investigated and deployed at the laboratory, pilot and commercial (field) scale, yet many of these approaches can lead to the formation of PIDs. This section first summarizes how PIDs are generally produced during PFAS destruction and then outlines destructive technologies that show promise with respect to field-scale application, with an emphasis on their efficiency as characterized by PFAS destruction parameters (such as DREs and PID formation), scalability, and suitability for real-world applications.

PID formation during PFAS destruction

Destruction technologies generate a range of PIDs, although the specific species and their quantities strongly depend on the technology, its operating conditions, matrix constituents of the treated material (for example AFFF, soil, solid waste, ion-exchange resins, GAC), and the presence of other chemicals in the treated material such as co-adsorbed halogenated species on GAC. Although liquid and solid-phase PIDs are produced by some PFAS destruction technologies, airborne PIDs have received substantially less attention and thus are the focus of this Review.

Computational efforts provide insight into PID formation and help to identify the optimal conditions needed to minimize the formation of PIDs during PFAS destruction. Simulations suggest that perfluoroalkenes, perfluoroalkanes, and hydrofluoroalkanes can be the major PIDs formed upon cleavage of the terminal head group during the destruction of PFASs[63–70]. Many of these intermediates and smaller gaseous PIDs (such as CF_4 and C_2F_6) have also been observed experimentally[71–75]. The presence of PIDs indicates that there are operational conditions and kinetic bottlenecks preventing complete PFAS mineralization. Other oxidation and/or pyrolysis intermediates have been identified in theorized reaction pathways[63–67], including perfluorinated α-lactones, acyl fluorides, aldehydes, n-alkyl radicals, and head-group radicals[67]. Some of these classes, along with other intermediates such as non-polar semivolatiles (for example fluorotelomer alcohols[76]), have also been observed experimentally (including some short-lived radicals[77]).

Hydrogen sources are essential for reducing PID formation during PFAS destruction. If fluorinated radical species are formed, for example through the cleavage of carboxylic acid or sulfonic acid head groups, and then recombine, PIDs can potentially be generated that have a higher

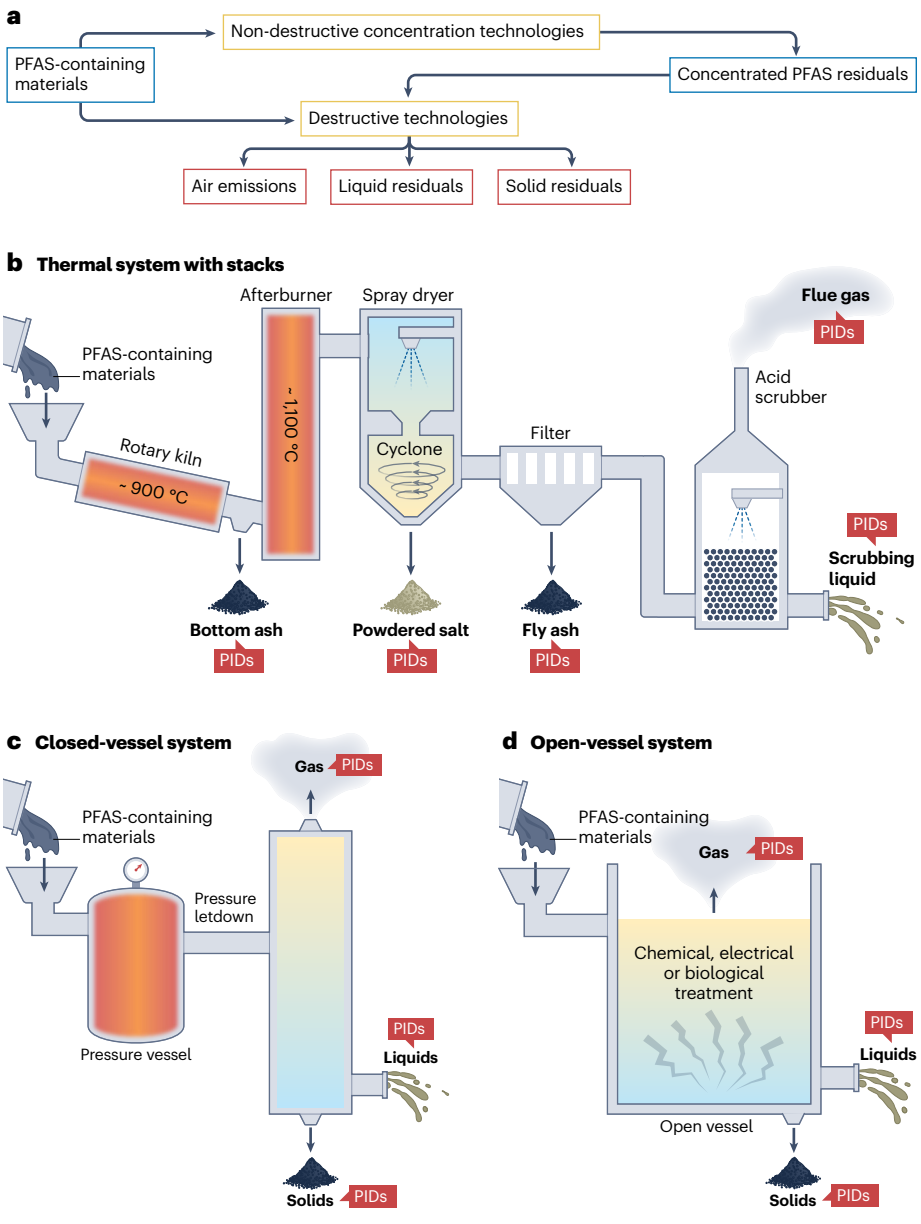

Fig. 2 | Strategies for managing PFASs. **a**, Non-destructive technologies generate concentrated per- and polyfluoroalkyl substance (PFAS) residuals that require subsequent management. Alternatively, destructive technologies aim to break down PFASs but can produce various outputs including air emissions, liquid residuals and solid residuals that might contain products of incomplete destruction (PIDs). **b**, Schematic of a typical hazardous waste incineration system used to manage PFAS-impacted residuals by combusting the waste in an incinerator. The flue gases are typically treated through emission control systems, such as afterburners, spray dryers, filters and scrubbers, before being released. **c**, Schematic of a closed-vessel system where PFAS-impacted liquids and slurries are exposed to high pressure and temperature. The treated effluent is separated in a gas–liquid separator. **d**, Schematic of a general open-vessel system, which uses chemical, electrical or biological means to destroy PFAS-impacted wastes and residuals. PIDs formed by destructive technologies are released into the environment in various phases.

Table 1 | PFAS destruction technologies

Technology	Temperature (°C)	Current technology scale[a]	Major PID types detected	PID detection approach	Air pollution control systems required
Thermal destruction technologies with stacks					
Incinerators[16–20,32]	~650–1,200	Commercial	COF_2, CF_4, C_2F_6, TFA and longer-chain per- and polyfluoroalkanes and -alkenes	FTIR, LC-MS, GC-MS, CIMS	Yes, secondary combustion chamber, quench system, spray dry absorber, baghouses, electrostatic precipitator or scrubber
Pyrolyser and gasifier[33,71,73,74,88]	~500–1,100	Commercial	Perfluoroalkenes	IR spectroscopy, GC-MS	Yes, wet scrubber
Cement kilns[22]	~1,200–1,800	Commercial	Unknown	Unknown	Yes, baghouses, electrostatic precipitator, or scrubbers
GAC reactivation furnaces[23,96,97]	~700–950	Commercial	Perfluoroalkenes	LC-MS, GC-MS	Yes, thermal oxidizer
Closed-vessel systems					
Hydrothermal alkaline treatment[24,98]	~300–350	Pilot scale	Short-chain PFCAs; unknown gas emissions	LC-MS, GC-MS	No
Supercritical water oxidation[25,100]	>374	Commercial	Perfluorohexane, perfluoroheptane	LC-MS, GC-MS, CIC	Yes, activated carbon adsorber
Open-vessel systems					
Advanced oxidation processes[29,30]	Ambient	Bench scale	Short-chain PFASs, perfluorinated alkanes	LC-MS, GC-MS	No
Advanced reduction processes[28]	Ambient	Bench scale	Polyfluorinated alkenes and alkanes, short-chain PFASs	LC-MS, GC-MS	No
Plasma-based methods[27]	Ambient	Pilot scale	Short-chain PFASs; unknown gas emission	LC-MS	No
Sonolysis[26]	Ambient, localized temperatures of up to 4,730 °C	Pilot scale	Short-chain PFASs; unknown gas emissions	LC-MS	No
Biological methods[31]	Ambient	Bench scale	Short-chain PFASs	LC-MS	No

[a]Technology scale reflects the current state and operational scale of these technologies. Commercial-scale systems can process much more material than technologies operating at smaller scales (pilot scale and bench scale). CIMS, chemical ionization mass spectrometry; FTIR, Fourier-transform infrared spectroscopy; GAC, granular activated carbon; GC-MS, gas chromatography–mass spectrometry; IR, infrared; LC-MS, liquid chromatography–mass spectrometry; PFASs, per- and polyfluoroalkyl substances; PFCA, perfluorocarboxylates; PID, products of incomplete destruction; TFA, trifluoroacetic acid.

degree of fluorination and/or a higher number of carbon atoms than the parent PFASs. To avoid the recombination of radical species (particularly in incineration), hydrogen sources such as water or natural gas can be added to generate volatile hydrofluoroalkanes, which can further transform through defluorination to simpler organic fluorine species, potentially resulting in complete mineralization to inorganic fluorine species[70]. Calcium hydroxide ($Ca(OH)_2$) is added in some destruction technologies to decrease PID formation[78–80], by providing hydrogen and a means of forming CaF_2 in place of HF (refs. 78–81). The addition of Ca^{2+} can also enhance gasification reactions during GAC reactivation[82].

Various PFAS destruction technologies are available and differ in their PID formation, energy requirements, and availability at scale (Table 1). Although many technologies achieve high DREs[83,84], only a few have demonstrated complete mineralization of PFASs to inorganic fluorine species such as HF, silicon tetrafluoride (SiF_4, which readily reacts with water), fluoride salts (such as CaF_2) and non-fluorinated gases such as CO_2. The nature and extent of PID formation differs across technologies, but very limited data are available as of yet, and additional research is required to directly characterize and quantify PIDs.

Thermal destruction technologies with stacks

Thermal destruction technologies rely on elevated temperatures, often combined with oxidizing or catalytic environments, to break the strong C–F bonds in PFASs. These technologies generally have high DREs (>99.99%), but PIDs can still form, particularly at low temperatures or under suboptimal operating conditions. Because many thermal technologies produce large volumes of heated air and air emissions, their designs typically include tall stacks to release these emissions to higher elevations, promoting broader atmospheric dispersion.

Incineration. Conventional incinerators, including hazardous waste incinerators (HWIs), municipal waste incinerators (MWIs), and sewage sludge incinerators (SSIs), operate with an oxidizing environment at temperatures ranging from about 650 °C to 1,100 °C or more[16,17,32]. Among these, HWIs are the most effective at mineralizing organic contaminants because they operate at high temperatures and consist of multiple combustion stages (see, for example, Fig. 2b). These stages often include a rotary kiln that serves as the primary combustion chamber with a residence time of 10–90 min at ≥650 °C (ref. 85). The exhaust from the primary chamber is sent to an afterburner, a type of thermal oxidizer, that serves as the secondary combustion chamber with a residence time of 2–4 s at ≥950 °C to enhance mineralization of remaining organic compounds and reduce harmful emissions[16,20,70]. In these incinerators, the waste itself can be used as an energy source rather than external fuels. Under typical operating

conditions of a HWI treating waste feeds at a commercial scale, high DREs (>99.9999%) were achieved for selected PFASs, and emissions showed low to non-detectable levels of PIDs[86]. Additionally, in the afterburner, DREs for spiked C_2F_6, a common PID that is difficult to destroy, were >99.99%. A high DRE for C_2F_6 can serve as a potential indicator for effective PFAS destruction[86]. Apart from afterburners, conventional incinerators also include air pollution control systems, such as scrubbers and baghouses, to manage emissions by further destroying or capturing PIDs[20].

Incinerator operating conditions can have a substantial impact on the formation of PIDs. The presence of a hydrogen source such as the waste, hydrocarbon fuel, or steam is needed to promote the mineralization of PFASs to HF; therefore, low hydrogen-donor content can potentially lead to PID formation[21]. A sufficiently high temperature, temperature uniformity (which can be achieved through mixing), and a sufficiently long residence time are also critical for achieving effective PFAS destruction. For example, although the cleavage of PFAS head groups occurs at temperatures ≤500 °C, temperatures of >950 °C are required for complete mineralization of hydrofluoroalkanes, including 1*H*-perfluoroalkanes, to occur in the gas phase and in the absence of catalysts[70]. There is a substantial knowledge gap regarding air emissions from incinerators that operate at lower temperatures, especially SSIs, as PID formation can reach 15% in SSIs and MWIs[17,32].

Thermal desorption (TD) technologies can be applied to contaminated soils when specific geotechnical characteristics of the soil might be required for final disposal or beneficial reuse. TD systems operate at low temperatures (350–600 °C)[87] in the primary combustion chamber to thermally release PFASs and PIDs that are formed at these temperatures. The flue gas is typically sent to an activated carbon bed to remove the released PFASs and PIDs, generating a waste product, or sent to a thermal oxidizer to destroy the released PFASs and PIDs.

Thermal oxidizers are occasionally used as stand-alone systems for treating gaseous waste streams, such as emissions from fluorochemical manufacturing. They operate at high temperatures (>1,000 °C) and are often equipped for heat recovery[88]. Thermal oxidizers were originally designed to destroy volatile organic compounds (VOCs), but they have been adapted for treating PFAS emissions[89]. Although DREs exceeding 99.99% have been reported for thermal oxidizers, comprehensive data on PID formation and fluorine mass balances remain limited for full-scale applications[33]. For example, a study that reported such high DREs tested for only five PFASs[33]; however, a separate test for volatile organic fluorine compounds in the emissions of the same facility detected only CF_4 (ref. 90).

Laboratory-scale investigations reveal that incineration processes produce various airborne PIDs. In controlled laboratory-scale experiments, the thermal decomposition of perfluorooctane sulfonate (PFOS) formed PIDs at temperatures ranging from 500 °C to 1,000 °C, including trace amounts of perfluoroalkenes and carbonyl difluoride (COF_2), which can rapidly form HF and CO_2 in the presence of water[18]. Additionally, the thermal decomposition of fluoropolymers such as polytetrafluoroethene (PTFE) produced PIDs, including perfluoroalkanes, perfluoroalkenes, and hydrofluoroalkanes[91]. Difluoromethyl radical ($\bullet CHF_2$) fragments identified in the PIDs produced from PFOS combustion in complex environmental matrices that contain hydrogen, such as sewage sludges, point to the formation of 1*H*-perfluoroalkanes[78]. In a pilot-scale test, the combustion of AFFF concentrates at low temperatures (760 °C) produced more short-chain PFASs such as trifluoroacetic acid (TFA) than at higher temperatures (820 °C)[37]. The demonstrated formation of PIDs from incineration processes highlights the importance of thermal oxidizers or afterburners in reducing PID emissions from incineration processes and their role in enhancing PFAS mineralization.

Pyrolysers and gasifiers. Pyrolysis and gasification units limit the amount of oxygen available for reactions during thermal treatment. During pyrolysis at temperatures between 500 °C and 800 °C, PFASs volatilize or partially decompose to form PIDs[92,93]. Although PFAS concentrations in the waste might be reduced by one or more orders of magnitude after treatment[92,93], PFASs might accumulate in the pyrolysis oil[94]. Early bench-scale research investigating the thermal decomposition of salts of long-chain perfluorocarboxylates (PFCAs) in a pyrolytic environment found that volatile perfluoroalkenes formed with yields >97% after cleavage of the carboxylate head group from the parent compound[73]. Similarly, perfluoroalkenes have been identified during the decomposition of PFOS at 450 °C to 1,000 °C (refs. 21,71,74). The pyrolysis of substances that contain complex mixtures of PFASs, such as AFFF and fluorosurfactant concentrates, yielded a broad range of PIDs, including perfluoroalkyl aldehydes, - per- and polyfluoroalkenes, per- and polyfluoroalkanes, and fluorotelomer alcohols (FTOHs)[76]. In general, small amounts of 1*H*-perfluoroalkanes have been observed when hydrogen from NaOH or steam ($H_2O_{(g)}$) was present[21,72].

Gasification units operate at higher temperatures than pyrolysis units, typically up to 1,000 °C, with the goal of producing syngas. Given these elevated temperatures, high DREs (>99.99%) have been reported for gasification systems[33]. However, data on PID formation and fluorine mass balances are limited and PID characterization has largely been confined to controlled laboratory studies. Collectively, these findings indicate that PID formation can be expected in pyrolysers and gasifiers with fluorinated alkenes and alkanes being the dominant species.

Cement kilns. Cement kilns operate at very high temperatures (1,200–1,800 °C) in high-pH environments. When PFAS-containing materials are placed directly in cement kilns, high DREs (>99.99%) for PFASs have been observed[22]. Cement kilns offer the advantage of integrating waste destruction within an existing material production process. PID formation is expected to be low because the high operating temperatures exceed those typically achieved by afterburners or thermal oxidizers. However, further research is needed as only limited field-scale data are available, and no measurements of potential PFAS-derived PID formation have been attempted[22].

GAC reactivation furnaces. Spent GAC is commonly reactivated in furnaces operating at 700 °C to 950 °C, typically with afterburners or thermal oxidizers being used to destroy PFASs present in the flue gas[23]. A full-scale GAC reactivation facility reported DREs >99.99% for PFASs after the thermal oxidizer; however, sampling and quantification of emissions and residuals only accounted for 61% of the fluorine mass balance[95]. Additionally, without a thermal oxidizer, up to 10–20% PID formation has been observed[23,96,97]. A bench-scale study found that PFAS mineralization was enhanced when PFASs were adsorbed to GAC, relative to treating non-adsorbed PFASs, and that this mineralization was further enhanced by the presence of NaOH (refs. 23,96). However, the fluorine mass balance was not closed[23,96]. Tentatively identified PIDs from these systems include perfluoropropene from perfluorobutanoate (PFBA) and perfluoro-1-butene from perfluoropentanoate (PFPeA)[36].

Closed-vessel systems

In addition to conventional thermal treatment methods, several emerging thermal technologies using closed vessels have been developed (Fig. 2c). These vessels are typically closed to maintain higher temperatures and pressures with PFAS-impacted water, so any PIDs formed are released when the effluent from these systems is vented into a receiving storage vessel at ambient pressure.

Hydrothermal alkaline treatment. Hydrothermal alkaline treatment is a closed-system process that can mineralize PFASs using alkaline conditions at moderate temperatures (300–350 °C). The process is performed under elevated pressures (2–22 MPa). Hydroxide additives enhance the reactivity of PFASs, generally leading to stoichiometric fluoride ion generation and complete fluorine mass balances[98]. There is no evidence that PFAS-derived PIDs are formed under optimal conditions; however, more extensive testing is needed for confirmation and to define limitations that would lead to suboptimal treatment such as matrix effects, co-contaminants and reaction times[98]. PID formation can occur if there is insufficient reaction time or if the base additive concentrations are too low[99]. There are limited field data on hydrothermal alkaline treatment, and its scalability remains under evaluation[24], largely because it is difficult to produce reactor materials that can withstand the high temperatures, high pressures and corrosive alkaline conditions involved.

Supercritical water oxidation. Supercritical water oxidation (SCWO) systems operate above the supercritical point of water (>374 °C, >22 MPa), enabling the homogeneous oxidation of PFASs to CO_2, water and fluoride. Temperatures of more than 650 °C are required to achieve complete defluorination of recalcitrant PFASs[25]. SCWO has high DRE potential (>99.9%) and can be designed to produce minimal air emissions by ensuring condensation of water vapour upon release from the pressurized vessel[100]. However, high capital and operational costs, along with the need for corrosion-resistant materials, present challenges for implementation. Additional work is needed to characterize PID formation, although initial results are encouraging. For example, in a pilot-scale study, destruction of AFFFs by SCWO generated only trace levels of aqueous PIDs. Gas-phase PIDs including perfluorohexane, perfluoroheptane and some chlorinated–fluorinated alkanes, were also detected at concentrations <300 μg m^{-3} (ref. 100).

Open-vessel systems

Thermal and non-thermal destruction technologies are being developed to target PFAS destruction through chemical, electrical, or biological means in open-vessel systems (Fig. 2d). These systems, which typically operate at ambient pressures and are thus open to the atmosphere, aim to mineralize PFASs with lower energy inputs and to realize easier integration with existing treatment systems. However, many open-vessel approaches remain in early development stages, with limited full-scale deployment[101].

Advanced oxidation processes. Advanced oxidation processes (AOPs) use highly reactive radicals (for example, sulfate radicals) to oxidize PFASs. These processes typically degrade PFASs into short-chain PFCAs and gaseous PIDs such as fluorinated alkanes. Radicals can be generated in various ways, including through the photolytic or thermal activation of radical precursors such as persulfate, through photocatalysts, and through electrochemical reactions. Conventional oxidants such as ozone and hydrogen peroxide are generally insufficient to decompose PFASs[102]. Some AOPs can partially oxidize PFCAs, but oxidation of perfluoroalkyl sulfonates (PFSAs) is more difficult[29]. Precursors of perfluoroalkyl acids (PFAAs) are generally more susceptible to oxidation but often result in the formation of more recalcitrant PFAAs[103]. AOPs often require high energy input and specific conditions such as high or low pH, the presence of certain chemical reagents, the absence of radical scavengers, and carefully optimized operational parameters[29].

The formation of PIDs in AOPs is common but is not yet well understood. Although most studies focus on production of aqueous PIDs, gaseous PIDs such as perfluoroalkanes have also been identified[30]. For example, oxidation of PFOA with sulfate radicals at room temperature produced a complex mixture of short-chain PFCAs and 18 distinct perfluoroalkane species[30]. The detected perfluoroalkanes constituted up to 25% of the converted PFOA and were predominantly linear with various chain lengths, although branched isomers and traces of 1*H*-perfluoroalkanes (<0.1 mol%) were also detected[30]. Higher temperatures favoured mineralization: oxidation at 70 °C generated only short-chain PFCAs and fluoride, suggesting more complete degradation and reduced formation of gaseous PIDs, although the fluorine mass balance remained incomplete[104]. Incomplete fluorine recovery has also been reported for other advanced oxidation methods, such as photocatalysis and electrochemical oxidation[105,106].

Advanced reduction processes. Advanced reduction processes (ARPs) use strong reducing species such as solvated electrons. These processes, with DREs of over 99.9%, typically defluorinate PFASs by reductively cleaving the C–F bonds to form fluoride, shorter-chain PFASs and polyfluorinated compounds[28]. Although ARPs can make PFASs more biodegradable, achieving complete mineralization is challenging. Additionally, the process can generate PIDs, including fluorinated alkanes and alkenes[107]. For example, volatile iodinated PIDs such as $CFHI_2$, C_2F_4HI and $C_6F_{13}I$ were produced in the reduction of various PFASs using ultraviolet irradiation with iodide, which are presumably from the incorporation of iodine radicals into intermediate products[28]. Under the same conditions, PFOS produced more diverse volatile iodinated intermediates than PFOA[28,108,109], indicating that headgroup chemistry can have important implications with respect to the types of PIDs formed when PFASs are subjected to ARPs.

Non-thermal plasma-based technologies. Non-thermal plasma-based technologies use hydrated, high-energy electrons and radicals produced by plasma at the gas–liquid interface to cleave the C–F bond and cause PFAS fragmentation. These technologies have demonstrated high (>90%) DREs for PFOA and PFOS, but DREs can be reduced by co-contaminants such as salts[110]. Although pilot demonstrations exist, commercial systems are rare[27]. Additionally, understanding of byproduct formation is still evolving, but it seems that the formation of volatile fluorinated cyclic alkanes and short-chain acids is common. Gaseous byproduct formation during plasma treatment of PFOA and PFOS was shown to depend on the exposure time. Concentrations of cyclic perfluoroalkanes (C_4F_8 to C_8F_{16}), which probably formed via intramolecular free-radical cyclization, peaked at 30 minutes (reaching up to 110 μg l^{-1} from an initial 8.3 mg l^{-1} PFOA), then decreased with continued treatment[111]. The concentrations of the airborne byproducts accounted for less than 0.5% of the initially added organic fluorine and were 1–2 orders of magnitude lower than those of the aqueous PIDs[111].

Sonolysis. Sonolysis, which generates localized high temperatures through cavitation, can destroy PFASs with DREs of 50 to >99%[26].

Acoustic fields with frequencies between 20 and 1,000 kHz are applied to produce microbubbles that create extreme localized conditions (~4,730 °C and 2×10^8 Pa) when they collapse, leading to the pyrolysis of water vapour and the formation of reactive species that facilitate PFAS destruction[112]. PFAS destruction primarily occurs via pyrolysis at gas–water interfaces[26]. Although shorter-chain PFCAs can be formed in the aqueous phase[113], potential gas-phase and aerosol-phase emission products of PFASs from sonolysis have not been characterized. This technique consumes very large quantities of electricity, so its potential applications are currently limited to treating highly concentrated, small-volume waste streams[110].

Biological processes. Specialized microorganisms can slowly transform some PFASs under specific conditions, leading to partial defluorination and transformation rather than complete mineralization to CO_2 and fluoride. PIDs can form as PFASs transform into aqueous short-chain or partially fluorinated compounds. Minimal gaseous products are usually formed and typically consist of only CO_2 and methane (CH_4) from substrate consumption[31].

Summary

To summarize, existing PFAS destruction technologies have different strengths and weaknesses (Fig. 3). Thermal methods are the most commonly used PFAS destruction techniques, owing to their effectiveness and implementability within the existing waste infrastructure. However, these approaches typically require high temperatures, substantial energy input, and often dedicated secondary air pollution controls to minimize environmental impacts. Non-thermal approaches might offer lower energy demands and, in some cases, more selective reaction pathways, but they frequently rely on the addition of chemical reagents, and further validation is required to ensure consistent PFAS destruction and control of secondary emissions.

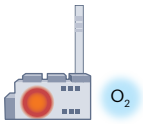
Characterization of PIDs

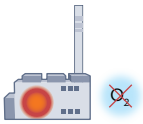
Methods for characterizing gas-phase and aerosol-phase PIDs are still in the relatively early stages of development, making it difficult to fully understand the PID formation potential of PFAS destruction technologies. High-temperature combustion can achieve PFAS destruction, but it is unclear whether this process can form new fluorinated or mixed halogenated byproducts. Other technologies can exhibit high DREs for certain PFASs, but in many cases, little is known about the extent of mineralization and PID formation. Moreover, DREs alone are insufficient to assess PFAS destruction, because this metric does not ensure the absence of gas-phase or aerosol-phase emissions or residuals containing potentially high risk PIDs that could have an impact at low concentrations. This section discusses the categorization of airborne PIDs and approaches for PID identification and monitoring during PFAS destruction.

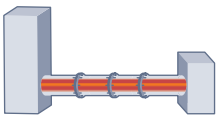
Categorizing PFAS-derived PIDs

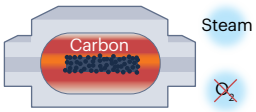
The wide range of potential PID species combined with concerns about the operation of PFAS destruction processes at suboptimal conditions has spurred efforts to measure specific PIDs. To achieve such measurements, it is important to categorize PIDs, because different analytical approaches must be developed to target different chemical species.

In general, PFAS-derived PIDs can be categorized, at least for the purposes of their chemical determination, according to their polarity and volatility into the following groups: polar volatile, polar semivolatile, non-polar volatile, and non-polar semivolatile (Fig. 4). Examples of PFAS-derived PIDs that represent polar semivolatile fluorinated compounds are PFAAs with four or more carbon atoms. In contrast, examples for non-polar semivolatile PIDs include highly fluorinated alkanes and alkenes with boiling points above about 100 °C. Polar volatile fluorinated compounds are characteristically smaller and include ultrashort-chain PFASs such as TFA. Gaseous non-polar volatile fluorinated PIDs include fluorinated alkanes (C1–C8) and alkenes (C2–C7). Additionally, some PIDs represent intermediates that can further transform; for example, perfluorinated acyl fluorides hydrolyse to form PFCAs in the presence of liquid water[70]. Different sampling and analysis techniques are needed to identify PIDs in each of these categories, owing to the physicochemical properties of each of the PIDs.



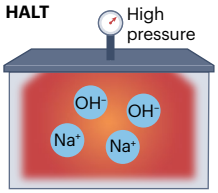


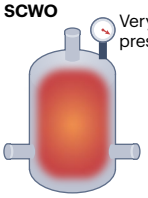




Characterization methods

Efforts to develop an understanding of air emissions from PFAS destruction technologies primarily focus on off-line analytical methods, in which a sample is collected and taken to a laboratory for analysis. These analytical methods for gas-phase and aerosol-phase PIDs can be used for regulatory compliance. Such off-line methods are essential for characterizing potential PIDs[67,114], and quantifying organic and inorganic fluorinated target compounds to determine the fluorine mass balance during PFAS destruction processes[79,96,115,116]. The US Environmental Protection Agency (EPA) has developed additional methods under Other Test Methods (OTMs) for fluorinated organic compounds that are intended to serve as comprehensive tools for characterizing gas-phase and aerosol-phase emissions. Each of these methods has strengths and weaknesses, and some modifications to these methods might be warranted to increase confidence in their ability to comprehensively assess PIDs associated with PFAS destruction (Box 2). To date, use of these OTMs to explore the fate of PFASs in PFAS destruction technologies has been limited.





OTM-45. OTM-45 is a standardized method for sampling and analysing polar fluorinated compounds (ionic PFASs). This method was developed to quantify 49 PFASs from stationary sources[117]. It consists of a multicomponent sampling train (involving a filter to capture aerosol-bound PIDs and XAD-2 resins and impingers containing basic water to capture gaseous PIDs) and is modelled after US EPA Method 23 (ref. 118). OTM-45 relies on targeted liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) to determine both gas-phase and aerosol-bound ionic PFASs. The generated extracts can also be used for non-targeted analysis to identify additional PIDs. The extraction and analysis protocols in OTM-45 are influenced by other standardized methods for PFAS analyses, including US EPA Methods 533, 537.1, 1633 and 8327, and ASTM Method D7968[118].

OTM-45 has been used to evaluate PID formation and determine DREs of PFASs in various PFAS-impacted waste streams[17,38,116,119]. For example, OTM-45 stack sampling was used in both a full-scale thermal reactivation study to investigate DREs for PFASs adsorbed to GAC[116] and by the US EPA in pilot-scale thermal destruction experiments with PFAS-based AFFF. Both studies reported DREs of >99.99%[38,116]. A modified OTM-45 sampling train was used to collect emissions during the use of SCWO to mineralize concentrated liquid PFAS waste streams and found equally high DREs[119]. However, only 63% of the fluorine was accounted for, which was likely a result of data being limited only to the PIDs targeted by OTM-45. In a separate effort, emissions from a full-scale SSI were collected using a method based on OTM-45 and analysed for total organic fluorine using combustion ion chromatography and for ionic PFASs[17]. No specific PFASs from

Fig. 3 | Classification of PFAS destruction technologies. An overview of conventional thermal technologies with stacks and emerging thermal and non-thermal technologies with closed or open vessels used for the destruction of per- and polyfluoroalkyl substances (PFASs), highlighting the formation of gas-phase or aqueous-phase products of incomplete destruction (PIDs), temperature, energy consumption, the need for additional chemicals (such as NaOH, oxidants, solvents), selectivity for PFASs and other halogenated organic substances, and whether additional methods of air pollution control are required to treat waste streams to meet regulatory permits[4,20,26,27,29,31,33,98,100,101,105,106,108,110,181]. The energy consumption indicated does not account for energy contributions from potential energy-recovery systems such as those used in incinerators. Common PFAS destruction methods are classified by their thermal and operational characteristics, with each technology evaluated on key criteria that can affect PID formation. AOP, advanced oxidation process; ARP, advanced reduction process; GAC, granular activated carbon; HALT, hydrothermal alkaline treatment; SCWO, supercritical water oxidation.

the targeted methods could be identified as contributing to the total organic fluorine measurements, suggesting that other fluorinated PIDs were being formed.

OTM-50. OTM-50 can characterize PFAS-derived PIDs that are non-polar and volatile. It is similar to US EPA Methods TO-15A and 327 in that evacuated canisters are used to capture a gaseous sample that

is analysed via gas chromatography–mass spectrometry (GC-MS)[118]. In OTM-50, gas samples pass through a heated filter (which removes particulates) and an optional series of impingers containing deionized water (which remove acidic gases such as HCl and HF) before being sampled into the canister. The method targets 30 PIDs with one to eight carbon atoms, including persistent gases, such as CF_4 and C_2F_6, and longer-chain perfluoroalkanes, such as perfluorooctane. Although the method is based on targeted GC-MS analysis, non-targeted GC-MS analyses can also be performed on OTM-50 canister samples to tentatively identify PIDs not quantified in this method[38,120]. If analytical standards are commercially available for tentatively identified PIDs, the identity of such PIDs can be validated, and they can be subsequently incorporated into the target analyte list.

OTM-50 was introduced in 2024; therefore, most prior research characterizing non-polar volatile PFAS-derived PIDs used earlier methods such as TO-15A and was largely exploratory. For example, the collection of gas-phase emissions with TO-15A during the pyrolysis of PFAS-impacted biosolids found that the concentrations of all 17 targeted volatile fluorinated PIDs were below the method detection limits[121]. Despite this finding, it was concluded that the potential for the formation of semivolatile PFAS-derived PIDs raises concerns and warrants further investigation[122]. During a field demonstration of a mobile SCWO system treating AFFF, gaseous effluents were collected using a modified TO-15A sampling train, revealing trace amounts of perfluoroalkanes[100]. Additionally, fluorinated gas-phase emissions collected with TO-15A during the thermal application of fluoropolymer dispersion coatings on fabrics at temperatures up to 400 °C suggested that the dispersions underwent transformation to C1–C8 fluorocarbons including tetrafluoroethylene (TFE) and heptafluoropropyl-1,2,2,2-tetrafluoroethyl ether (fluoroether E1)[120].

Since its release, OTM-50 has been applied in several studies to characterize emissions from PFAS destruction technologies. For example, OTM-50 demonstrated that CF_4 was consistently found in the emissions of a thermal oxidizer unit at a fluorochemical manufacturer[90]. Furthermore, application of OTM-50 showed that all C1–C8 1*H*-perfluoroalkanes were formed at concentrations of 0.2–9 mg m^{-3} during the incineration of PFOS-based AFFF at 810 °C, a non-ideal condition at which DREs ranged from 45.7% for PFBA to >99.97% for most of the targeted PFSAs[38]. At a temperature of 1,090 °C, PID formation decreased substantially, with only pentafluoroethane and trichlorofluoromethane detected at concentrations <1 μg m^{-3}, and DREs were >99.99% for all targeted PFAAs[38]. Such findings demonstrate that it is important to characterize PIDs, particularly non-polar volatile PFAS-derived PIDs, when assessing the performance of destruction technologies. Importantly, to enable the characterization of all gas-phase PFAS-derived PIDs potentially emitted during PFAS destruction, the target analyte lists of OTM-45 and OTM-50 could be expanded to include additional PIDs that have been identified in other investigations (such as perfluoroheptene isomers)[121].

Additional methods. Although OTM-45 and OTM-50 cover a broad range of potential PIDs, a method is still needed to collect and analyse non-polar, semivolatile PFASs such as FTOHs[123,124] and other longer-chain PFAS-derived PIDs[73]. OTM-55 is under development and is expected to combine elements of US EPA Methods 8270E and 0010[125]. Early versions of this method are being incorporated into current evaluations of PFAS destruction technologies[126]. For example, a GC-MS method, modelled after US EPA Method 8270E (SW-846), was used to target five FTOHs in emissions from the incineration of PFAS-laden sewage sludge; none of the samples yielded reportable levels of FTOHs[17]. The lack of a standardized sample collection and analysis method is likely, at present, to be a major impediment to broader efforts to characterize this subclass of PFAS-derived PIDs.

Furthermore, a standard method is still needed to characterize polar volatile PIDs such as TFA. LC-MS/MS methods for the analysis of TFA and other ultrashort-chain PFASs are available[127], but sampling

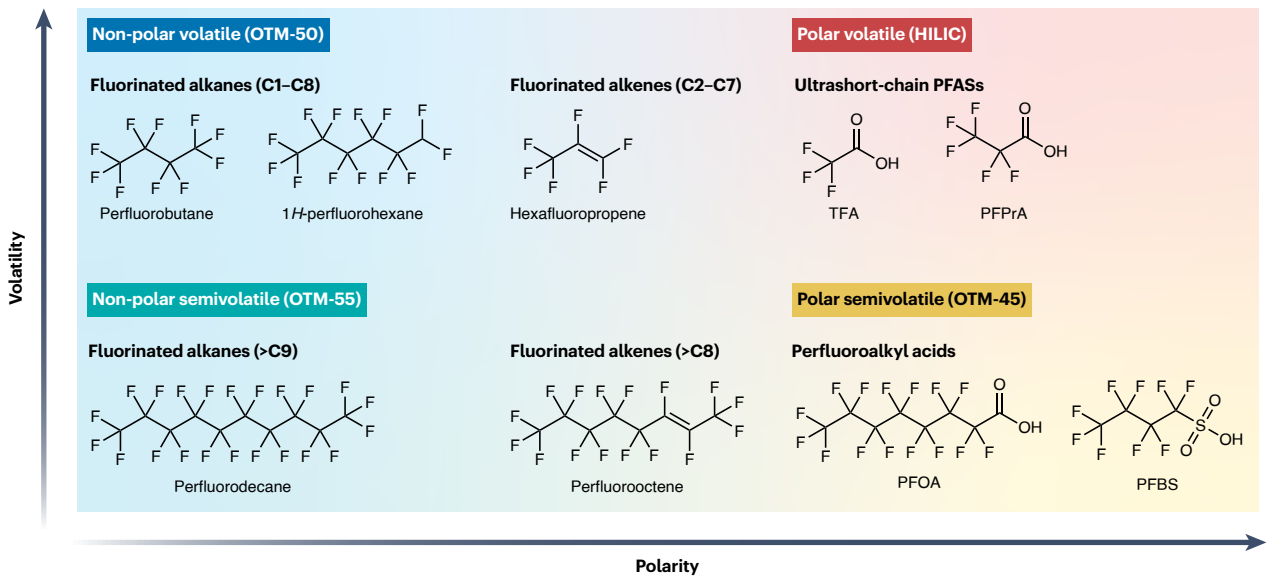

Fig. 4 | Categorizing PIDs. Categories of products of incomplete destruction (PIDs) from per- and polyfluoroalkyl substances (PFASs) based on their polarity and volatility. The analytical methods used to measure PIDs from each category are stated in parenthesis; note that OTM-55 is still under development. Different analytical approaches are needed to target different chemical species. Box 2 | Analytical methods for PID characterization

OTM-45

Strengths

- Currently includes 49 targeted per- and polyfluoroalkyl substances (PFASs) (C4 and larger)[117]
- Quantifies the targets through isotope dilution, which provides highly accurate quantitative data
- Analysis largely derived from US Environmental Protection Agency (EPA) Methods 533, 537.1 and 1633; this aids in wider adoption by commercial labs and simplifies interpretation[197–199]
- Performance based, and thus can be modified without substantial effort as analytical technologies improve

Weaknesses

- Complex sampling train and only snapshots of emissions
- Potential contamination of targeted analytes due to the complex sampling train, potentially leading to false positives[118]
- Acyl fluorides are converted to perfluorocarboxylates in aqueous impingers, which limits any ability to distinguish between these two classes of compounds[70]
- Analytical costs can be high, leading to less-frequent sampling

Potential modifications

- Non-targeted analysis of extracts can be used to determine additional products of incomplete destruction (PIDs)
- Integration with OTM-50 sampling train lines to enable simpler sample collection
- Sample collection protocol for closed and open reactor systems

Method 320/ASTM D6348

Strengths

- Obtains real-time Fourier-transform infrared spectroscopy data[129,131]
- Can be used to monitor CF_4 and C_2F_6 emissions to provide an indicator of effective PFAS destruction and PID emission
- Can measure inorganic and organic compounds, such as HF, CO_2 and volatile organic fluorine

Weaknesses

- Poor sensitivity unless a very long path cell is used
- Moisture can interfere and impact sensitivity
- Fluorinated compounds can have overlapping peaks
- Reference spectra needed for all potential compounds in the sample

Potential modifications

- Increase path cell length (>100 m) to improve sensitivity
- Use deconvolution and machine learning techniques to circumvent the issue of overlapping peaks

OTM 50

Strengths

- Currently includes 30 known and suspected PIDs[118,200]
- Considers non-targeted analysis to identify new compounds and incorporate them into the target list[38,120]

Weaknesses

- Expansion of current target list limited by the availability of commercially available standards
- Requires specialized instrumentation for analysis
- Analytical costs can be high, leading to less-frequent sampling
- Only snapshots of emissions

Potential modifications

- Include standardized guidance for the identification and incorporation of tentatively identified compounds
- Include guidance on the use of surrogate compounds, such as CF_4 and C_2F_6, as an indicator of effective PFAS destruction and PID emission
- Integration with OTM-45 sampling train lines to enable simpler sample collection

Chemical ionization mass spectrometry

Strengths

- Real-time measurement[143,144]
- High sensitivity[141,147]
- Can do targeted and non-targeted (time-of-flight mass spectrometry only) analysis[146,147]

Weaknesses

- Compound detection is dependent on the reagent gas used
- The generation of quantitative gas-phase standards for semivolatile compounds for calibration is challenging
- No commercial vendor available for field testing
- Requirement of specialized system and high-expertise users will add to costs

Potential modifications

- Design a system with multiple reagent gases to avoid needing to switch

trains need to be evaluated for their efficiency in quantitatively sampling polar volatile PIDs from emissions generated by PFAS destruction technologies.

Real-time analytical methods

Although off-line methods are often used for regulatory compliance sampling, more frequent and (near) real-time analysis of gaseous streams is sometimes helpful for pilot-scale and full-scale evaluations to enable real-time adjustments to operational parameters. Such measurements can be achieved with in-line and on-line methods, which continuously measure the actual gas or side (slip) stream of interest, respectively. There are two promising commercial analytical techniques that have been developed and partially validated for PFASs and PFAS-derived PIDs: Fourier-transform infrared (FTIR) spectroscopy (Method 320/ASTM D6348) and chemical ionization mass spectrometry (CIMS).

FTIR spectroscopy can be used for semiquantitative analysis of incinerator stack emissions[128–130]. The C–F bond absorbs infrared radiation strongly from ~900 cm^{-1} to 1,500 cm^{-1}, enabling the use of FTIR to identify and quantify some PFAS-derived PIDs[131,132]. This approach is a viable candidate for the analysis of gas-phase PIDs and initial laboratory-scale efforts to examine PFAS-derived PIDs relied on infrared spectral analysis[73]. FTIR can also be used for regulatory compliance sampling, particularly for emissions of fluorocarbons containing one to two carbons[129]. Advances in data processing algorithms could enable real-time analysis[133–137]. Additionally, the analytical sensitivity of the technique could be increased by increasing the cell path length, but this development often reduces the temporal resolution. Efforts are being made to establish FTIR reference spectra for PFAS-derived PIDs to increase the accuracy and sensitivity of the measurements[118,131].

CIMS is a commonly used and potentially field-deployable tool for the analysis of volatile and semivolatile compounds in air[138–142]. In CIMS, gas-phase compounds react with a reagent gas to form an ion that can be detected by mass spectrometry[143,144], with different reagent gases being used to selectively ionize different compounds. A specific type of commercially available CIMS system, chemical ionization time-of-flight mass spectrometry (CI-TOF-MS), can acquire data for a broad range of compounds (FTOHs, PFCAs, hexafluoropropylene oxide dimer acid (HFPO-DA) and HF) very quickly (within 100 ms) and can detect target and non-target chemicals. CIMS[145,146] and specifically CI-TOF-MS[147–149] systems have been used for PFAS analysis with various reagent gases and ionization approaches[147–154]. CI-TOF-MS is attractive as a tool for in-line or on-line analysis of gaseous PFASs and PFAS-derived PIDs owing to its low detection limit (1.4 pptv)[147] and the broad range of compounds that can be detected[37,147,151,152]. The success of CIMS depends on the choice of reagent gas and the development of more reliable and robust approaches and algorithms for the quantitative detection of semivolatile compounds.

Other emerging mass spectrometry methods, some of which are field portable[155,156], can theoretically perform real-time measurements. However, these techniques have limited quantitative capabilities or have been limited in their application to PFAS-derived PIDs. Ambient ionization, which can be performed under ambient atmospheric conditions, has emerged as a potential means to achieve real-time analyses[157–160] through approaches such as desorption electrospray ionization[161] and direct analysis in real time (DART)[162]. For example, the DART approach has been used to characterize volatile PFASs in situ[163]. Other approaches using ambient ionization, such as dielectric barrier discharge ionization[164,165], low-temperature plasma ionization[166,167] and microwave-induced plasma ionization[168], have been used to detect gas-phase and volatile organic compounds for alternative applications. Although these systems have not yet been applied to gas-phase PFASs, they can provide suitable ionization sources for in-line, on-line and off-line analysis. Secondary electrospray ionization has also been used for ambient vapour analysis[169–174]. When combined with mass spectrometry, this approach can achieve extremely low detection limits[175] and can be applied to environmental analyses[176,177], suggesting that it could be a strong contender for analysing gaseous PFAS-derived PIDs.

Environmental and toxicological impacts of PIDs

Owing in part to the strength of their C–F bonds, PFAS-derived PIDs can be persistent in the atmosphere, capable of long-distance transport, and subject to complex transformation and degradation pathways. The environmental behaviour, receptor exposure, and toxicological impacts and therefore the risk of PFAS-derived PIDs are largely unknown. However, insights can be gained from extensively studied compounds, specifically perfluoroalkanes such as CF_4 and C_2F_6, and the perfluoroalkene tetrafluoroethene (C_2F_4). Perfluoroalkanes predominantly originate from industrial sources and are persistent gases with extended atmospheric half-lives of the order of 10^5 years[178]. In contrast, perfluoroalkenes have much shorter atmospheric half-lives, typically hours or days (US National Toxicology Program).

Exposure to PFAS-derived PIDs via inhalation is a risk for communities living near PFAS destruction technologies and PID-producing industries (Fig. 1). Inhalation toxicity assessments for PFAS-derived PIDs are very limited[118]. Although exposure to perfluoroalkanes can cause asphyxiation when they displace enough oxygen, with the risk increasing for heavier molecules, their general chemical toxicity is considered low[179]. There is also some evidence that perfluoroalkenes could be human carcinogens (US National Toxicology Program).

The known environmental and toxicological impacts highlight the importance of the development and optimization of effective PFAS destruction technologies. The goal of these technologies should be to avoid the emission of PFAS-derived PIDs with long-term environmental persistence that could pose a risk to human and ecological receptors. To achieve this goal, further efforts are needed to optimize operating conditions, reactor design, and the management of emissions to guide the decomposition process toward complete mineralization.

Summary and future perspective

There is an urgent need to destroy PFASs in materials such as AFFF, contaminated environmental matrices, and residuals from non-destructive concentration technologies that remove PFASs from air, water, and soil. Numerous incumbent and emergent technologies can achieve high DREs for PFASs known to be present in affected materials. However, DREs alone are insufficient to ensure the absence of harmful air emissions and residuals from destructive technologies. There is computational and experimental evidence that PIDs with a wide range of physicochemical characteristics can form during PFAS destruction. Therefore, multiple off-line, in-line, and on-line methods have been developed or are under development to comprehensively characterize gas-phase and aerosol-phase emissions from PFAS destruction technologies. Despite these advances, understanding of what PIDs are produced, and of their risks to humans and the environment, remains limited.

There are very limited data available so far on air emissions and residuals from PFAS destruction technologies. It is important, therefore, to use existing offline and in-line analytical methods to provide confidence that destructive technologies effectively destroy PFASs while limiting PID formation. Additionally, robust data collected under real-world conditions that evaluate DREs and the presence of PIDs will help to identify viable options for PFAS destruction. To this end, the US EPA has released interim guidance on the destruction and disposal of PFASs and materials containing PFASs[85]. It focuses on the current state of the science for large-scale technologies that can destroy PFASs and includes a framework for evaluating emerging technologies for PFAS destruction and disposal. The EPA is required to update the guidance as appropriate, but no less frequently than every three years.

Data for PFAS destruction technologies should be collected at optimal and suboptimal operating conditions to understand the potential for harmful emissions under various conditions, including system failures. Furthermore, existing data and data being collected in ongoing and future research efforts should be deposited in a database. Such a database would

enable meta-analyses to identify the most promising PFAS destruction technologies and potential risks associated with system failures.

It is important to understand the identity of PFAS-derived PIDs to ensure that air pollution control devices are designed and operated to manage undesirable PIDs. Although several methods exist to characterize gas-phase and aerosol-phase emissions from PFAS destruction technologies, they do not cover the entire spectrum of potential PIDs that might form. Therefore, standard methods are needed for non-polar semivolatile PFASs (such as anticipated with OTM-55) and polar volatile PFASs such as ultrashort-chain PFASs, including TFA. Analyte lists for targeted methods, such as OTM-45 and OTM-50, could also be expanded based on findings from non-targeted analysis workflows. Such methods should be complemented by approaches to measure the total gaseous fluorine to assess whether targeted methods are missing important PFAS-derived PIDs[180]. In addition, real-time (or near real-time) methods should be developed and implemented to assess process performance, particularly for identifying compounds that are indicators of system failure or suggest that a system is operating at suboptimal conditions.

The human health and environmental risks associated with gas-phase emissions of PFAS-derived PIDs remain poorly understood. The toxicity of individual PIDs, mixtures of known PIDs, and whole gas-phase emissions should be assessed through various approaches, including effect-directed analysis to identify PIDs of toxicological relevance; screening with high-throughput methods to identify important toxicological endpoints; and toxicity testing to establish reference doses for individual PIDs. Additionally, the potential for environmental harm associated with the operation of and emissions from PFAS destruction technologies needs to be determined. Gases such as CF_4 and C_2F_6 are common byproducts of multiple technologies and are hard to avoid. Therefore, life cycle analyses should be conducted to assess the environmental cost or benefit of PID destruction: for example, comparing the environmental impacts of CF_4 emissions with the emissions from additional energy required to fully destroy CF_4.

Finally, there is a clear need to communicate what is known and what remains unknown with potentially affected communities. Clear and transparent communication should focus on existing methods for PFAS-derived PID sampling and analysis, and the performance of current waste management technologies to provide a comparison baseline for emerging technologies. Such focused communications can also aid in explaining what is currently known about airborne emissions, and how this knowledge can be used in identifying sources of exposure to PFASs and their relative risk. Standard methods should be used to determine PFASs and PFAS-derived PID concentrations in the ambient air of communities near facilities that are manufacturing, using or destroying PFASs. Coupled with source apportionment and risk assessment, this information would be important for community outreach. Although PFAS mineralization can require high energy input to destroy potential PIDs, minimizing the overall human and environmental impacts is paramount to maximizing risk reduction from PFAS destruction.

Acknowledgements

The views expressed in this article are those of the authors and do not necessarily represent the views or policies of the US Environmental Protection Agency (EPA) or Department of Defense (DOD). Any mention of trade names, manufacturers or products does not imply an endorsement by the United States Government or the US EPA or DOD. US EPA and DOD and its employees do not endorse any commercial products, services or enterprises. This review was supported, in part, by funding from the US Army Corps of Engineers (W912HZ-23-2-0009) and various Strategic Environmental Research and Development Program (SERDP) and Environmental Security Technology Certification Program (ESTCP) projects through the US DOD.

Author contributions

S. Silsby provided overall coordination for the Review. S. Silsby, S. Sühnholz, D.R.U.K. and C.P.H. developed the concept for the Review. Initial draft writing was conducted by S. Silsby, S. Sühnholz, M.Q., K.D., C.Y., D.R.U.K. and C.P.H. Figures were drafted by S. Silsby, S. Sühnholz, M.Q. and N.S. All authors contributed views and opinions, and reviewed the final manuscript.

Competing interests

R.S.G. is an employee of Alcoa Corporation, which is involved in bauxite mining, alumina refining and aluminium smelting operations worldwide. R.S.G. is an inventor of patents US9795920B2, US9327237B2, US8894748B2, US8137649B2, US7906089B2, US7645430B2 and EU2265357 in the area of gas exhaust treatment as well as patents US8673152B2, US8206586B2, US8157995B2, US7897049B2 and US5837145 in the area of water treatment. C.P.H., T.J.S. and S.H. are inventors on patent US11577111 related to the use of hydrothermal alkaline conditions for PFAS destruction. T.J.S. is also a paid technical advisor for Aquagga, Inc., which has licensed patent US11577111. The remaining authors declare no competing interests.

HIGHLIGHTS

- Two leachates were collected from landfill gas systems: condensate and well pumpout.
- Gas condensate is not colored, contains ammonia, alkalinity, and some metalloids.
- Gas well pump-out is dark in color, resembles leachate, high chloride concentrations.
- Condensate has lower total PFAS abundance, but greater diversity of species.
- PFAS which are more abundant in condensate include semi-volatile FTOHs and FASEs.

ABSTRACT

While per- and polyfluoroalkyl substances (PFAS) have been reported extensively in municipal solid waste (MSW) landfill leachate,they have rarely been quantified in landfill gas or in discrete landfill liquids such as landfill gas condensate (LGC), and the potential for PFAS to partition to the condensate has not been reported. LGC and leachate collected from within gas wells known as gas well pump-out (GWP) from three MSW landfills underwent physical-chemical characterization and PFAS analysis to improve understanding of the conditions under which these liquids form and to illuminate PFAS behavior within landfills. LGC was observed to be clear liquid containing ammonia and alkalinity while GWP strongly resembled leachate – dark in color, high in chloride and ammonia. Notably, arsenic and antimony were found in concentrations exceeding regulatory thresholds by over two orders of magnitude in many LGC samples. LGC contained a lower average concentration of ΣPFAS (19,000 ng L) compared to GWP (56,000 ng L); however, LGC contained more diversity of PFAS, with 53 quantified compared to 44 in GWP. LGC contained proportionally more precursor PFAS than GWP, including more semi-volatile PFAS which are rarely

measured in water matrices, such as fluorotelomer alcohols and perfluoroalkane sulfonamido ethanols. This study provides the first detailed comparison of these matrices to inform timely leachate management decisions.

Environmental Implications Statement

The US EPA is proposing to designate two PFAS (PFOA and PFOS) as hazardous substances. While both were phased out of production decades ago, they continue to enter landfills through consumer waste and are the degradation product of precursor PFAS. PFAS have been measured consistently at high concentrations in landfill leachate; however, little is known about PFAS behavior under full-scale landfill conditions. Here, we characterize PFAS and other constituents in two distinct liquids collected from landfill gas systems to explore each liquid's origin, inform the most appropriate management strategy, and to identify possible sources of PFAS leaving landfills.

Data availability

Data will be made available on request.

1. Introduction

Waste decomposition within a landfill produces gas (landfill gas; LFG) consisting primarily of methane and carbon dioxide, which are often collected and either flared to oxidize methane or processed into a renewable fuel source. During the vacuum collection of LFG, gas from the warm, moist interior of the landfill comes into contact with ambient air temperatures, and that water vapor condenses to form a liquid which can accumulate in the landfill gas collection and control system (GCCS). GCCS liquids are often broadly described as gas condensate [6], but true leachate, derived from within the waste mass itself, which collects in the gas wells (referred to here as gas well pump-out, or GWP), constitutes another major source of liquids in the GCCS. Liquids from a landfill GCCS are normally mixed with leachate intercepted at the bottom of the lined landfill but could be isolated if desired. Commonly referred to as landfill gas condensate (LGC), GCCS liquids are removed from pipes and wells installed and operated to extract and convey the gases produced as a result of waste decomposition. A diagram of a GCCS is included in Fig. 1 to illustrate the discrete sources of these liquids. LGC typically represents a small fraction of a landfill's total leachate generation and is commonly mixed with other sources of landfill leachate for disposal. The US Environmental Protection Agency (US EPA) estimated landfill LGC generation for an individual landfill site in the range of 2700 to 7500 L per day [6]. For comparison, the landfills used in this study generate approximately 100,000 L of leachate per day. An example calculation to estimate LGC generation based on LFG production is included in Section S1 of the supplemental information (SI).

Per- and polyfluoroalkyl substances (PFAS) are an emerging constituent of concern which present an operational challenge with landfill leachate due to their toxicity, persistence, and lack of viable treatment technologies [14,16,20,28,31,39,5,56,59,60]. Studies have reported diverse and significant concentrations of PFAS in landfill leachate worldwide [28,5,8]. The most well-studied PFAS, perfluorooctanoic acid (PFOA) and perfluorooctanesulfonic acid (PFOS), have been detected in leachate at concentrations ranging from ng L^{-1} to μg L^{-1} [16]. In the US, PFOA and PFOS have been measured at concentrations as high as 50 μg L^{-1} [47] in landfill leachate, and PFAS regulations are being promulgated across the US and globally [19,42,49,54,53]. Although landfill leachates are not usually subject to regulation, the recent proposal to designate PFOA and PFOS as CERCLA Hazardous Substances [55] may determine how leachate is managed in the future, as any wastewater treatment effluent requirements will have upstream impacts on leachate management decisions.

While leachate has been described extensively in scientific literature, recent studies have placed focus on studying the behavior of PFAS (e.g., partitioning, transformation, and potential volatilization) within municipal solid waste (MSW) landfills [29]. Gas and air measurement of PFAS is comparatively limited in the literature; however, PFAS have been measured in ambient air above landfills and wastewater treatment plants [22], suggesting that they are either volatilizing or aerosolizing and entering the air [23]. To this point, PFAS have been shown to travel great distances through the air and have been measured in soil, water, and biota in remote locations such as the arctic [62]. The term "semi-volatile" is defined in different ways across the literature in reference to PFAS as well as other chemicals and might refer to compounds which possess a specified range of vapor pressures, or by their observed partitioning behaviors. Several PFAS, including fluorotelomer alcohols,

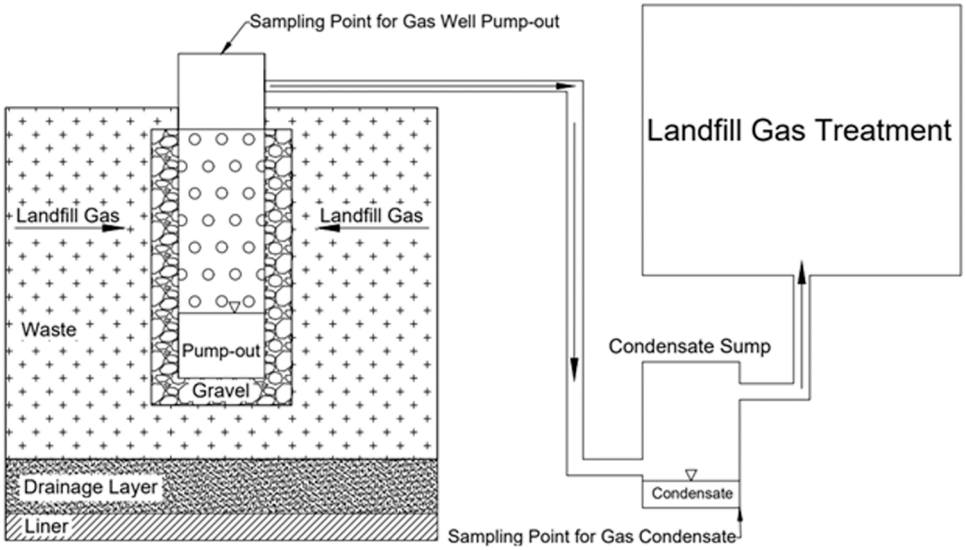

Fig. 1. Schematic of typical gas collection system layout and example gas condensate and gas well pump-out sampling points.

KD2609

perfluoroalkane sulfonamides and sulfonamido substances, and terminal perfluoroalkyl acids, have been quantified using both gas and liquid chromatography, indicating their presence in both phases [36,37] Because of their different origins, LGC and GWP are expected to differ significantly from each other in chemical composition. Differences between LGC and GWP are anecdotally recognized within the solid waste industry, although some misconceptions persist. To explore these differences, with a focus on PFAS, LGC and GWP were collected from three MSW landfills in central Florida and underwent PFAS analysis and other characterizations. This is the first study of its kind to evaluate these landfill liquids, and the results of this investigation provide critical insight for the management of discrete sources of leachate within the landfill, and also shed light on the partitioning and transformation behavior of PFAS within MSW landfills.

2. Materials and methods

2.1. Sample collection

Twelve LGC and five GWP samples were collected from three active MSW landfills (referred to as Landfill A, B, and C) in Florida between July and October 2021. Table S1 provides detailed information regarding each site. GWP samples were collected using in-place submerged pumps already installed in the gas wells. The flexible hose connecting these pumps to the leachate collection system was removed from the pipes and used for collection. LGC samples were collected at the condensate knockouts at low points in the GCCS. Pumps installed in the knockouts were used for collection. Samples were collected into one methanol-rinsed 2-L high-density polyethylene (HDPE) bottle for PFAS analysis and two methanol-rinsed 500-mL HDPE bottles, with preservatives, for the physical-chemical parameters. During sampling, an HDPE bottle with PFAS-free water was opened and poured into another HDPE bottle to serve as a field blank. Samples were transported between the field and laboratory on ice and stored at −20 °C. All samples were stored and preserved according to each analysis method specifications in the laboratory (Table S2 in the SI).

2.2. Field and laboratory physical-chemical characterization

LGC and GWP samples were analyzed for pH, conductivity, chloride, biochemical oxygen demand (BOD), chemical oxygen demand (COD), ammonia-nitrogen, alkalinity, and trace metals. Conductivity and pH were measured in the field upon sample collection using a field probe (YSI 556 Multi-probe system, Xylem, Inc., Washington, DC). Ammonia-nitrogen (NH_3-N) in the leachate was measured using the salicylate method (Method 10031; Hach Company, 2012) and spectrophotometric analysis (DR 3900, Hach Company, Loveland, CO). COD was measured in the LGC and GWP using the reactor digestion (Hach Method 10212) and spectrophotometric analysis method (DR 3900, Hach Company, Loveland, CO). Chloride and alkalinity were analyzed using the colorimetric method (HACH Method CD-51 and 10239, respectively). LGC and GWP samples also underwent digestion according to EPA Method 3010 A [50], followed by analysis by inductively coupled plasma – atomic emission spectroscopy (ICP-AES; Thermo Scientific iCAP series 6000) according to EPA Method 200.7 [51] to quantify metals in solution. Select subsamples were sent to Katahdin Analytical Services (Scarborough, ME) on ice for BOD analysis according to Standard Method 5210 B [1].

2.3. PFAS extraction, analysis, and quantitation

The sample extraction method for PFAS was adapted from Robey et al. [44]. Leachate was centrifuged to remove the particulate matter and a 50-mL subsample was taken from the centrifuged sample and adjusted to pH 4–5 using glacial acetic acid (source, location), then spiked with 25 μL of mass-labeled internal standards (Tables S3 and S5 in the SI). Strata-X-AW, 100-μm Phenomenex polymeric weak anion exchange cartridges (500 mg/6 mL), were conditioned with 4 mL of 0.3 % ammonium hydroxide in methanol, followed by 3 mL of Optima-purity grade methanol (Fisher Scientific, Hampton,NH) and 4 mL of an ammonium acetate/acetic acid buffer solution (pH = 4). After loading the sample at a rate of one drop per second, cartridges were washed with the buffer solution (4 mL) then eluted with methanol (2 mL) and 0.3 % ammonium hydroxide in methanol (6 mL). Extracts were concentrated to 1 mL at 32 °C under a constant flow of ultra-high purity nitrogen gas using a Biotage TurboVap II.

Extracts were analyzed for 92 PFAS (full list in the accompanying SI Table S3; 68 were purchased from Wellington Laboratories Inc. [Guelph, ON, Canada] and 24 were donated by Synquest Laboratories Inc. [Alachua, FL, USA, abbreviated as Syn #] and Oakwood Products Inc. [Estill, SC, USA, abbreviated as Oak #]) using a Thermo Scientific Vanquish ultra-high pressure liquid chromatograph (LC) coupled to a TSQ Quantis triple quadrupole mass spectrometer (UHPLC-MS/MS). The LC and MS parameters and accompanying compound abbreviations can be found in Section S3 of the SI (Tables S3 and S4). PFAS were quantified using a 14-level calibration (from 10 to 100,000 ng L^{-1}) developed through dilutions of multiple primary stock solutions. Isotopically-labeled internal standards for 27 compounds (also purchased from Wellington Laboratories, Inc.) were added to each calibration level at 800 ng L^{-1}. If an internal standard was not available for a compound or had poor response on the instrument, another internal standard similar in retention time or structure was used for quantitation. The corresponding mass-labeled standard for each targeted compound are indicated in Table S3 in the SI. Scheduled selected reaction monitoring transitions were used to detect and quantify PFAS in a total of 18 samples and 7 controls (including blanks). The most intense transition was used to quantify PFAS, while the second transition was used to confirm identification (if possible). Acquisition and peak integration were performed using Xcalibur v.4.1 (Thermo Fisher Scientific, Waltham, MA). PFAS were quantified following integration of the peak area for the most intense transition of each analyte. A linear regression model was used to build the calibration curves (individual concentrations listed in Table S5 of the SI), with intercept, slope, and correlation coefficient values calculated over the linear dynamic range for each PFAS species. Instrument detection and quantification limits (LOD and LOQ, respectively) were calculated for each compound using the calibration curve and visual signal-to-noise (S/N) determination (S/N of 3 and 10 for LOD and LOQ, respectively). Detection limits were also calculated using the method described by US EPA; however, for most compounds, the visual method produced a higher (i.e., more conservative) LOD, and seven replicates of each limit showed higher reproducibility (relative standard deviation < 15 %) than the EPA approach, so the visual method was employed in this study.

2.4. PFAS quality control (QC) and extraction efficiency

A detailed discussion of the QA/QC procedures is included in section S4 of the SI. QC samples included field blanks, extraction blanks, solvent blanks, and laboratory control samples. Field blanks consisted of Optima-purity grade water (Fisher Scientific, Hampton, NH) water exposed to ambient air and conditions at the landfills sites in order to capture potential contamination in the entire workflow. Extraction blanks were prepared with Optima water and extracted along with the LGC and GWP samples to identify contamination derived from the extraction process. A solvent blank was run within the instrument method queue every five samples to monitor potential carryover and instrument-derived contamination. Pooled samples of each matrix (LGC and GWP) were used as laboratory control samples to measure extraction efficiencies (see Table S6).

KD2610

2.5. Data analysis

To calculate summary statistics across samples, physical-chemical constituents (e.g., chloride, BOD, COD, ammonia-nitrogen, and trace metals), which were not detected, were given a value of one half the detection limit for each type of analysis. Because the data were non-normally distributed, a Mann-Whitney-test (a = 0.05) was used to compare the results between matrix types to determine if they were in fact significantly different from one another. Relative concentrations of individual PFAS in each matrix type (LGC and GWP) were compared as a function of chain length and functional group in order to explore the role of PFAS structure on partitioning behavior within the landfill. A two-tailed spearman correlation was used to find correlations between constituents. A correlation p value less than 0.05 was considered significant.

3. Results and discussion

3.1. Physical-chemical parameters

Although little has been published comparing LGC and GWP matrices, an understanding of the sources of each effluent type informs the expectation of significant differences between the two. For example, GWP, like landfill leachate, is expected to be dark in color and higher in organic matter and water-soluble constituents, such as chloride. Ammonia, on the other hand, might be present under certain conditions as either a gas or water-soluble ion and is likely to be found in both sample types. LGC is expected to be (and was observed to be) clear in appearance, as shown in the picture in Fig. 2. This figure also demonstrates the stark difference between these liquids, which are often conflated or misidentified in the landfill industry. Box-and-whisker plots comparing the range of values for bulk physical-chemical parameters (chloride, alkalinity, COD, pH, ammonia-nitrogen, and conductivity) are included in Fig. 3.

Chloride and conductivity, which are proxies for total ions present in solution, were both significantly higher ($p = 0.002$ for both) in the GWP (mean chloride: 4840 mg L^{-1}, mean conductivity: 24.4 mS cm^{-1}) than in the LGC (mean chloride: 110.8 mg L^{-1}, mean conductivity: 7.33 mS cm^{-1}), with chloride below the detection limit of 20 mg L^{-1} in 58 % of the LGC samples. Average alkalinity and pH were higher in GWP (mean alkalinity: 9200 mg L^{-1}, mean pH: 8.1) than in the LGC (mean alkalinity: 4000 mg L^{-1}, mean pH: 7.2) ($p < 0.02$ for both). While microbially-driven processes within the landfill can contribute to acidic pH in landfill leachate (and, presumably, GWP), especially in the early years of landfill operation [34,43], carbonate-driven alkalinity results from high levels of carbon dioxide generated during organic waste decomposition [35] – this carbonate alkalinity also contributes to highly buffered LGC. The wider range of pH measured in the LGC samples (5.1–8.2) was representative of the difference in landfill conditions; LFG constituents such as hydrogen sulfide can have a significant impact on condensate pH [38].

Fig. 2. Sample of gas well pump-out (GWP) (left) and gas condensate (LGC) (right). The gas well pump-out is a dark brown in color, while the gas condensate is clear.

The decomposition of organic matter, especially food waste, produces ammonia. The distribution of ammonia gas (NH_3) and ammonium ion (NH_4^+) is driven by pH – at pH less than 7, very little ammonia gas is present, and at pH of 9, the distribution is approximately 50 % of each. Within the range of pH measured in the GWP in this study, ammonia gas was likely present in the landfill gas, which could have then partitioned to the LGC. Ammonia-nitrogen, a measurement of the total ammonia/ammonium content of a sample, was lower, on average, in the LGC (mean: 912 mg L^{-1}) than in the GWP (mean: 1870 mg L^{-1}) samples ($p = 0.01$). COD, analyzed in all samples, averaged 5180 mg L^{-1} in the LGC and 13,200 mg L^{-1} in the GWP ($p = 0.04$). BOD, which makes up a fraction of COD and is a measurement of biologically available organic matter, averaged 139 mg L^{-1} in the three LGC samples for which BOD was measured, and 962 mg L^{-1} in the GWP samples ($n = 5$).

While metals concentrations in the GWP were typical of MSW leachate [24,26,35,58], nearly all metals were significantly lower or below detection limits in the LGC samples – with the exception of arsenic and antimony, two metalloids which have been previously reported in MSW landfill gas [40,13,21]. Arsenic concentrations ranged between 0.034 mg L^{-1} and 0.85 mg L^{-1} (mean: 0.47 mg L^{-1}) in the GWP and between 0.055 mg L^{-1} and 2.85 mg L^{-1} (mean: 1.06 mg L^{-1}) in the LGC. Antimony concentrations ranged between 0.015 mg L^{-1} and 0.29 mg L^{-1} (mean: 0.19 mg L^{-1}) in the GWP and between 0.060 mg L^{-1} and 2.20 mg L^{-1} (mean: 0.60 mg L^{-1}) in the LGC. A box and whisker plot of arsenic and antimony concentrations in both matrices is included in Fig. 4. While mean concentrations were not significantly different between the matrices, at the high end of the range, LGC samples were over 100-times the risk-based thresholds for both metalloids. In the top 25 % of samples, arsenic exceeded the Florida groundwater cleanup target level (GCTL) – based on the EPA primary drinking water standard (DWS) of 10 μg L^{-1} – by a factor of more than 150, and antimony exceeded the GCTL of 6 μg L^{-1} by a factor of 200 in the top quartile of samples [12,52]. Although other metals/metalloids are known to volatilize in the environment or under landfill conditions (e.g., Cd, Pb, Se, and Sn) [40,33,41], none of these except for arsenic and antimony were detected consistently in the LGC. Concentrations of all metals in both sample types are included in Table S6 in the SI.

A balance of the total ions measured in the aqueous form for each matrix illustrates their fundamental differences. Among the LGC samples, ammonia and alkalinity (as bicarbonate) constituted 86 % of the 3380 mg L^{-1} total measured solids, while metals and anions made up the remaining 14 %. GWP was more evenly distributed, with metals/metalloids accounting for an average of 18 %, ammonium an average of 11 %, and anions an average of 30 % of the total solids (16,149 mg L^{-1}). The percent difference between anions and cations was 8.1 % and 4.3 % for LGC and GWP, respectively. These distributions are visualized in Fig. 5, with the unaccounted-for portion of the anions/cations represented as the “Balance”.

3.2. PFAS profiles in LGC and GWP

The total PFAS concentration ($\sum_{92}$PFAS) in LGC and GWP samples ranged from 3000 to 50,000 ng L^{-1} and 36,000–74,000 ng L^{-1}, respectively; the average $\sum_{92}$PFAS was three times higher in the GWP (56,000 ng L^{-1}) than in the LGC (19,000 ng L^{-1}). These concentrations are comparable to the range of PFAS concentrations measured in leachates collected from MSW landfill leachate collection systems [10,

KD2611

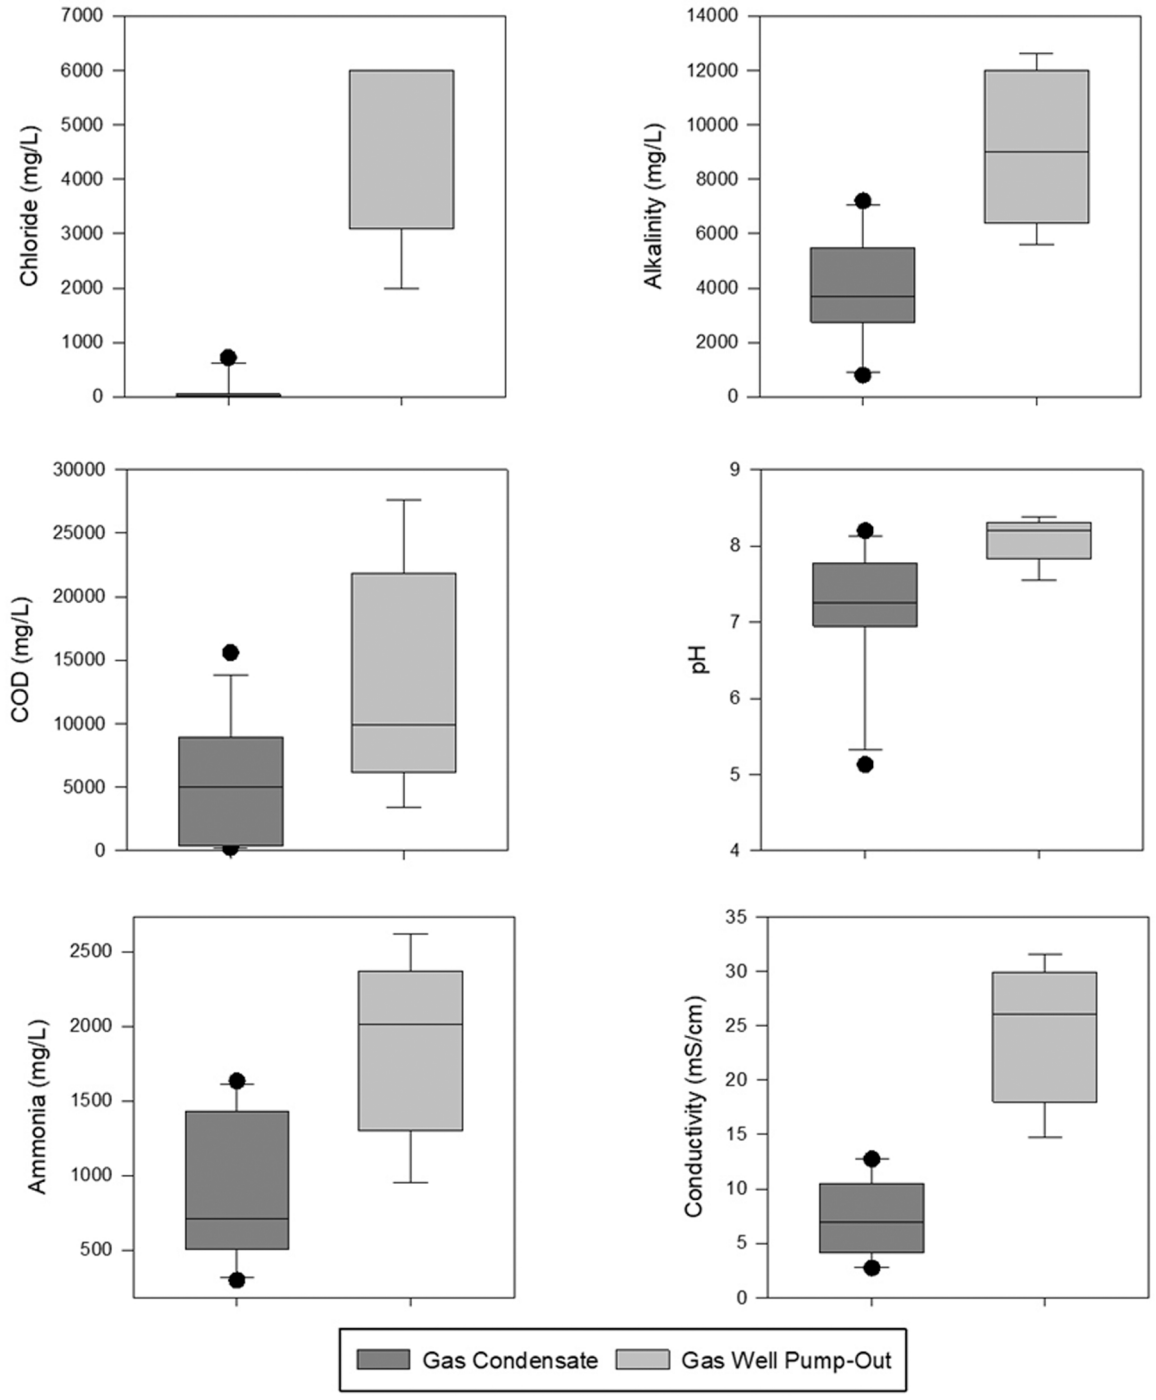

Fig. 3. Chloride, alkalinity, COD, pH, ammonia, and conductivity measurements in gas condensate (LGC) and gas well pump-out (GWP). Box-and-whisker plots represent 10-, 25-, 50-, 75-, and 90th percentile values.

44,46]. Like the physical-chemical constituent profiles of these matrices, the distribution of PFAS in each liquid matrix sheds light on the behavior (i.e., partitioning, transformation) of PFAS within the waste mass of an MSW landfill. Although concentrations were higher in the GWP, the diversity of PFAS (total number of quantified PFAS) was higher in LGC; 53 PFAS were quantified in LGC samples and 44 PFAS were quantified in GWP samples. This difference is illustrated in Figs. 6 and 7, which present the distribution of PFAS among class, subclass, and species for LGC and GWP, respectively. Seventeen PFAS (six PFAAs, six fluorotelomers, and five sulfonamides) were quantified in 100 % of LGC samples, and five PFAS (two PFAAs, two fluorotelomers, and one other precursor) were quantified in 100 % of GWP samples. Additionally, the ratio between terminal species (i.e., the breakdown product of other PFAS and which are known to not break down further under environmental conditions) and precursor species (i.e., PFAS known to degrade into terminal species) varied between the two matrices. Precursor PFAS represented the majority of $\sum_{92}$PFAS in both sample types, but a proportionally larger fraction in the LGC (70 % in the GWP vs 85 % in the LGC).

The detection frequency, mean, and median concentrations for terminal PFAS (which are further broken down into subclasses: perfluoroalkyl carboxylic acids [PFCAs], perfluoroalkane sulfonic acids

KD2612

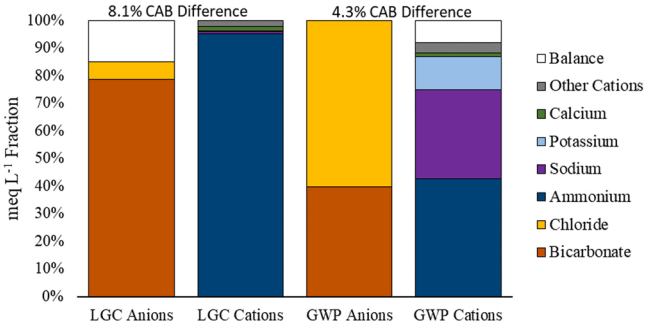

Fig. 5. Cation-anion balance (CAB) of the gas condensate (LGC) and gas well pump-out (GWP) matrices by the dissolved ions measured in solution.

[PFSAs], perfluoroalkane sulfinic acids [PFSiAs], and perfluoroalkyl phosphinic acid (PFPiAs) are detailed in Table 1 and in Fig. S1 in the SI for select species. Among the 28 terminal PFAS targeted in this analytical method, 19 were quantified in LGC or GWP samples. Again, while the total concentration of terminal PFAS ($\sum_{28}$Terminal) was higher in the GWP, the diversity of terminal PFAS in the LGC was higher – with 19 quantified in at least one LGC sample and 16 quantified in at least one GWP. Fifteen terminal PFAS were quantified in over half of the LGC samples and only nine in the GWP. (Tables 1, 2, and 3). Fig. 8.

While GWP was approximately evenly split between the two largest subclasses of terminal PFAS (58 % PFCAs and 42 % PFSAs), LGC was dominated by PFCAs, which represented 86 % of the $\sum_{28}$Terminal. PFSAs require higher temperatures for volatilization than PFCAs [11, 61], suggesting that PFCAs are also more abundant than PFSAs in LFG. This is notable because, while previous studies have reported thermal desorption of PFAS at temperatures between 100 °C and 500 °C [30,48], typical MSW landfill temperatures are only between 35 and 55 °C [27]. Perfluorobutanesulfinic acid (Syn34), a recently identified terminal PFAS [2], which has not previously been identified in landfill leachate, was quantified in over half of the samples of both matrix types. Long-chain PFCAs (>C10) were measured in LGC samples at concentrations similar or higher than those reported previously in landfill leachate [28,29,44] and at higher concentrations in the LGC than the GWP.

The detection frequency,mean and median concentrations for

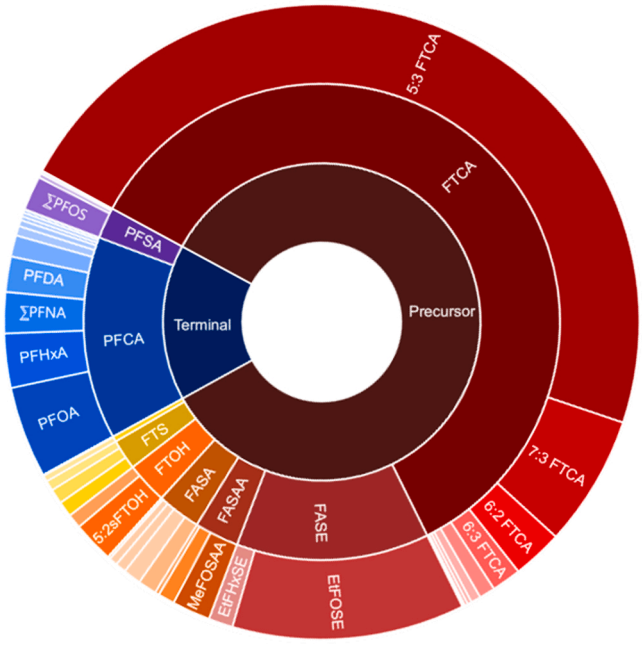

Fig. 6. PFAS distribution in landfill gas condensate (LGC). In the interest of legibility, only compounds which represented > ~1 % of $\sum_{92}$PFAS are labelled, mean concentrations for all PFAS are included in Tables 1, 2, and 3. precursor PFAS are detailed in Table 2 (fluorotelomers) and Table 3 (sulfonamides and other precursors). Box and whisker plots of all sample measurements are also included in Figs. S2 (fluorotelomers) and S3 (other precursors) in the SI. Of the 38 PFAA-precursors measured, 35 and 29 were detected in LGC and GWP samples, respectively. Precursors in both matrices were dominated by one PFAS: 5:3 FTCA, a fluorotelomer carboxylic acid which is well documented in landfill leachates and leachate-contaminated media [18,17,25,4,32]. 5:3 FTCA was detected in 100 % of both sample types and accounted for 55 % of the $\sum_{38}$Precursor in LGC and 87 % of the $\sum_{38}$Precursor in GWP. The remaining balance of $\sum_{38}$Precursor in GWP consisted primarily of other

KD2613

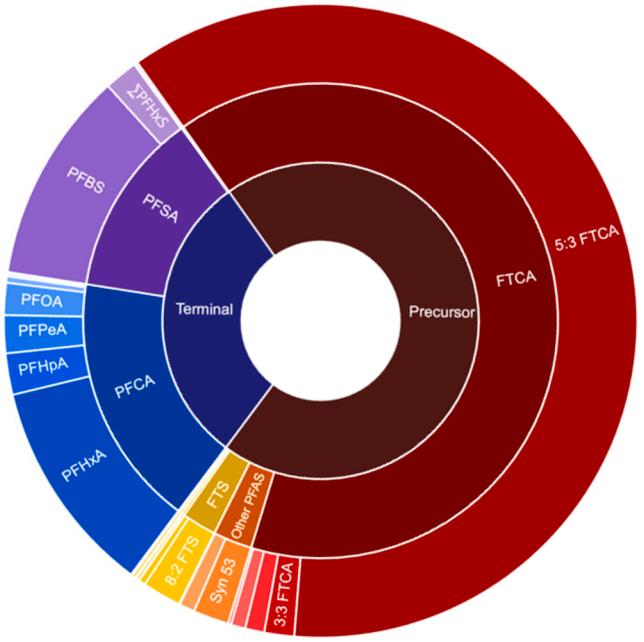

Fig. 7. PFAS distribution in landfill gas well pump-out (GWP). In the interest of legibility, only compounds which represented > ~1 % of $\sum_{92}$PFAS are labelled, mean concentrations for all PFAS are included in Tables 1, 2, and 3. fluorotelomer compounds (predominantly FTCAs and fluorotelomer sulfonates [FTSAs]). LGC contained a greater variety of precursor PFAS, especially sulfonamides, which represented not only a more significant fraction of the LGC (18 % of the $\sum_{92}$PFAS) compared to GWP (1.7 % of the $\sum_{92}$PFAS) but were found in higher concentrations in the LGC as well. An emerging PFAS of note, 6:2 fluorotelomer phosphate diester (6:2 diPAP), was measured in both the LGC (77 % detection frequency, mean: 500 ng L^{-1}) and in the GWP (80 % detection frequency, mean: 720 ng L^{-1}).

Select PFAS which have been measured in air samples and described as volatile or semi- volatile, were detected in aqueous matrices in this study. Fluorotelomer alcohols (FTOHs) are a class of PFAS known to volatilize which have been measured in air samples near MSW landfills and wastewater treatment facilities [3,57]. FTOHs are not commonly measured in liquid matrices; however, they are known to degrade into FTCAs and further into PFCAs, both of which are prevalent in MSW landfill leachate [62,7]. The two FTOHs targeted by this analysis (5:2 and 7:2 FTOH) were quantified in 77 % and 69 % of LGC samples, respectively, and in 0 % and 20 % of GWP samples, respectively. The other class of semi-volatile species included in this analytical method which are not frequently measured in liquid matrices, perfluoroalkane sulfonamido ethanols (FASE), were also identified in the LGC at a greater frequency and at higher concentrations than in the GWP. N-ethyl perfluorooctane sulfonamido ethanol (N-EtFOSE), which is a PFOS precursor, was quantified in 100 % of LGC samples at an average concentration of 2200 ng L^{-1} (compare with GWP, where it was measured in 80 % of samples at a mean concentration of 180 ng L^{-1}). N-ethyl perfluorohexane sulfonamido ethanol (N-EtFHxSE), a PFHxS precursor, was measured in 54 % of LGC at an average concentration of 230 ng L^{-1} and was not measured above LOD in any GWP samples.

A spearman correlation analysis was performed on both LGC and GWP to examine the relationships between physical chemical parameters and PFAS within each type of leachate. The results of the spearman correlation on the LGC data showed that there was no significant correlation ($p < 0.05$) between $\sum_{92}$PFAS and any of the physical-chemical parameters. Individual PFAS, however, did show positive correlation with select physical-chemical parameters, suggesting that these PFAS might share common release pathways into the LGC. 5:3 FTCA, which makes up almost half of the $\sum_{92}$PFAS in LGC, was most strongly correlated to chloride ($r = 0.628$, $p = 0.038$). The second most abundant fluorotelomer, 7:3 FTCA, was most strongly correlated with ammonia ($r = 0.800$, $p = 0.010$) and chloride ($r = 0.861$, $p = 0.001$). The small number of GWP samples limited the number of correlations that could be performed. The only significant correlation was a negative correlation between iron and $\sum_{92}$PFAS ($r = -0.900$, $p = 0.037$). Correlation coefficients between the most abundant PFAS across samples and physical-chemical parameters are included in the SI Tables S8 (LGC) and S9 (GWP).

3.3. Gas condensate partitioning as a function of carbon chain length

While $\sum_{92}$PFAS was greater, on average, in GWP than in LGC, the structure of individual PFAS correlated with partitioning behavior and the relative abundance of homologous PFAS in each matrix. The effect of carbon chain length on partitioning behavior has been studied previously in the interfacial layer [15,45,61,9], indicating a positive

Table 1
Percent of samples in which each terminal PFAS (carboxylic acids, sulfonic acids, and sulfinic acids) was detected and mean (standard deviation) and median concentrations of PFAS quantified in gas condensate and gas well pump-out samples. Mean, standard deviation, and median are in units of ng L^{-1}.

Analyte	Gas Condensate n = 12				Gas Well Pump-out n = 5			
	Detection Frequency	Mean (SD)		Median	%	Mean (SD)		Median

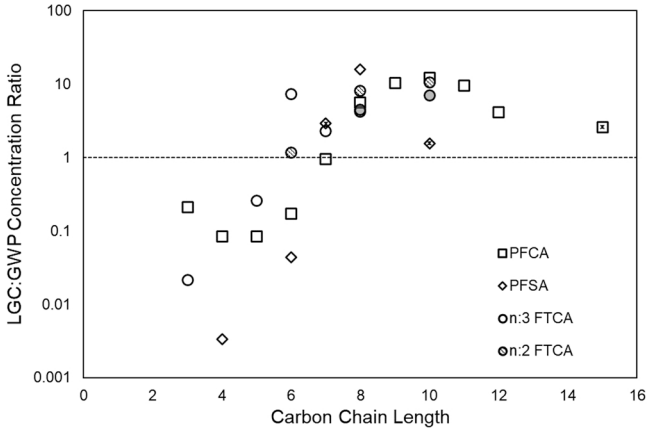

Fig. 8. LGC:GWP concentration ratio as a function of carbon chain length for PFAS in the PFCA and PFSA terminal classes and for FTCAs, the most abundant class of PFAS identified in this study. PFHpS, PFDS, and PFHxDA, indicated with asterisks (*) in the figure, were not measured in any GWP samples and one-half of the approximate detection limit was substituted to allow the calculation of a LGC:GWP ratio.

correlation between chain length and air-water interfacial partitioning. In a study of landfill leachate foam separation, Robey et al. [44] found a similar relationship among short chain PFAAs, which then reversed as air-water interface partitioning appeared to decrease among the longest chain PFAAs. While PFAS volatilization studies are less common, Zhang et al. [63] derived vapor pressures for nine PFAS and found a logarithmic relationship between the number of carbons in the compounds' carbon-fluorine chains and both vapor pressure and sublimation enthalpy. For every two-carbon increase in chain length, vapor pressure was found to decrease by approximately ten times, suggesting longer-chain PFAS have a lower propensity to volatilize. As illustrated in Fig. 7, the results of this study indicate that longer chain-length PFCAs, PFSAs, and FTCAs (the most abundant class identified in these samples) have a greater tendency to partition to the LGC, although this relationship weakens among the longest chain PFAS. These findings, placed in the context of the aforementioned studies, suggest that PFAS in LGC are a result of interfacial partitioning and potentially aerosolization, not volatilization. Compounds like PFHxDA, PFHpS, and PFDS were not measured in any GWP samples, so to estimate a relative concentration, one-half of the detection limit for these compounds was substituted for the mean concentration. This trend can also be seen in the box and whisker plots of the series included in the SI Figs. S1, S2, and S3.

4. Conclusion

The results of this study shed light on the conditions under which gas condensate and leachate are produced, and these findings provide valuable information about the fate and behavior of PFAS within MSW landfills. As PFAS regulations are promulgated at the state and federal level, as well as internationally, the results of this study contribute to a better understanding of how PFAS in waste contribute to PFAS in landfill effluent, which includes leachate and LFG. While the two leachate matrices studied here are typically combined and managed in the same manner as any other leachate type, separate management might reduce, for instance, precursor PFAS concentrations in leachate, which is treated using standard wastewater treatment techniques that has the potential to transform precursor PFAS to terminal PFAS, which are more likely to be regulated and are of concern. While active landfills may not be able to separate these leachate streams due to the infrastructure already in place, this could be considered for those that are able to as well as new facilities and landfill cells. This study represents the most in-depth characterization of these discrete liquid leachate matrices to date.

Previous research comparing PFAS in landfill leachate collection from waste collection vehicles prior to landfill disposal to leachate collected form a landfill liner system has found that under landfill conditions, PFAS are likely to transform from precursor species to terminal species [29]. Much less is known, however, about transformation, partitioning and potential volatilization of PFAS within the landfilled waste mass itself. In this study, two discrete leachate streams which have not been studied previously – LGC, a clear liquid formed when moisture in landfill gas condenses at ambient air temperatures, and GWP, a dark leachate formed in the upper layers of waste which collects in gas wells and is removed prior to reaching the bottom liner system – from three MSW landfills, were characterized using physical-chemical and PFAS analyses. Unsurprisingly, pH, conductivity, chloride, COD, ammonia-nitrogen, and alkalinity concentrations between the matrices were significantly different from one another based on a Mann-Whitney test for non-parametric data. Concentrations of two metalloids, which have been documented to volatilize under landfill conditions – arsenic and antimony – exceeded risk-based thresholds for groundwater by factors of 150 and 200, respectively, in some LGC samples; however, the mean concentrations in each matrix were not found to be significantly different from one another.

While total concentrations of PFAS ($\sum_{92}$PFAS) were higher in the GWP, the distribution of PFAS among classes was notably different – LGC contained a greater variety of PFAS (53 detected) than GWP (44 detected), including proportionally more precursor PFAS and more semi-volatile PFAS (FTOH and FASE classes). These semi-volatile PFAS have also been documented in air samples close to landfills and are presumed to leave landfills via LFG, although this is the first time this has been demonstrated with the analysis of landfill-collected samples. Among terminal PFAS, LGC contained proportionally more PFCAs than PFSAs, while GWP contained an approximately equivalent fraction of each type of PFAAs – corroborating previous studies which found that PFCAs more readily volatilize than PFSAs. This is the first report of PFAA volatilization at MSW landfill temperatures (35–55 °C). Inherent variability associated with the collection of discrete leachate samples from full scale landfills may limit the representativeness of these samples, however, this study provides a first look at the physical-chemical and PFAS profiles of these unique leachate types. Future work should corroborate and expand upon this data, potentially to include PFAS and physical-chemical parameter partitioning in landfill gas. Members of the solid waste community can use these results to make informed decisions on managing liquids within the landfill, including managing these leachate streams separately.

EDITOR'S NOTE:

This article is part of the special series "Ecological Risk Assessment for Per- and Polyfluorinated Alkyl Substances." The series documents and advances the current state of the practice, with respect to ecotoxicological research, environmental exposure monitoring and modeling, ecologically based screening benchmarks, and risk assessment frameworks.

Abstract

Bees provide pollination services to managed and wild ecosystems but are threatened globally due to multiple stressors, including exposure to contaminants. Perfluorooctane sulfonate (PFOS) is a widely detected and persistent contaminant that accumulates and biomagnifies in food chains. In this exposure effect study, small whole colonies of *Apis mellifera* (1000 bees) were exposed to PFOS using a purpose-built cage system over a 4-week period. The PFOS exposure concentrations were provided to bees in sugar syrup at concentrations detected in the environment, ranging from 0 to 1.6 mg L^{-1}. A range of biological and behavioral responses were monitored. Bee tissue, honey, and fecal matter were analyzed using isotope dilution combined with liquid chromatography–tandem mass spectrometry adapted for bee and honey matrix analysis. Bee mortality increased significantly with PFOS exposure at 0.8 mg L^{-1} or greater, and brood development ceased entirely at 0.02 mg L^{-1} or greater. Colony activity, temperament, hive maintenance, and defense were adversely affected in all PFOS exposure treatments compared with the control, even at the lowest PFOS exposure of 0.02 mg L^{-1}. Perfluorooctane sulfonate was detected in bee tissue with a mean bioaccumulation factor of 0.3, and it was also identified in honey and in feces collected from the hive cages. These findings provide the first evidence that PFOS exposure adversely affects honey bee colonies and may transfer to honey. With PFOS contaminating thousands of sites worldwide, our study has implications for exposed bee populations under natural conditions, pollination services, the honey industry, and human health. *Integr Environ Assess Manag* 2021;17:673–683. © 2021 SETAC

KEYWORDS: BAF, Bioaccumulation, Ecotoxicity, Effect trial, Honey, PFAS, PFOS

INTRODUCTION

Perfluorooctane sulfonate (PFOS) is an environmental contaminant that is highly persistent in the environment and causes detrimental effects upon a range of receptors (Jian et al., 2018; Mommaert et al., 2011; Mudumbi et al., 2017; Stahl et al., 2011). PFOS has been used globally in thousands of consumer and industrial applications since the 1950s, including protective coatings on cooking pans and fire-retardant products such as aqueous film-forming foam extensively used from the 1970s to 2000s (Gluge et al., 2020). Widespread use and inappropriate disposal have resulted in PFOS-contaminated soil, sediments, and water worldwide, and hundreds of contaminated sites show PFOS in various environmental compartments at concentrations exceeding current guidelines (AECOM, 2016; Chen et al., 2018; DAWE, 2016; Gilljam et al., 2016; Lin et al., 2014). PFOS accumulates and biomagnifies in food chains and affects the reproduction, development, and general fitness of wildlife (Houde et al., 2006; Squadrone et al., 2015). PFOS is now listed on the International Stockholm Convention for Persistent Organic Pollutants under Annex B, for restriction of production and use (Stockholm Convention, 2019), and over recent years, many jurisdictions have been developing regulations and protective guidelines in response to the emerging concerns.

Bees are ecologically and economically important to wild and managed ecosystems due to the pollination services

they provide (Ballantyne et al., 2017; Ollerton et al., 2011; Winfree et al., 2011). Honey bees also support a $6 billion (US) global honey market and a range of other bee product industries (Australian Government, Department of Agriculture, 2016). Yet bee populations are under threat due to multiple stressors including land-use change and intensification, pests, diseases, and exposure to a multitude of environmental contaminants (Bekic et al., 2014; Simon-Delso et al., 2014; vanEngelsdorp et al., 2009). Evidence supporting the adverse impact of pesticides on bee health is increasing, particularly for neonicotinoid pesticides (Alburaki et al., 2017; Goulson et al., 2015; Long & Krupke, 2016). Bees, however, may be exposed to many other contaminants in the environment, including PFOS, for which the consequences are little understood.

A number of potential exposure routes for bees to PFOS exist. Plants are reported to uptake PFOS from contaminated soils and water via the roots through a mechanism thought to be similar to systemic pesticide uptake (Alburaki et al., 2015; Long & Krupke, 2016), and relatively high PFOS concentrations are tolerated (up to 800 mg L^{-1}) with no detrimental effect on growth or flowering potential (Felizeter et al., 2014; Qu et al., 2010). For example, Felizeter et al. (2014) demonstrated that zucchini (*Curcubita pepo* var. Black Beauty) and tomatoes (*Solanum lycopersicum* var. Moneymaker) grown hydroponically and exposed to PFOS concentrations ranging from 10 to 10 000 ng L^{-1} accumulated 303 ± 130 ng g^{-1} PFOS in the leaves, but only low concentrations were detected in the fruit (0.22 ± 0.12 ng g^{-1}) (Felizeter et al., 2014). Therefore, bee exposure via plant pollen and nectar while foraging on contaminated plants may occur, although translocation to plant pollen and nectar has not yet been confirmed (Blaine et al., 2014; Felizeter et al., 2014). Furthermore, plant nectar and pollen may become contaminated by deposition of PFOS-contaminated soil or aerosol drift of contaminated water (Alburaki et al., 2017; Long & Krupke, 2016). Water consumption may also provide exposure because bees obtain dietary salt from pools of brackish water and access water for hive cooling (Stabentheiner et al., 2021), and this may provide a direct exposure pathway to PFOS in contaminated water (Lau & Nieh, 2016).

Studies of PFOS effects on bees appear to be limited to two controlled laboratory studies by Mommaert et al. (2011) and Wilkins (2001a, 2001b). Mommaert et al. (2011) studied lethal and sublethal effects on the survival, nest growth, reproduction, and foraging behavior of the bumblebee (*Bombus terrestris* L.) at PFOS concentrations ranging from 0 to 10 mg L^{-1} in spiked sugar syrup. Mortality increased significantly and reproduction ceased at PFOS concentrations of 1 mg L^{-1} or greater with PFOS accumulation reported at a mean of 655 ± 109 ng per worker bee whole body (Mommaert et al., 2011). Wilkins (2001a, 2001b) examined PFOS toxicity on European honey bees (*Apis mellifera*) but used individuals rather than colonies. The authors reported a 72-h LD50 value of 0.40 µg/bee for an oral dose (Wilkins, 2001a) and a 96-h LD50 value of 4.78 µg/bee for a contact dose (Wilkins, 2001b). Little is known about PFOS accumulation and elimination in bees, nor transfer to honey; however, one study analyzing samples from seven European countries reported PFOS detected in honey for a limited number of samples, but at concentrations below the method limit of quantification, which was 0.134 ng g^{-1} (Surma et al., 2016).

Studies on bee colonies, rather than individuals, are critical to fully understand the impacts of exposure to contaminants such as PFOS on bee populations, and the pollination services provided to ecosystems (D'Hollander et al., 2014; Stahl et al., 2009). Exposure effect studies on whole colonies provide multigenerational information on the long-term impact of stressors, including contaminants (Khoury et al., 2011; Torres et al., 2015; Uzunov et al., 2015). To the best of our knowledge, it appears that the effects of sublethal exposure of honey bees or whole colonies to PFOS have not yet been examined. The aim of this study was to evaluate biological and behavioral responses of small colonies of the European honey bee (*A. mellifera*) to PFOS exposures. Whole bee colonies were exposed to environmental concentrations in spiked sugar syrup over a 4-week period in a purpose-built cage environment and a range of colony metrics were assessed together with concentrations in bee tissue, honey, and feces.

MATERIALS AND METHODS

Three replicate PFOS exposure-response assessments were conducted, each for a period of four weeks. These were run consecutively between 9 February to 30 May and 26 October to 29 November 2017. Each replicate comprised two honey bee colonies for each exposure concentration treatment, which included six different PFOS concentrations and a control (i.e., seven treatments for each replicate, with each treatment using two bee colonies). For each replicate, the bee colonies were housed in seven randomly assigned cages (one per exposure treatment) in a glasshouse. Bees were exposed using PFOS-spiked 55% sugar syrup, and biological and behavioral responses were recorded. At the completion of each replicate, the colonies were euthanized and stored in a freezer, and PFOS concentrations in bee tissue, feces, and honey determined.

The specialized cage system (Sonter et al., 2019) used for this exposure trial was installed in a dedicated bay of the glasshouse complex at the University of New England, Armidale, NSW (Australia) (Supporting Information Figure S1). Modifications to the cages and hive boxes to prevent PFOS cross-contamination included removable covers on hive box lids, water feeders, floors, cage walls, and temperature monitors. These covers were completely removed and replaced between replicates, and entire cages were washed with dilute phosphate-free detergent and rinsed with distilled water. Each cage was provided with 2 × 100 mL 55% w/w sugar syrup solution (spiked or not spiked) (Huang, 2010), as a substitute for plant nectar. Water and also pollen and protein supplement as Jarrah pollen (10 g) and Bee Build Protein Sausage™ (20 g) (Penders

15513793, 2021, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/ieam.4421 by John Jay Coll Criminal Justice, Wiley Online Library on [10/11/2026]. Beekeeping Supplies) were supplied weekly for each bee colony. All hive boxes, including the frames, wax foundation, and wax comb, were frozen for a period of 48 h before the start of each replicate to kill any pest eggs. Ambient temperature in the glasshouse bay was maintained between 24 °C and 28 °C with 40%–60% humidity for the duration of the experiment. Hive box and ambient temperature were monitored (Jumbo Display In/Out Thermometer, model QM7310; Jaycar Electronics Pty Ltd.) with a temperature probe attached to the center of each hive box.

Each replicate was run with 14 individual young bee colonies (two in each of the seven treatments), each comprising approximately 1000 bees and a young fertile queen bee (Root, 1978; Winston, 1987). Each colony was initially housed in a hive box with a brood frame to encourage colony establishment and also two empty frames to allow colony expansion (Eckert et al., 1994). The colonies were acclimatized for one week before exposure during which each cage was provided with nonspiked sugar syrup, water, and food supplements, as previously described. Immediately before PFOS exposure, the brood frames were removed from each hive box and replaced with a frame with a wax comb to enable the queen to lay eggs.

Bee colonies were exposed to PFOS in 55% sugar syrup as a nectar substitute to ensure PFOS intake. Water consumption by bees occurs largely to cool the hive, and in a caged environment, this was considered insufficient to guarantee exposure. Furthermore, Mommaert et al. (2011) have demonstrated that exposure using spiked sugar syrup was successful for individual bees. The PFOS standard solution used to make up exposure concentrations was supplied as 40% in H_2O (the standard available in Australia at the time) (Sigma-Aldrich). Validation at National Measurement Institute (NMI) confirmed the concentration as 63%. The PFOS solution was diluted with ultrapure water for a working stock (TKA Micropure UV/UF-ST 50132372), followed by 55% w/w sugar syrup for PFOS exposure solution concentrations of 0.02, 0.08, 0.2, 0.3, 0.8, and 1.6 mg L^{-1} in 55% w/w sugar syrup, with a control of nonspiked 55% w/w sugar syrup. The exposure concentrations were developed from the range of concentrations reported for surface and groundwater at PFOS-contaminated sites in the absence of ecological guidelines for PFOS at the time of experimental set-up (AECOM, 2016; Ahrens & Bundschuh, 2014; Lin et al., 2014; Oliaei et al., 2014). The exposures also encompassed concentrations considered sublethal to bees, based on available research (Mommaert et al., 2011; Wilkins, 2001a). The working stock solution was prepared fresh at the start of each replicate. The two colonies allocated to each cage shared the same PFOS sugar syrup solution, provided as 2 × 100 ml in two feeding containers, with fresh solution provided each week (Supporting Information Figure S1).

Biological responses after PFOS exposure were recorded weekly and included brood development (i.e., presence of eggs, larvae, pupae, and young adults), hive box temperature, mortality (i.e., worker bee and queen death (Supporting Information Equations 1–3), gastric health (i.e., presence or absence of dysentery in the form of dark, streaky deposits on a scale of 1–4, with 1 being no dark or streaky fecal deposits and 4 being greater than 50 dark or streaky fecal deposits (Supporting Information Table S1 and Figure S2), and bee weight. Population change was measured at the end of the treatment period (Supporting Information Equation 4).

Behavioral responses recorded included colony establishment, colony response to any incidental queen mortality (i.e., remaining in the hive box and raising a replacement queen, or leaving), activity (i.e., the number of bees sitting and/or crawling, and flying, outside the hive boxes), temperament (ranked on a scale of 1–5, with 1 being calm and 5 being aggressive) (Supporting Information Table S2), hive maintenance (i.e., cleanliness of hive box ranked on a scale of 1–5, with 1 being free of dead bees and debris and 5 being greater than 20 dead bees, evidence of debris and/or fecal deposits; Supporting Information Table S3), and pest management (i.e., presence of small hive beetles, wax moths, or cockroaches inside the hive boxes indicating low defense against pests). Bee activity, the response to queen mortality (if applicable), and the colony temperament were monitored twice each week. Hive maintenance (Supporting Information Table S3) and pest management (Supporting Information Table S4) were monitored weekly. Colony establishment was determined by colonies remaining in the hive boxes for the duration of the replicate.

Analyses of bee tissue, honey, and feces were performed by NMI, North Ryde, Australia, using an isotope dilution method combined with liquid chromatography–tandem mass spectrometry (LCMS) adapted for bee tissue (O'Connor et al., 2018). Bee tissue samples (0.5 g) were analyzed from the 0, 0.02, and 1.6 mg L^{-1} PFOS treatment groups for each of the three replicates. Honey was only produced in the control and the 0.02 mg L^{-1} treatment in all replicates, and samples (1 g) were analyzed from each of these treatments for one replicate. Fecal deposits (0.5 g) were analyzed from one replicate of the 1.6-mg L^{-1} treatment. Detailed analytical procedures including quality assurance and quality control are described in the Supporting Information, with the suite of 18 polyfluoroalkyl substance (PFAS) compounds analyzed including PFOS. The limit of quantitation (LOQ) for PFOS in bee tissue, honey, and feces was 0.0003 mg L^{-1}. Mean PFOS recovery for control spike samples was 92% and that of the other PFAS compounds analyzed was 89% to 121% (PFOA = 89%), with precision less than 11% for PFOS based on the recovery of extraction internal standard from bee tissue and honey samples. The bioaccumulation factor (BAF) was calculated for each exposure concentration analyzed, by dividing the mean PFOS concentration in bee tissue samples ($n = 3$) by the PFOS exposure concentration in that treatment group, and the elimination factor was calculated by dividing the fecal PFOS concentration (mg kg^{-1}) by the bee tissue PFOS concentration (mg kg^{-1}) (refer to Supporting Information for Equations).

Generalized linear mixed-effects models (GLMMs) were used to assess the effect of PFOS on measured honey bee

15513793, 2021, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/ieam.4421 by John Jay Coll Criminal Justice, Wiley Online Library on [10/11/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

responses. These were constructed using the 'glmmTMB' function in the *glmmTMB* package in RStudio (Harrison et al., 2018). The effect of PFOS on honey bee biology was determined by the fixed effect of PFOS exposure concentration with the response variables of egg and larvae production, hive box temperature, bee weight, population growth, and gastric health. To determine the effect of PFOS on honey bee behavior, the fixed effect was PFOS concentration and the response variables were temperament, hive maintenance, and pest management. Variability in the responses among weeks and replicates was accounted for by nesting the trial and replicate number within week, as random effects. The most suitable response distribution was applied for each GLMM and was determined by comparing Akaike information criterion values between models for each response variable fitted with different response distributions.

Associations between the bioaccumulation of PFOS in bee tissue, transfer to honey, and the elimination in feces could not be tested due to the small sample size. In-text numerical data are presented as mean (*M*) and standard error (±). Bee and queen mortality were compared between each PFOS concentration treatment using pairwise comparisons in the *lsmeans* package (Lenth, 2016; R Core Team 2016), and significance was determined using false discovery rate (FDR)-corrected *p* values (at $\alpha = 0.05$) (Verhoeven et al., 2005). All statistical analyses were conducted in R version 3.4.3 (R Core Team 2016) and bar graphs were constructed with Excel 2019.

RESULTS

Biological response metrics

Hive box temperature decreased when colonies were exposed to each of the PFOS treatment concentrations over the 4-week exposure period (Supporting Information Figure S3). The highest mean (*M*) temperature ($M = 29.3\,°C \pm 1.1\,°C$) was recorded in the control and the lowest in the 1.6 mg L^{-1} treatment group ($M = 26.4\,°C \pm 1.2\,°C$), with a significant difference ($df = 715$, $p < 0.001$) between the control and all other treatment groups, including the lowest PFOS exposure concentration tested (0.02 mg L^{-1}), but no dose–response effect was evident.

Eggs were laid in all treatment groups, but the maximum number was in the control ($M = 63 \pm 14$), which showed significantly more eggs ($df = 167$, $p < 3.49^{e-05}$) than all the PFOS-treated groups (Figure 1A), although a dose–response relationship was not evident. Due to the reduced number of eggs laid in the PFOS treatment groups, a reduced number of larvae developed, only observed in the 0.02 mg L^{-1} ($M = 2 \pm 2$) and 0.08 mg L^{-1} ($M = 1 \pm 1$) PFOS exposure groups, compared with the controls which had significantly greater larval numbers ($M = 10 \pm 5$) ($df = 167$, $p = 0.0161$). Larvae progressed to pupae in all controls ($M = 15 \pm 6$) and in only one replicate of the 0.08-mg L^{-1} PFOS treatment ($M = 3 \pm 1$), but the pupae in this PFOS treatment were removed by the worker bees, indicating that the pupae were dead. Pupae in the controls for all replicates appeared healthy, and in one control, replicate young adults, of normal size and appearance, emerged by Week 4 ($M = 15 \pm 7$) (Supporting Information Figure S4). The data suggest that when *A. mellifera* colonies were exposed to PFOS (≥0.02 mg L^{-1}) over four weeks, egg viability was compromised. Tests of significance were not undertaken for pupae and young adults because these life stages were only observed in the control treatments.

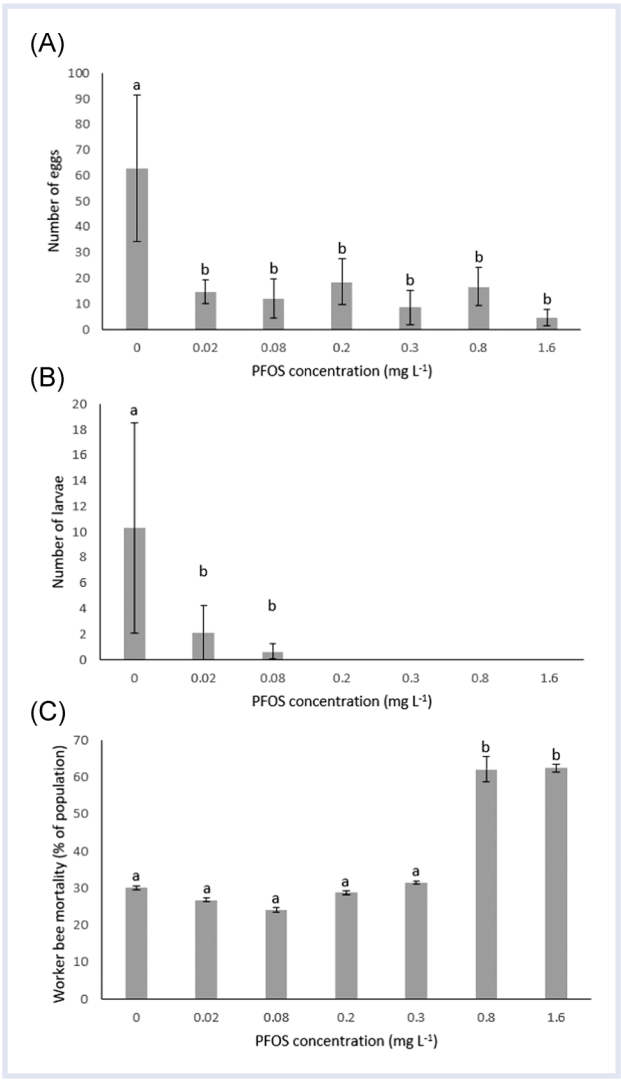

FIGURE 1 Biological responses observed as (A) eggs and (B) larvae in brood development, and (C) worker bee mortality at four weeks of PFOS exposure. Bar graph indicates the mean of three replicates and error bars indicate standard error. Letters indicate significant differences ($p < 0.05$)

Worker bee mortality increased with PFOS exposure and this became significant at exposure concentrations of 0.8 mg L^{-1} or greater ($df = 71$, $p < 4.84^{e-13}$) (mean mortality was 75.6 ± 3.82% at 1.6-mg L^{-1} PFOS exposure) (Figure 1C). Queen bee mortality was least in the control and in the 0.2 mg L^{-1} PFOS exposure treatment, with one death in each of these treatments over the three replicates. Two queens died in the 0.02, 0.08, and 0.8 mg L^{-1} treatment groups and three queens died at 0.3 and 1.6 mg L^{-1} PFOS exposure.

15513793, 2021, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/ieam.4421 by John Jay Coll Criminal Justice, Wiley Online Library on [10/11/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Queen mortality was significantly lower in the control compared with the 0.3 mg L^{-1} ($df = 17$, $p = 0.0379$) and 1.6 mg L^{-1} ($df = 17$, $p = 0.0105$) treatment groups, but not significantly different from any other PFOS treatment group.

The colony population decreased in the control and all PFOS treatment groups (Supporting Information Figure S5), but the % decrease was larger at higher PFOS exposures and became significant at PFOS exposure of 0.2 mg L^{-1} or greater ($df = 17$, $p < 3^{e-04}$). The mean population decrease in the control was 33.26 ± 12.4%, and 75.6 ± 13.3% in the 1.6 mg L^{-1} treatment group. Mean bee weight was similar in the control ($M = 0.0863 \pm 0.0164$ g) and the 0.02, 0.08, and 0.2 mg L^{-1} PFOS exposure groups, but it was significantly smaller ($df = 1008$, $p < 2^{e-16}$) at PFOS exposures of 0.3 to 1.6 mg L^{-1}, with maximum colony weight loss at 1.6 mg L^{-1} PFOS exposure ($M = 0.0659 \pm 0.0169$ g) (Supporting Information Figure S6). Dysentery was observed only in the PFOS treatments, which started at Week 2, and the incidence increased at Weeks 3 and 4. Dysentery was not observed in any control treatment; however, gastric health measurements did not differ significantly among treatment groups ($df = 89$, $p = 0.0624$) (Supporting Information Table S5).

Behavioral response metrics

During the acclimatization week, the bee colonies successfully established in the hive boxes with no colonies absconding. The consumption of resources and bee activity in the cages increased or did not change over the week. Throughout the subsequent four weeks of PFOS exposure, consumption of resources varied in treatments. All of the sugar syrup, pollen, and protein sausage were consumed in the control treatment each week, but resource consumption decreased with PFOS exposure and ceased almost entirely by Week 4 in the 0.3 mg L^{-1} or greater PFOS treatment groups. Honey production was observed only in the control and lowest, 0.02 mg L^{-1}, PFOS treatment group, with approximately 4 × 4 cm of uncapped honey produced on frames in each of these treatments in all three replicates. When a queen death was observed in a control colony, the colony continued to operate as an individual colony (as opposed to joining the other colony in the cage) and remained in the hive box for the remainder of the trial. The PFOS treatment group colonies responded differently to queen death, and these colonies were observed to combine and, on one occasion, abscond from the hive.

Bee activity, as percent of the remaining population of bees in the cage sitting and/or crawling, and flying in the control was significantly ($df = 143$, $p < 2^{e-16}$) greater at both observation times (10:00 a.m. and 3:00 p.m.), compared with all other treatment groups, except the 0.02-mg L^{-1} for bees sitting and/or crawling (Figure 2). The data for the 0.02-mg L^{-1} treatment were influenced by colony absconding after queen death in one replicate, resulting in a large percentage of bees in the cage at all times. Bee activity was lowest in PFOS exposure 1.6 mg L^{-1} (Figure 2). Temperament in the control colonies was calm for the duration of the trial (*Mode* = 2 and 3), the 0.02 to 0.3 mg L^{-1}

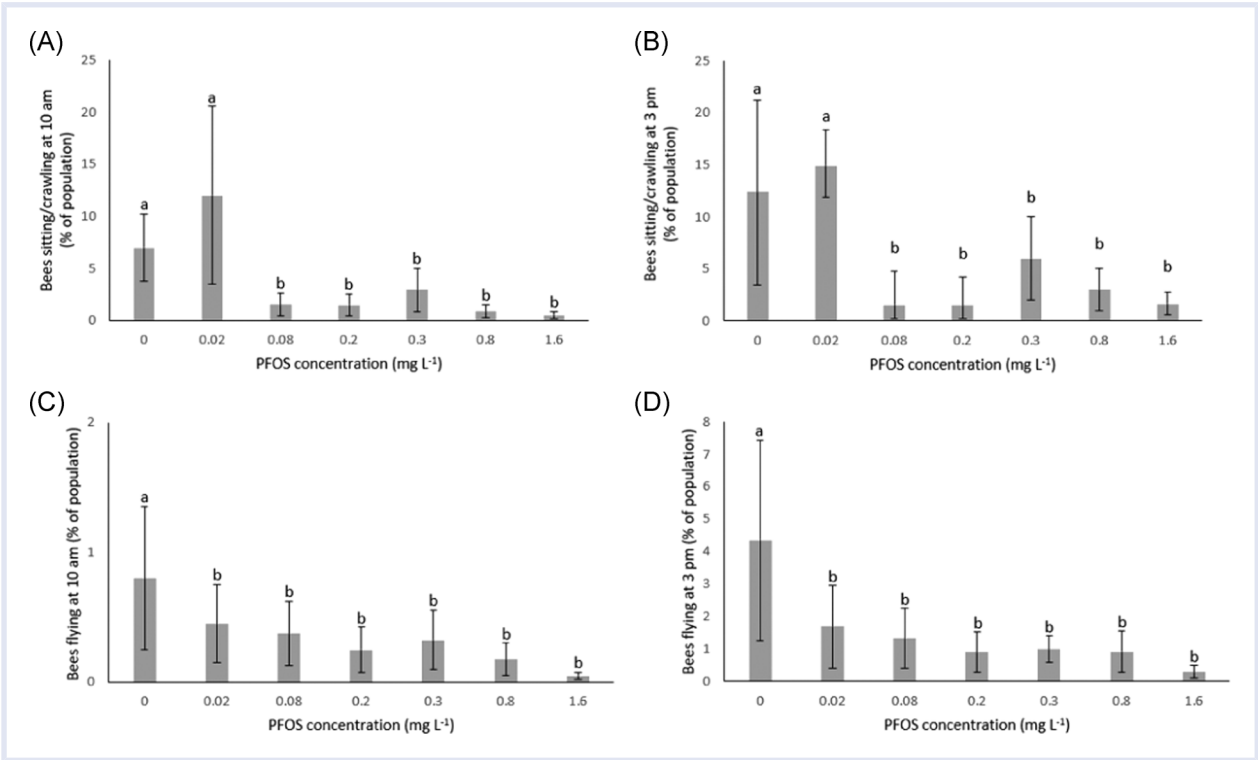

FIGURE 2 Bee activity observed during the PFOS exposure experiment: (A) bees (% of remaining population) sitting and/or crawling in the cage at 10 a.m. and (B) 3 p.m. and (C) bees (% of remaining population) flying at 10 a.m. and (D) 3 p.m.. Bar graphs indicate the mean of three replicates over four weeks of observation, and error bars indicate standard error. Letters indicate significant differences ($p < 0.05$)

15513793, 2021, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/ieam.4421 by John Jay Coll Criminal Justice, Wiley Online Library on [10/11/2026]. treatment groups displayed agitation (*Mode* = 4), but the 0.8 and 1.6 mg L^{-1} treatment groups were very calm (*Mode* = 1) (Supporting Information Table S6). There was a significant relationship between PFOS exposure and temperament in all treatment groups ($df = 143$, $p < 0.001$) when compared with the control.

Hive maintenance behaviour deteriorated in all PFOS treatment groups as compared with the control, and by Week 4, all PFOS exposure treatments scored a poor maintenance value of 4 in at least one replicate, significantly lower than the control which maintained the optimum value of 1 ($df = 181$, $p < 0.001$) (Supporting Information Table S7). Pests were observed in the 0.08, 0.8, and 1.6 mg L^{-1} treatment groups by Week 2 and in all treatment groups, except the control by Week 4, with a significant increase in pests in 0.08 mg L^{-1} or greater PFOS exposure treatments when compared with the control ($df = 194$, $p < 0.001$), indicative of decreased colony defense.

PFOS accumulation, transfer, and elimination

Perfluorooctane sulfonate was detected in all bee tissue, honey, and feces samples analyzed from the PFOS exposure treatments (0.02 and 1.6 mg L^{-1} for bee tissue, 0.02 mg L^{-1} for honey, and 1.6 mg L^{-1} for feces), but it was not detected in any of the samples collected from the controls (Table 1). The nondetects in controls confirm no cross-contamination between treatments, nor contamination of water, sugar syrup solution, or food supplement. Seven additional PFAS compounds (including PFOA) were detected in samples from PFOS exposure treatments but at significantly smaller concentrations than PFOS. The PFOS accumulated in the bee tissue at a mean BAF of 0.3 for the two exposure concentrations assessed. Assuming the honey was contaminated directly from bees, the transfer factor from bees in tissue to honey was approximately 0.4 at PFOS exposure of 0.02 mg L^{-1}. Fecal deposit analysis from the 1.6 mg L^{-1} treatment group showed a PFOS concentration

of 0.013 mg kg^{-1}, indicating that PFOS was eliminated from the bees in feces with an elimination factor of 0.04 (Supporting Information Equation 5). Statistical analysis was not possible for bee tissue, honey, or feces concentrations due to the small sample size.

DISCUSSION

Bees are adversely impacted by organic contaminants, such as neonicotinoid and pyrethroid pesticides (Alburaki et al., 2015; Aliquane et al., 2009; Chaimanee et al., 2016; Oliver et al., 2015; Williamson et al., 2014), but the effect of PFOS on honey bees is little studied and has not been examined previously using whole bee colonies. Understanding the effects on whole colonies is essential because the survival of bees and the services they provide are inherently dependent on colony health. The PFAS compounds, including PFOS, are widespread in the environment and are reported at high concentrations on thousands of contaminated sites (Groffen et al., 2018; Hepburn et al., 2019). Foraging bees are potentially exposed in contaminated areas through contaminated surface water, plant pollen, and nectar; however, the relative importance of these exposure routes has not yet been quantified. To date, LC50 values for bees have been determined only on individuals in two rather limited studies, with almost nothing known about sublethal and chronic exposure, EC50 values, or colony-level effects. This significantly hinders development of robust protective and management guidelines.

Our study is the first to evaluate PFOS effects on whole colonies of the European honey bee (*A. mellifera*). In the absence of ecological guidelines for PFOS at the time of experimental establishment, we used a PFOS exposure concentration range that included concentrations known to cause mortality in individuals (1.01 mg L^{-1} specified as the LD50 value for bumble bees) (Mommaert et al., 2011) and the range of values reported in contaminated surface and groundwater, including data from a contaminated site in Australia, which is within foraging range (<1–8 km) of numerous managed beehives (AECOM, 2016).

A healthy bee colony can generally maintain colony temperature, produce brood, maintain a low incidence of pests, and sustain a low rate of mortality for population growth (Winston, 1987). In our experiment, all of these responses, essential to colony survival, were adversely affected, and at PFOS concentrations not previously known to affect colonies (Wilkins, 2001a). In our experiment, all the colony biological responses monitored were adversely affected to some degree in treatment groups exposed to PFOS. This included brood development, maintenance of colony temperature, worker and queen bee mortality, gastric health, and bee weight. Although the cage environment provided for successful brood development (Winston, 1987), as evidenced by successful brood development in the controls (Sonter et al., 2019), even at the lowest PFOS exposure concentration of 0.02 mg L^{-1}, the development from eggs to young adults ceased. Larval death was possibly due to nurse bees feeding the larvae PFOS-contaminated food, rather than PFOS residue in the brood comb due to the short time period of exposure and use of noncontaminated frames (Wu-Smart & Spivak, 2016; Zhu et al., 2014). Although the mean brood temperature recorded in controls was lower than considered optimum (32–36 °C; Winston, 1987), successful development of brood in controls occurred, in contrast to the PFOS-exposed colonies where temperature decreased with PFOS exposure. This suggests that the PFOS-exposed colonies may not have been able to maintain social homeostasis. This finding may be a consequence of a range of factors including increased mortality resulting in a decreased number of worker bees available to maintain cluster warmth, worker bees not being able to effectively activate wing muscles, a breakdown of communication within the colony, and disorientation of worker bees (Colin et al., 2019; Meikle et al., 2019).

Worker bee mortality significantly increased with PFOS exposure at concentrations of 0.8 mg L^{-1} or greater. Bees in the 1.6 mg L^{-1} treatment group were exposed to approximately 0.02 µg PFOS per bee per day (assuming 11 µL^{-1} syrup ingested; Huang, 2010), with 20 days of exposure required (i.e., 0.02 µg^{-1} per day × 20 days) to attain the 72-h LD50 value of 0.40 µg/bee for an oral dose reported by Wilkins (2001a). In our experiment, mortality increased by more than 50% over the four weeks of exposure at 1.6 mg L^{-1}, which is relatively consistent when extrapolating from data using individuals (Wilkins, 2001a). The slightly higher mortality evident in the control, compared with the 0.02 mg L^{-1} treatment group (although not significant), could be a consequence of brood care requirements in a healthy colony requiring greater resource consumption and energy expenditure (Munch et al., 2013; Wolf & Schmid-Hempel, 1989).

The mechanism of bee toxicity with PFOS exposure is unclear, but Mommaert et al. (2011) reported that PFOS triggers the production of reactive oxygen species at the cellular level, which causes cell death. In line with an increase in bee mortality, populations decreased with PFOS exposure and this became significant at 0.2 mg L^{-1} or above. Although populations decreased also in the control, the decrease was less than that observed in PFOS treatments. Over a greater time period, as young emergent adults develop (observed in replicate 1), a population increase would be expected in a healthy colony (Nye, 1962; van Praagh, 1972). It is not clear whether the increase in mortality observed in the higher PFOS treatment groups was due to chemical toxicity response or a result of reduced feeding. Nevertheless, the increase in mortality observed can be attributed to PFOS exposure, even if indirectly.

Honey bee gastric health deteriorated even at the lowest PFOS exposure concentration of 0.02 mg L^{-1}, and dysentery was observed in all treatments except the control. PFOS-spiked sugar syrup solutions showed no significant difference in pH as compared with the control, confirming that pH was not the cause of dysentery (Demares et al., 2016). Recent research that supports these findings indicates that contaminants can adversely affect the bee gut microbiome,

15513793, 2021, 4, Downloaded from https://onlinelibrary.wiley.com/doi/10.1002/ieam.4421 by John Jay Coll Criminal Justice, Wiley Online Library on [10/11/2026]. compromising the immune system and resulting in susceptibility to viral, bacterial, and/or fungal infections (Blot et al., 2019; Dai et al., 2018; Motta et al., 2018). Blot et al. (2019), for example, reported that glyphosate reduced the growth of beneficial microbiota, thereby allowing pathogen development, such as *Nosema ceranae* which reduces the general health and longevity of honey bees. Bee weight was also reduced with PFOS exposure concentration, and significantly in the 0.3 mg L^{-1} or greater PFOS treatment groups. Factors influencing the reduced bee weight may include poor gastric health (H. Zheng et al., 2017) and reduced consumption of the PFOS-spiked sugar syrup, pollen, and protein supplement due to avoidance or poor health (B. Zheng et al., 2014). In our study, the slightly smaller mean bee weight (not significant) recorded for the control as compared with 0.02 and 0.2 mg L^{-1} treatment groups was possibly influenced by the emergence of the young adult bees in the control which are lighter than mature adult bees (Winston, 1987).

Behavioral response to queen death altered with PFOS exposure. Instead of remaining in the nest (as seen in the controls), the bees from the colony that had lost the queen joined the queened colony in the same cage. It is also unusual for a queened colony to accept a queenless colony, when a queen dies. A possible explanation may be reduced olfactory memory specificity, as observed in honey bees exposed to pesticides at sublethal concentrations (Aliquane et al., 2009; Blacquiere et al., 2012; Chakrabarti et al., 2015; Williamson et al., 2013). Honey bee activity was also adversely affected with PFOS exposure, and flying was reduced even in the lowest PFOS concentration treatment group of 0.02 mg L^{-1}. Temperament was altered with PFOS exposure and bees were more agitated at PFOS exposure of 0.02-mg L^{-1} or above, but calmer in the 0.8-mg L^{-1} or greater PFOS treatment groups. The lower exposure elicited a response that stimulated defensive behavior (possibly due to stress) (Wray et al., 2011), but at higher exposures, metabolic changes as a result of toxicity, or lower energy due to reduced food consumption probably suppressed temperament (Oliver et al., 2015; Williamson et al., 2014). We also observed a deterioration in hive maintenance in all PFOS exposure concentration treatment groups and an increased number of pests, compared with the controls. This may be due to lower bee numbers in PFOS treatments and/or a reduced colony capacity to redirect to normal functional tasks, suggesting a reduced capacity to maintain the hive and defend against pests (Chakrabarti et al., 2015; Couvillon et al., 2010; Williamson et al., 2013).

Our results demonstrated that PFOS exposure adversely affected a wide range of biological and behavioral responses in honey bee colonies. Effects varied depending on response and PFOS exposure concentration. The mechanism of toxicity for honey bees exposed to PFOS is not understood, but honey bees exposed to pyrethroid and neonicotinoid insecticides show symptoms consistent with an impaired nervous system. At sublethal concentrations, overstimulation of the nervous system occurs and death results (Soderlund & Bloomquist, 1989; Williamson et al., 2014). PFOS effects on the honey bee nervous system can be considered as one possible hypothesis for the effects observed in our study, but toxicity response and mechanisms require further exploration.

Our study confirms that PFOS (and other PFAS) accumulated in honey bee tissue in the colony environment exposed to PFOS. The only other study available examined the transfer of PFOS to bee tissue of bumblebee (*Bombus terrestris*) workers directly fed 100 µl^{-1} PFOS-spiked sugar syrup (Mommaert et al., 2011). The PFOS accumulated to 2184 ± 365 ng wet body weight in bees, equivalent to a much higher BAF value of 27.9 (Mommaert et al., 2011) than observed in our study, as would be expected in a direct feeding trial. Moreover, our study also demonstrates that PFOS transfers to honey, which supports the results of the European survey that detected PFOS in honey samples, though the PFOS source was unknown (Surma et al., 2016). In addition, we provide evidence that PFOS can be eliminated from the bee body in the feces, with potential additional contamination of hive parts, bees, and surrounds.

CONCLUSION

We investigated the exposure of European honey bee colonies to the water-soluble and persistent contaminant, PFOS. Our results showed that PFOS exposure resulted in a range of adverse biological and behavioral colony responses. Mortality increased at PFOS exposures of 0.8 mg L^{-1} or above and brood development ceased entirely even at the lowest PFOS exposure concentration of 0.02 mg L^{-1}. Adverse behavioral changes were observed at PFOS exposure of 0.02 mg L^{-1} or above. The PFOS accumulated in bee tissue of the colony; it appeared to be partially eliminated in feces, but it also transferred to honey.

The PFOS exposure pathways for bees in the field are little understood, but foraging bees are potentially exposed in contaminated areas through contaminated surface water, plant pollen and nectar. The relative importance of these exposure routes is not yet quantified, nor have relevant field exposure concentrations been identified. Thus, the next steps to our work are to establish colony-based EC50 and LC50 values, understand toxicity mechanisms and further investigate PFOS transfers and transformations. Field-based investigation is needed to understand the relative importance of exposure routes and field exposure concentrations for the development of comprehensive ecological risk assessment and colony-based protective guidelines for honey bees. Honey bees pollinators in wild and managed ecosystems, and they produce products for human consumption. Hence, the development of this work has important implications for food chain contaminant movement, food security, and the establishment of robust guidelines for the protection of the environment and humans.

Stockholm Convention on Persistent Organic Pollutants

Persistent Organic Pollutants Review Committee
Twelfth meeting
Rome, 19–23 September 2016

Report of the Persistent Organic Pollutants Review Committee on the work of its twelfth meeting

Addendum

Risk profile on pentadecafluorooctanoic acid (CAS No: 335-67-1, PFOA, perfluorooctanoic acid), its salts and PFOA-related compounds

At its twelfth meeting, by its decision POPRC-12/2, the Persistent Organic Pollutants Review Committee adopted a risk profile for pentadecafluorooctanoic acid (CAS No: 335-67-1, PFOA, perfluorooctanoic acid), its salts and PFOA-related compounds on the basis of the draft contained in the note by the Secretariat (UNEP/POPS/POPRC.12/3), as revised during the meeting. The text of the risk profile as adopted is set out in the annex to the present addendum. It has not been formally edited.

Executive summary

1. The POPs Review Committee concluded that PFOA fulfilled the screening criteria in Annex D and that issues related to the inclusion of PFOA-related compounds that potentially degrade to PFOA and the inclusion of PFOA salts should be addressed in the draft risk profile (see Decision POPRC-11/4). The substances covered by this risk profile include pentadecafluorooctanoic acid (CAS No: 335-67-1, EC No: 206-397-9, PFOA, perfluorooctanoic acid) including its isomers, its salts and PFOA-related compounds.

2. PFOA and its salts are most widely used as processing aids in the production of fluoroelastomers and fluoropolymers, with polytetrafluoroethylene (PTFE) being an important fluoropolymer. PFOA-related compounds are used as surfactants and surface treatment agents (e.g. in textiles, paper and paints, fire-fighting foams) and for the manufacture of side-chain fluorinated polymers. Due to their physico-chemical properties, PFOA, its salts and PFOA-related compounds are used in a wide variety of applications and consumer products across many sectors.

3. PFOA, its salts and PFOA-related compounds are subject to a number of national regulations. Norway has banned its use in consumer products (currently the substance is being phased out); while in the U.S. there is a voluntary initiative to phase out its use. Elsewhere in Canada and the EU, steps are underway towards the setting of legally binding conditions to restrict or ban the substance.

4. From 1951 to 2004, the estimated total global production of PFOA and APFO (ammonium perfluorooctanoic acid) was 3600 – 5700 t. Current production of PFOA is predominantly carried out in China where the production of PFOA and its salts has tripled from around 30 t in 2004 to around 90 t in 2012. The most recent data that is publically available concerning global production of APFO indicates that an average 200-300 t of PFOA were produced annually (1995-2002). It is expected that current production is significantly lower due to the voluntary phasing out of the substance by U.S., EU and Japanese companies. However, its current use at global level in the production of fluoroelastomers and fluoropolymers demonstrates that there is an ongoing production and use.

5. Direct releases to the environment occur from the production of the raw substance (including PFOA as impurity in the manufacturing of PFOA-related compounds and some alternatives), during the processing, use and disposal of the chemical, from treated articles and from products contaminated with PFOA. Main emission vectors of PFOA and its salts are water, wastewater and dust particles. Historic releases to the environment from PFOA manufacturing are available from a plant in the U.S. into air and water between 1951 and 2003. Some estimates of releases during the disposal of the chemical are available, particularly from sewage treatment plants, wastewater treatment plants and landfill sites. Indirect releases occur from the degradation or transformation of precursors. PFOA-related compounds are released to air and (waste) water and will degrade to PFOA in the environment and in organisms. An assessment of sources of PFOA to the Baltic Sea estimated that 30% of the releases were due to transformation of fluorotelomers. Thus releases of PFOA from degradation contribute a major share to the releases of PFOA to the environment.

6. Degradation results show that PFOA is persistent and does not undergo any abiotic or biotic degradation under relevant environmental conditions. The monitoring data show that PFOA in soil leaches over time and can be a long term source to underlying groundwater. On this basis it is concluded that PFOA is highly persistent in all environmental compartments, with a strong resistance to all conventional mechanisms of degradation under relevant environmental conditions.

7. PFOA has a low to moderate potential to accumulate in aquatic (i.e. water breathing) species, but there is evidence that PFOA and its salts accumulate and biomagnify in air breathing terrestrial and marine mammals (BMFs, TMFs > 1).

8. Worldwide monitoring of water, air, sediment and biota at remote locations all detect the presence of PFOA and related compounds. Equally environmental modeling data suggest that the capacity for long range transport does exist, while others have identified key mechanisms which would make long range transport plausible. On this basis it can be concluded that PFOA directly or through precursors is subject to long range transport.

9. PFOA exposure of the general public typically takes place “human via environment” by consumption of drinking water and food including breast feeding, via uptake of contaminated indoor air and dust or from consumer products containing PFOA, its salts and related compounds. PFOA has been detected in humans in blood and breast milk from various countries. Humans are very slow eliminators of PFOA compared with other species with an estimated half-life of PFOA elimination ranging from 2 to 4 years. PFOA accumulates in humans with increasing levels with age.

10. PFOA exhibits low acute toxicity in aquatic organisms. In fish, PFOA inhibited expression of genes involved in thyroid hormone biosynthesis, induced vitellogenin gene expression, developed oocytes in the testes of males and caused ovary degeneration in females. PFOA has the potential to affect endocrine function where visible effects may not be apparent until the organisms reach adulthood.

11. Effects of repeated oral PFOA exposure in animals such as alterations to the liver, reproductive/developmental toxicity and endocrine disruption have been identified. Developmental effects that are of relevance for the oral route are perinatal mortalities, reduced pup body weight gain and development, cyanosis and necrosis, delayed ossification, changes in mammary gland development and delayed maturation.

12. In the European Union, PFOA has a legally-binding harmonized classification as Carc. 2, Repr. 1B and STOT RE 1 (liver). PFOA is quickly absorbed, not metabolised and distributed in the body, transferred to foetus through placenta and infants via breast milk. A considerable number of adverse health effects associated with PFOA exposure in humans have been reported. The C8 Science Panel (a large-scale epidemiological study conducted in the US on PFOA exposure and health effects) concluded that there was a probable link to PFOA exposure for diagnosed high cholesterol, ulcerative colitis, thyroid disease, testicular cancer, kidney cancer and pregnancy-induced hypertension. Scientific data have demonstrated PFOA-mediated immunotoxicity, primarily suppression of antibody response, in humans. There have also been other reported adverse health effects (e.g. altered reproductive or developmental effects, endocrine disruption, impaired neurodevelopment, immunotoxicity, etc.) associated with PFOA exposure in humans.

13. PFOA is persistent, bioaccumulative and toxic to animals including humans. There is widespread occurrence of PFOA and a number of PFOA-related compounds in environmental compartments and in biota and humans. Therefore, it is concluded that PFOA, its salts and related compounds that degrade to PFOA are likely, as a result of their long-range environmental transport, to lead to significant adverse human health and/or environmental effects such that global action is warranted.

1. Introduction

14. In June 2015 the European Union and its Member States submitted a proposal to list pentadecafluorooctanoic acid (CAS No: 335-67-1, PFOA, perfluorooctanoic acid), its salts and PFOA-related compounds in Annex A, B, and/or C of the Stockholm Convention (UNEP/POPS/POPRC.11/5). This proposal was considered by the Persistent Organic Pollutants Review Committee (POPRC) at its eleventh meeting held in October 2015.

15. PFOA, its salts and PFOA-related compounds fall within a family of perfluoroalkyl and polyfluoroalkyl substances (PFASs). PFASs consist of carbon chains of different chain length, where the hydrogen atoms are completely (perfluorinated) or partly (polyfluorinated) substituted by fluorine atoms (Buck et al., 2011; OECD, 2013; ECHA, 2015a). The very stable bond between carbon and fluorine is only breakable with high energy input. Therefore, perfluorinated acids, like PFOA, are not degradable in the environment. Certain polyfluorinated substances can be degraded to persistent perfluorinated substances like PFOA under environmental conditions and are therefore precursors. Those PFASs, which can be degraded to PFOA in the environment, are referred to as PFOA-related compounds. PFOA and its salts are most widely used as processing aids in the production of fluoroelastomers and fluoropolymers, with PTFE being an important fluoropolymer. PFOA-related compounds are used as surfactant and for the manufacture of side-chain fluorinated polymers (ECHA, 2015a). Due to the surfactant properties of both PFOA and its related non-polymeric surfactants, applications exist for the use of these substances, e.g. fire-fighting foams, wetting agents and cleaners. Side-chain fluorinated polymers provide durable water, oil and stain repellency and find use as surface finishes for textiles and apparel, leather, paper and cardboard, paints, lacquers and other uses (non-woven medical garments, floor waxes, and stone/wood sealants, thread sealant tapes and pastes, adhesives, products for apparel) (UNEP/POPS/POPRC.11.5; FluoroCouncil, 2016).

16. PFOA has been manufactured since 1947 when 3M developed the production process via electrochemical fluorination (ACS, 2015). PFOA-related compounds (such as fluorotelomer alcohols) have also been in use, notably with the development of fluorotelomer technologies in the 1960s and their subsequent commercialization in the 1970s and thereafter. The perfluorooctyl iodide fraction of fluorotelomers was oxidized to PFOA and subsequently used as a fluoropolymerization aide by several fluoropolymer producers globally (DuPont, 2010; FluoroCouncil, 2016). However growing concerns regarding health and environmental effects of PFOA have meant stricter controls and phase-out plans under legislation such as the regulation on registration, evaluation, authorization and restriction of

chemicals (REACH EC 1907/2006) in the EU and the *Canadian Environmental Protection Act 1999* (CEPA) as well as voluntary efforts such as the US EPA PFOA Stewardship Program (US EPA, 2015) and work by industry (OECD, 2015). With a voluntary move by the Telomer Research Program (TRP) and Fluoropolymer Manufacturing Group (FMG) members in 2006, eight of the main manufacturers of C8-substances (fluorochemicals related to eight fully fluorinated C8-atoms) in the US, Europe and Japan agreed on a 2-stage stepwise global phase out of PFOA and related long-chain substances by the end of 2015 (ACC, 2015; FluoroCouncil, 2015/2016). A similar program existed in Canada[1]. All Stewardship Program participants were successful at virtually eliminating those chemicals globally from facility emissions and product content. Beyond possible impurities, Stewardship Program participants no longer manufacture, use, or sell PFOA and related long-chain substances. The voluntary phase out does not include manufacturers using PFOA in countries like China, India or Russia (ECHA, 2015a). After the Stewardship participants announced they were phasing out PFOA and related long-chain substances, companies who were not part of the Stewardship Program increased capacities (FluoroCouncil, 2016).

17. In 2011, PFOA-relevant technology and products were added to the Catalogue for the Guidance of Industrial Structure Adjustment in China (NDRC, 2013), including that new installation of PFOA production facilities shall be restricted and that PFOA-containing paints and fluoropolymers that use PFOA in the polymerization shall be eliminated. In 2013, fluoropolymers that use PFOA in the polymerisation were recognized as products with high pollution and high environmental risk ("dual-high" products) in the Comprehensive Catalog for Environmental Protection (China MEP, 2015).

18. The proposal to list PFOA, its salts and PFOA-related compounds in Annex A, B and/or C of the Stockholm Convention (UNEP/POPS/POPRC.11.5) highlighted concerns that the presence of PFOA in the environment is also influenced by the degradation of PFOA-related compounds, including side-chain fluorinated polymers. Hence the addition of PFOA alone to the Stockholm Convention would not be sufficient to protect human health and the environment. For some substances, e.g. for the fluorotelomer alcohol 8:2 FTOH[2] degradation to PFOA has been proven by experiment. Furthermore, potential PFOA-related compounds can be substances containing a perfluorinated alkyl chain with the formula $F(CF_2)_n$- (n=7 or 8) and that is directly bonded to any chemical moiety other than a fluorine, chlorine or bromine atom or a phosphonic, phosphinic or sulfonic group. Such substances can undergo abiotic degradation resulting in release of PFOA (Nielsen, 2013, 2014; Wang et al., 2014a; Ellis et al., 2004a). C8-substances (e.g. PFOA) may occur as impurities in the C6 alternatives. Thus, the C6 alternatives also contain C8 (and longer chain) residual substances, which can be released into the environment. (ECHA, 2015a).

1.1 Chemical identity

19. The proposed substances defined within the screening dossier (UNEP/POPS/POPRC.11/5) include pentadecafluorooctanoic acid (CAS No: 335-67-1, EC No: 206-397-9, PFOA, perfluorooctanoic acid) including its salts and PFOA-related compounds.

20. Taking into account the background document to the restriction proposals for PFOA, PFOA salts and PFOA-related compounds (ECHA 2015a; ECHA 2015c), the risk profile covers:

(a) PFOA (including its isomers);

(b) Its salts; and

(c) PFOA-related compounds which, for the purposes of this risk profile, are any substances that degrade to PFOA, including any substances (including salts and polymers) having a linear or branched perfluoroheptyl group with the moiety (C7F15)C as one of the structural elements, for example:

(i) Polymers with C8 to C16 based fluorinated side chains;[3]

(ii) 8:2 fluorotelomer compounds;

[1] Environmental Performance Agreements and Results: Perfluorinated Carboxylic Acids (PFCAs) and their Precursors (2010-2015), from http://www.ec.gc.ca/epe-epa/default.asp?lang=En&n=0D8C879E-1#X-2013092511492112

[2] FTOHs are polyfluorinated compounds typically characterized by even numbered perfluorinated carbons and two nonfluorinated carbons adjacent to a hydroxyl group (Dinglasan et al., 2004). For FTOHs, the prefix 'C8:2' denotes that for "X:Y", X = the number of perfluorinated carbons within the alkyl chain, and Y = the number of non-fluorinated carbons within the alkyl chain.

[3] DuPont, 1998. Technical information: Zonyl fluorochemical intermediates.

(iii) 10:2 fluorotelomer compounds.

PFOA-related compounds do not include:

(i) C8F17-X, where X= F, Cl, Br;

(ii) Fluoropolymers[4] that are covered by CF3[CF2]n-R', where R'=any group, n>16; or

(iii) PFOS, its salts and PFOSF as listed in Annex B to the Stockholm Convention.

21. Data on PFOA are presented in Table 1 and Table 2. The screening dossier (UNEP/POPS/POPRC.11/5) also further includes information on salts of PFOA and PFOA-related compounds based on the study carried out by the OECD (2007, 2011) as well as information from an assessment conducted by Environment Canada and Health Canada (2012). To maintain a concise document tables of data for PFOA salts and related PFOA compounds are provided in a background document to this risk profile (see section 1.1 of document UNEP/POPS/POPRC.12/INF/5).

Table 1: Identity of PFOA

CAS number:	335-67-1
CAS name:	Octanoic acid, 2,2,3,3,4,4,5,5,6,6,7,7,8,8,8-pentadecafluoro-
IUPAC name:	Pentadecafluorooctanoic acid
EC number:	206-397-9
EC name:	Pentadecafluorooctanoic acid
Molecular formula:	$C_8HF_{15}O_2$
Molecular weight:	414.07 g/mol
Synonyms:	Perfluorooctanoic acid; PFOA; Pentadecafluoro-1-octanoic acid; Perfluorocaprylic acid; Perfluoro-n-octanoic acid; Pentadecafluoro-n-octanoic acid; Pentadecafluorooctanoic acid; n-Perfluorooctanoic acid; 1-Octanoic acid, 2,2,3,3,4,4,5,5,6,6, 7,7,8,8,8-pentadecafluoro

Table 2: Overview of relevant physicochemical properties of PFOA

Property	Value	Reference/Remark
Physical state at 20°C and 101.3 kPa	Solid	Kirk, 1995
Melting/freezing point	54.3 °C 44 — 56.5 °C	Lide, 2003 Beilstein, 2005 cited in ECHA, 2013a
Boiling point	188 °C (1013.25 hPa) 189 °C (981 hPa)	Lide, 2003 Kauck and Diesslin, 1951
Vapour pressure	4.2 Pa (25° C) for PFO; extrapolated from measured data 2.3 Pa (20° C) for PFO; extrapolated from measured data 128 Pa (59.3° C) for PFO; measured	Kaiser et al., 2005; Washburn et al., 2005 Washburn et al., 2005 Washburn et al., 2005
Water solubility	9.5 g/L (25° C) 4.14 g/L (22°C)	Kauck and Diesslin, 1951 Prokop et al., 1989
Dissociation constant	<1.6, e.g. 0.5 1.5 — 2.8	Vierke et al., 2013 Kissa, 2001
pH-value	2.6 (1 g/L at 20 °C)	ECHA 2015a (reliability not assignable)

[4] Fluoropolymers are carbon-only polymer backbone with F directly attached to backbone C atoms.

22. There are two manufacturing processes to produce PFOA, its salts and PFOA-related compounds: electrochemical fluorination (ECF) and telomerization. From 1947 until 2002, the ECF process was mainly used to manufacture ammonium perfluorooctanoate (APFO) worldwide (80-90% in 2000) which results in a mixture of branched and linear isomers (78% linear and 22% branched isomers). The current extent of global ECF manufacturing is unknown; however, most of the manufacturers are using the telomerisation process nowadays, which mainly results in linear compounds (Wang et al., 2014a). Results from Jiang et al. (2015) suggest that ECF is still used by some manufacturers in China. ECHA (2013b) details the physico-chemical properties of APFO in the environment. The free PFOA stays in equilibrium with PFO, the conjugate base, in aqueous media in the environment as well as in the laboratory. The physico-chemical properties of PFOA and PFO are different. Therefore, the expected environmental fate will depend on the environmental conditions, which influence the equilibrium between base and acid (pH and pKa). APFO, which is often used in animal experiments, is very soluble in water. In aqueous solution it is present as anion PFO and the ammonium cation. Goss (2008) suggested that PFOA is expected to have a low pKa, such that >99% of the compound will occur in its anionic form (i.e., PFO) under most environmental conditions suggesting that the environmental partitioning of PFOA will be dominated by the anionic form. The dissolved anion PFO will stay in equilibrium with the corresponding acid in aqueous media. With currently available analytical methods it is not possible to distinguish between PFO and PFOA in samples. In the literature reporting human and environmental monitoring studies the concentrations are referred to as PFOA or APFO, but always both species (PFO and PFOA) are included in the given concentration (ECHA, 2013b).

23. A standardized method for the analysis of presence of PFOA in different matrices is currently not available. The unique chemical and physical properties of PFOA prevent it from being measured using conventional analysis. More complex methodology of liquid chromatography and tandem mass spectrometry (LC/MS-MS) has been proven most reliable for analyzing PFOA in biological and environmental samples and therefore the analytical method of choice (Xu et al., 2013; EFSA, 2008; Loos et al., 2007). This type of analysis has allowed for more sensitive determination of many perfluorinated chemicals (PFCs), including PFOA, in air, water, and soil (ATSDR, 2015).

1.2 Conclusion of the Review Committee regarding Annex D information

24. The POPs Review Committee evaluated the proposal regarding pentadecafluorooctanoic acid (CAS No: 335-67-1, PFOA, perfluorooctanoic acid), its salts and PFOA-related compounds (UNEP/POPS/POPRC.11/5) according to the requirements in Annex D of the Stockholm Convention at its eleventh meeting in Rome. The Committee concluded that PFOA fulfilled the screening criteria in Annex D. The Committee also decided to establish an ad-hoc working group to review the proposal further and prepare a draft risk profile in accordance with Annex E of the Convention and further that issues related to the inclusion of PFOA-related compounds that potentially degrade to PFOA and the inclusion of PFOA salts should be dealt with in developing the draft risk profile (Decision POPRC-11/4).

1.3 Data sources

25. The draft risk profile is based on the following data sources:

(a) Proposal submitted by the European Community and its member states that are Parties to the Convention (UNEP/POPS/POPRC.11/5), 2015;

(b) Information submitted by Parties and observers according to Annex E of the Convention: Albania, Austria, Canada, China, Germany, Hungary, Japan, Monaco, Norway, Romania Estonian Environmental Research Centre, FluoroCouncil, IPEN, Semiconductor Industry Associations;

(c) The Screening Assessment Report on PFOA, its salts and precursors prepared by Environment Canada and Health Canada, 2012;

(d) Screening Information Datasets (SIDS) on PFOA and the ammonium salt of PFOA prepared by the OECD, 2006, 2007, 2011, 2013;

(e) Support documents for the identification of PFOA and the ammonium salt of PFOA as a Substance of Very High Concern (SVHC) included under the EU Regulation on Registration, Evaluation, Authorization and restriction of Chemicals (REACH), (ECHA, 2013a, 2013b);

(f) Committee for Risk Assessment (RAC) and Committee for Socio-economic Analysis (SEAC) background document to the opinion on the Annex XV dossier proposing restrictions on PFOA, PFOA salts and PFOA-related compounds (ECHA, 2015a);

(g) Data from the United States Environmental Protection Agency (US EPA) PFOA Stewardship Programme;

(h) The Australian National Industrial Chemicals Notification and Assessment Scheme (NICNAS) Environment tier II assessment for both direct and indirect precursors of PFOA (NICNAS, 2015a and 2015b).

1.4 Status of the chemical under international conventions

26. PFOA is subject to one international convention. Under the Oslo/Paris Commission for the Protection of Marine Environment of the North-East Atlantic (OSPAR), a review of both PFOS and PFOA was conducted to assess the potential impact upon the environment. This led to the inclusion of PFOS on the list of chemicals for priority action in 2003. PFOA was not added to the list at that time pending additional research and review with the option for inclusion at a later date (OSPAR, 2006).

27. OECD provided a recent overview on risk reduction approaches for PFASs across countries (OECD, 2015). PFOA is subject to a number of national and/or regional regulations:

(a) In 2013, both PFOA and APFO were identified as Substances of Very High Concern (SVHC) upon their persistent, bioaccumulative and toxic properties and were included into the REACH-Candidate List (ECHA, 2013a, 2013b). Inclusion upon this list means the substances can be subject to further review and ultimately phased out under the Authorization process. Moreover, on request industry is obliged to inform consumers on the occurrence to the listed substances in consumer articles;

(b) In 2014 Germany and Norway lodged a joint proposal for the inclusion of PFOA within Annex XVII (restriction) of the REACH regulation within the EU (ECHA 2014a). The aim of the proposal was a total ban on manufacture, placing on the market and use (including import) of PFOA and its salts also including substances that may degrade to PFOA (PFOA-related compounds) in concentrations equal to or greater than 2 ppb. The proposed restriction also covers articles containing these substances. After submission of the proposal to the European Chemicals Agency (ECHA) stakeholders commented this proposal during the public consultation period and delivered new information. Subsequently, the proposal was updated by the Dossier Submitters together with ECHA's scientific committees RAC and SEAC and it has been transmitted to the European Commission for developing the final legislative proposal.

(c) PFOA was included under the Classification, Labelling and Packaging (CLP) Regulation (Regulation (EC) No 1272/2008), by the Commission Regulation (EU) No 944/2013 of 2 October 2013 (index number: 607-704-00-2). PFOA has been classified as Carc. 2 H351, Repr 1B H360D, Lact H362, STOT RE 1 (liver) H372, Acute tox 4 H332, Acute tox 4 H302 and Eye dam 1 H318.

(d) The Norwegian Environment Agency published an amendment to the consumer products regulation in 2014 banning the use of PFOA in consumer products and textiles. This has a transitional period allowing the import and sale of products before phase out;

(e) Within Canada following the screening assessment conducted in 2012, PFOA, its salts and precursors were found to meet the requirements of Section 64a of CEPA and were added to Schedule 1, the List of Toxic Substances. In June 2006, the Government of Canada published a Notice of Action Plan for the assessment and management of perfluorocarboxylic acids and their precursors. The Action Plan included measures to prevent the introduction of new substances into Canada that would contribute to the level of PFCAs (perfluorocarboxylic acids) in the environment, and to seek action from industry to address sources of PFCAs already in Canadian commerce. To this end, a voluntary Environmental Performance Agreement was signed on March 30, 2010. Signatories to the Performance Agreement agreed to reduce the amount of PFOA and long-chain perfluorocarboxylic acids in perfluorinated chemicals in Canadian commerce by 95% by December 31, 2010, and to virtually eliminate them by December 31, 2015. Furthermore in April 2015, the proposed *Regulations Amending the Prohibition of Certain Toxic Substances Regulations, 2012,* were published in Canada. These amendments propose to prohibit PFOA, its salts and precursors and products containing them, unless present in manufactured items. Furthermore, the amendments propose time-limited exemptions and ongoing permitted uses for certain applications where the development of alternatives is underway or where there are currently no known alternatives;

(f) In the United States of America, the US EPA established the PFOA Stewardship Programme in 2006. This is a programme that includes eight major manufacturers of PFOA, its salts and PFOA-related compounds (Arkema, Asahi, BASF, Clariant, Daikin, 3M/Dyneon, DuPont, Solvay

Solexis). The programme is a voluntary initiative to the phase-out the manufacture and use of PFOA, PFOA precursors and related higher homologue substances (US EPA, 2015).

(g) Russia regulates APFO in occupational air. A number of short- and middle chain PFASs are regulated in occupational air and water (OECD, 2013).

2. Summary information relevant to the risk profile

2.1 Sources

2.1.1 Production, trade, stockpiles

28. The following table summarizes information related to the production of PFOA, its salts, APFO and FTOH according to several literature sources. Further information is contained in section 2.1.1 of document UNEP/POPS/POPRC.12/INF/5.

Table 3: Production of PFOA, its salts, APFO and FTOH

Year/Period	Production	Value/Range [in t or t/y]	Reference
1992-2002	PFOA production 3M [in US]	113 t/y	3M communication to US EPA, 2003
2009	Estimated worldwide production of FTOH	11,000-14,000 t/y	Umweltbundesamt, 2009
2014	Production of PFOA related substances in the EU (actual volume is likely to be greater)	100 – 1,000 t/y	ECHA, 2015a
2003	Production of PFOA and its salts in China	30 t/y	Li et al., 2015
2012	Production of PFOA and its salts in China	90 t/y	Li et al., 2015

29. In 2005, producers were located in Italy, U.S., South America, Japan and China. Up until 2010, production was also carried out in Italy. All production of PFOA and its salts in the EU has now ceased, and manufacturing in Japan and the U.S. should now have stopped with the intention to phase out production by the end of 2015 (ECHA, 2015a). However, in China, the production of PFOA and its salts has tripled from around 30 t in 2004 to around 90 t in 2012 (Li et al., 2015).

30. In 2014, production of PFOA-related compounds in the EU was reported to be between 100-1,000 tonnes per annum (ECHA, 2015a). However, this volume is derived from a search in the ECHA-database of four PFOA-related compounds registered under REACH, and in its report ECHA concludes that the actual volume is likely to be greater. No other information concerning the production of PFOA-related compounds was identified in the submissions by parties, or in the literature reviewed.

31. Data concerning imports and exports of PFOA is limited and no information concerning global volume of trade flows has been identified owing to industry confidentiality claims (ECHA, 2015a).

32. PFOA ammonium salt was imported into Canada in quantities ranging between 0.1 to 100 t (2004 survey) (Environment Canada and Health Canada, 2012).

33. ECHA 2015a provides estimates on import figures for the EU. The main information related to imports is summarized in the following (detailed information see section 2.1.1 of document UNEP/POPS/POPRC.12/INF/5).

Table 4: Import of PFOA, its salts and PFOA related substances to the EU

Year	Imports to the EU	Value [in t]
2014	PFOA and its salts (decreasing trend since 2008)	~20
2014	PFOA and its salts (mixtures i.e. in fluoropolymer dispersions)	~10
2014	PFOA and its salts in articles (high uncertainty)	<10
2015	PFOA and its salts forecast to fall after 2015	<0.15
2014	PTFE	3 – 16
2014	PFOA related substances	100 – 1,000
2014	PFOA related substances in textiles (the total volume of PFOA related substances in imported articles is unknown)	1,000 – 10,000

Reference: ECHA (2015a)

34. According to the information gathered in a survey conducted by the OECD in 2009 (OECD, 2011), the reported concentration of PFOA in products containing the substance varies between <1-160 ppm. Concentrations of other PFOA-related compounds in products vary between 1-4,200 ppm, and concentrations of C8:2 fluorotelomers in products range between 5-35,000 ppm. Also ECHA (2015a) provides in its appendix data on concentrations of PFOA and related compounds in products such as outdoor clothing, workers protection clothing, membranes for apparel, treated home textile and upholstery, treated non-woven medical garments, leather finishing, carpets, impregnating sprays/ waterproofing agents, firefighting foams, treated paper, paints and inks, cleaning agents, floor waxes/wood sealants, lubricants and sealant tapes (refer to ECHA, 2015a, Appendix B, Tables A.B.2-4 and A.B.2-9 for more information).

35. Information on imports of products containing PFOA and PFOA-related compounds was only identified for Australia, Albania and the EU, as follows:

(a) Australia reported the import of an antifoam product containing less than 10% of a PFOA-related chemical (constituting ~10 kg of PFOA) in 2005 for use in a dyeing process with sulfur dyes (NICNAS, 2015b). Australia assesses individual chemical entities in consumer products and chemicals released from articles. Articles are not within the scope of the *Industrial Chemicals Notification and Assessment Act* (Australia 2016);

(b) In 2014, the EU reported the import of between 1,000-10,000 tonnes of PFOA-related compounds contained in textile articles (specifically within outdoor jackets). Of note, this volume is expected to decline after 2015 due to the availability of alternatives (estimated imports thereafter are between 300-3,000 tonnes per annum) (ECHA, 2015a);

(c) Albania provided information within the Annex E survey (Albania, 2015) for the quantity of goods imported that may contain PFOA for the years 2012–2015. This ranged between 3–20 tonnes for total net weight of all goods.

36. Stockpiles of firefighting foams containing PFAS including PFOA are likely to be present at military bases, airports, oil production facilities and rigs and other facilities (Baduel et al., 2015; Anderson et al., 2016; FluoroCouncil 2016). For example, the US military did possess approximately 11 million liters of aqueous fire-fighting foam containing PFCs including PFOA (Place and Field, 2012). Two studies report on estimated quantities of AFFF in the U.S. (Darwin, 2004, 2011).

2.1.2 Uses

37. Due to their physico-chemical properties, PFOA, its salts and its related compounds are used in a wide variety of applications and consumer products across many sectors (primarily automotive, electronics, construction and aerospace industries) (ECHA, 2015a; OECD, 2013). ECHA (2015a) provides estimation on the amounts of PFOA and its salts as well as on PFOA related substances used in the EU in different sectors/industries. The main information is summarized in the following.

Table 5: Use of PFOA, its salts and PFOA-related compounds in different sectors in the EU

Use in the EU	Sector/Industry	Value/Range [in t]
PFOA-related compounds	Textile and leather treatment	~1,000
	Paper treatment	>150 – 200
	Firefighting agents	>50 – 100
	Paints and inks	>50 – 100
	Others uses	>0.1 – 0.5
PFOA and its salts	Manufacture of fluoropolymers	<20
	Photo industry	1.0
	Semiconductor industry	<0.05
	Other uses 0.5-1.5 t	0.5-1.5

Reference: ECHA (2015a)

38. PFOA is predominantly used in the form of APFO in aqueous solution as an emulsifier and processing aid in the manufacture of many fluoropolymers, such as PTFE, FEP (fluorinated ethylene propylene), PFA (perfluoroalkoxy alkane) or PVDF (polyvinylidene fluoride) (Emmett et al., 2006; OECD, 2006; ECHA, 2015a). PFOA is a contaminant in fluorochemicals and telomer products (Emmett et al., 2006). Fluoropolymers are used across many sectors for different purposes, including: in the manufacture of hoses, cable and gaskets; non-stick coatings on cookware; and personal care products (Begley et al., 2005; Environment Canada and Health Canada, 2012; U.S.EPA, 2009; van der Putte et al., 2010; ECHA 2015a). APFO is also used in the processing of paint, photographic film additives and in the textile coating industry (OECD, 2006), and can be found in certain aqueous

fire-fighting foams (OECD, 2006; Prevedouros et al. 2006; Environment Canada and Health Canada, 2012). PFOA is also used, as a surfactant and processing aid in the manufacture of semi-conductors used in the photolithographic process (van der Putte et al., 2010; ESIA, 2015) and as a replacement for perfluorooctane sulfonate (PFOS) (ECHA, 2015a).

39. PFOA-related compounds are used as surfactants and/or fluorinated polymers for a variety of products including ski waxes (Freberg et al., 2010; Nilsson et al., 2010a, 2010b) and treatments for leather, other textiles (such as outdoor textiles and carpets) (Washburn et al., 2005; Begley et al., 2005), and paper packaging of microwave popcorn bags (Sinclair et al., 2007). High PFOA levels were identified in ski waxes (up to about 2000 µg/kg PFOA), outdoor textiles (up to 19 µg/m^2 PFOA) and some baking papers (up to 15 µg/m^2 PFOA) (Kotthoff et al., 2015). PFOA-related compounds are used as a surface treatment agent in both the stone and paper industries (China, 2015), in medical devices (Austria, 2015), as an antifoam products for use in the dyeing process using sulfur dyes (NICNAS, 2015b), and as a leveling agent in paints and inks. PFOA-related compounds are used as (1) non-polymeric substances for firefighting foams, wetting agents or cleaners (OECD, 2013; van der Putte et al., 2010) or (2) as part of side-chain fluorinated polymers, such as fluoroacrylate polymers (US EPA, 2009; van der Putte et al., 2010). Side-chain fluorinated polymers are used to provide a water, grease and soil protection, for example in applications such as textiles, products for apparel, leather, paper and cardboard (e.g. in food packaging), paints and lacquers (e.g. exterior and interior architectural paints), non-woven medical garments, floor waxes and stone/wood sealants, thread sealant tapes and pastes, adhesives or products for apparel. Fluorotelomers is a term often used in the literature, referring to substances produced with the telomerization process. Fluorotelomers might be PFOA-related compounds if they contain the respective chain length. For fluorotelomers it was reported that 80% are used in polymers and 20% in non-polymeric applications. Identified major uses of PFOA-related compounds in Europe are surface treated textiles, fire-fighting foam, surface treated paper and paints and inks (ECHA, 2015a).

2.1.3 Releases to the environment

40. Numerous direct and indirect sources of PFOA, its salts and PFOA-related compounds contribute to the overall release of PFOA to the environment. Direct releases to the environment occur from the production of the raw substance, during the processing, use and disposal of the chemical and of products containing the chemical. Main emission vectors are water, wastewater and dust particles. Indirect releases to the environment occur due to the formation of PFOA from PFOA-related compounds. They are released to air and waste water during manufacture of the substances themselves, from side-chain fluorinated polymers and during use and disposal of consumer articles treated with PFOA-related compounds. When emitted to the atmosphere, they can be degraded to PFOA, and deposited on soil or surface waters (see also para 2.1.3 of document UNEP/POPS/POPRC.12/INF/5). They are also washed out from the atmosphere via precipitation (ECHA, 2015a). The estimated global cumulative emission of PFOA ranged from 2078 to 18366 t over the period of 1951 to 2030, thus presenting the compound with the highest cumulative emission of the C_4-C_{14} PFCAs (Wang et al., 2014a). The study also indicates a decrease in estimated emissions in North America, Western Europe and Japan, concurrently with increases in India, Russia and China.

41. The manufacturing of PFOA has been identified as a major direct source of PFOA in the environment (Armitage et al., 2009; Prevedouros et al., 2006). During the manufacturing of PFOA the substance can be emitted into the environment either via waste water or into the air. Prevedouros and co-workers (2006) estimated global PFOA manufacturing emissions: 45 t in 1999, 15 t in 2004, 7 t in 2006. PFOA can also be directly released from manufacturing and use of PFOA-related compounds. (Pistocchi and Loos, 2009; Loos et al., 2008; Dauchy et al., 2012). As detailed by Wang et al. (2014a), releases related to the manufacturing and use of PFOA have likely changed along with changes in practices at manufacturing sites (i.e. with vs. without control measures of waste streams). A recent publication documents the first source-specific inventory for environmental releases of PFOA/PFO in China from 2004 to 2012 and estimates cumulative environmental releases reaching 250 tonnes (t) over a period of nine years (Li et al., 2015) and several studies confirm the relevance of PFOA in China. Chinese samples from river/estuary systems were highly polluted by an industrial point source discharging mainly PFOA (Heydebreck et al., 2015) and an individual plant producing PTFE and other fluoropolymers releases extraordinary high quantities of PFOA into a river (Wang et al., 2016). There is a positive correlation between the proximity to a fluoropolymer production facility and PFOA concentrations in rivers (Shi et al., 2015) and substantial levels of per- and polyfluoroalkyl substances were detected in outdoor dust in China with PFOA being a predominant substance (Yao et al., 2016). Historic releases to the environment from production are available for a U.S. plants in West Virginia (Emmett et al., 2006; Paustenbach et al., 2007; Lerner, 2005) and from other large scale production until 2002 (Minnesota State Dep, 2016; Oliaei et al., 2013; Minnesota Pollution Control Agency, 2016).

42. The manufacture of fluoropolymers is considered the main direct emission source of PFOA, where APFO is used as processing aid (Armitage et al., 2009; Prevedouros et al., 2006). From fluoropolymer production sites, PFOA is emitted to air (mainly particle bound) and water. Fluoropolymer dispersions are often used to coat metal and fabric surfaces. During the dispersion processing and subsequent use and disposal of consumer articles are released. Environmental releases from the direct use of PFOA are also possible from the photo industry and the semiconductor industry (van der Putte et al., 2010; ESIA, 2015; SIA, 2015).

43. Releases to the indoor domestic environment arise from the use of products containing PFOA and its related compounds for several products purchased from retail in the US, with the largest releases from use reported for professional carpet-care liquids, pre-treated carpeting, floor waxes and stone/tile/wood sealers and household textiles and upholstery (US EPA, 2009a). Emissions from outdoor jackets occur mainly during washing and impregnation procedures (Umweltbundesamt, 2014).

44. The use of PFOA-related compounds results in direct and indirect emissions of PFOA These result from impurities in fluorotelomer based products and from degradation of fluorotelomer based products as well as from the manufacture, use and disposal of side-chain fluorinated polymers (ECHA, 2015a; Environment Canada and Health Canada, 2012). The manufacture of side-chain fluorinated polymers represents one major industrial use of PFOA-related compounds (Russell et al., 2008; ECHA 2015a; Danish Ministry of Environment, 2013).

45. Releases to the environment occur from management of waste water and of solid waste consisting of or contaminated with PFOA, its salts or PFOA-related compounds. Industrial wastewater from fluoropolymer manufacturing is considered the most important point source of PFOA to surface water. Waste water treatment plants do not remove PFOA efficiently. Thus, a large share remains in the water phase and enters surface water bodies and degradation of PFOA-related compounds during the treatment can even lead to higher PFOA emissions (ECHA 2015a; Schultz et al., 2006; Bayerisches Landesamt für Umwelt, 2010; Houtz et al., 2016; UNEP/POPS/POPRC.12/INF/5). During solid waste management PFOA releases may result from incineration, landfilling and recycling (Yamada et al., 2005; Poulsen et al., 2005) and it is assumed that recycling of contaminated wastes contributes to environmental releases (ECHA, 2015a). There are a number of studies available related to waste water, sewage sludge or landfill leachate and waste treatment that include measurements of direct releases to the environment from the disposal of PFOA and its related compounds (Muir and Scott, 2003; Boulanger et al., 2005; Yan et al., 2015; Ikonomou, 2006; Busch et al., 2010; Guo, 2008; US EPA, 2009b; OECD 2011).

46. PFOA-related compounds will degrade to PFOA in sludge, soil, water and air (Wang et al., 2005a, 2005b; Moody and Field, 1999; IPEN, 2015; Dasu and Lee, 2016; Bizkarguenaga et al., 2016), and such degradation has been noted across many products containing PFOA-related compounds (Dasu et al., 2013; Ellis et al., 2003; Ellis et al., 2004a; Frömel and Knepper, 2010; Gauthier and Mabury, 2005; Hilal et al., 2004; Jackson and Mabury, 2013; Jackson et al. 2013; Rayne and Forest, 2010; Renner, 2008; Wang et al., 2005a; Wang et al., 2005b; Washington et al., 2009; Young and Mabury, 2010; Young et al., 2008; Zhang et al., 2013; Butt et al., 2014; Rankin et al., 2014; Washington et al., 2015). Release of PFOA to the environment results from its use in fire fighting foams. Aqueous film forming foams (AFFF) were developed in the early 1960s with PFASs as key components and constitute a remaining source of PFOA e.g. in firefighting training pads or around military aviation bases (Baduel et al., 2015; Australia, 2016).

47. There are no known natural sources of PFOA or their related compounds (Kissa, 1994; Environment Canada and Health Canada, 2012; IPEN 2015).

48. These above paragraphs provide overview information on releases to the environment. For more detailed information, please see section 2.1.3 of document UNEP/POPS/POPRC.12/INF/5.

Contribution from salts of PFOA and PFOA-related compounds to the environmental occurrence of PFOA

49. The nomination proposal for PFOA, its salts and PFOA-related compounds (UNEP/POPS/POPRC.11/5) highlights concerns that PFOA-related compounds could be contributing to environmental concentrations of PFOA through degradation. This point was raised by the Danish Ministry of Environment (2013) who suggests that: *"An assessment of PFOA to the Baltic Sea estimated with high uncertainty that 30% of the releases were due to the transformation of fluorotelomers"*.

50. Studies by Prevedouros et al. (2006) and Kim et al. (2012 and 2013) looked at the fate and behaviour of FTOHs (6:2 and 8:2 FTOHs) within terrestrial environments, suggesting that degradation products from 8:2 FTOHs will include PFOA. Prevedouros et al. (2006) estimate that around 1% of

PFCA emissions originate from fluorotelomer raw material degradation which would include PFOA; while Kim et al. (2012) highlights a biotransformation process within soils, whereby soil bacteria degraded FTOHs (both long and short chain) into a range of degradation products which include PFOA. Washington et al (2009) incubated an acrylate-linked fluorotelomer polymer in soil microcosms and monitored the microcosms for possible fluorotelomer and PFC degradation products. These and other results suggest that fluorotelomer-polymer degradation is a source of PFOA to the environment (Washington et al., 2009; Washington et al., 2014; refer to Koch et al., 2006, 2009; Russell et al., 2008, 2010 for a broader view of degradation and half-lives).

51. Thermolysis of PTFE also yields hexafluoropropylene and other compounds including PFOA (Ellis et al., 2001; Schlummer et al., 2015) while monomers used to make long-chain fluorotelomers and degraded from them can be biotransformed to PFOA (Butt et al., 2010a). Taylor (2009) and Taylor et al. (2014) in collaboration with DuPont could not detect PFOA during laboratory-scale combustion testing. Krusik and Roe (2004) and Krusik et al. (2005) studied the thermal decomposition of the ammonium salt of perfluorooctanoic acid (APFO) and PFOA. APFO and PFOA are thermally unstable at waste incineration temperatures (~1000°C). For example, the half-life for APFO is estimated to be less than 0.2 s at 350 °C. In light of the historically large production of fluorotelomer-based polymers (FTPs) and the poor efficacy of conventional treatments for recovery of PFCAs from waste streams, degradation of FTP based materials have the potential to increase environmental levels of PFCAs.

52. FTPs manufactured to date potentially could increase PFCAs 4- to 8-fold over current oceanic loads, largely depending on the integrity of disposal units to contain PFCAs upon hydrolytic generation from FTPs (Washington and Jenkins, 2015; refer to Koch et al., 2006, 2009; Russell et al., 2008, 2010 for alternative assessments indicating lower global loading potential).

53. PFOA is also found in packaging materials. For example, PFOA and related substances in fluoropolymer resin products vary up to 150 mg/kg and 5–3000 mg/kg in fluropolymer dispersion products in non-US based production locations. PFOA can also be extracted at low concentrations from textiles and packaging treated with side-chain-fluorinated polymers. The releases of substances from the different parts of the life cycle and the significance of the exposure of humans and the environment is still not fully understood and more information is needed (Danish Ministry of Environment, 2013).

54. Fluorotelomer carboxylic acids (FTCAs) and the corresponding unsaturated acids (FTUCAs) are intermediates in the biodegradation of industrially produced fluorotelomer alcohols (FTOHs) to environmentally persistent perfluorinated carboxylic acids (PFCAs). The fate of these compounds was investigated in a simple sediment–water microcosm system. Microcosms were spiked with 8:2 FTCA, 10:2 FTCA and 8:2 FTUCA, or 10:2 FTUCA. The FTCAs and FTUCAs investigated degrade rapidly. Identifiable degradation products of FTCAs and FTUCAs were observed and include PFOA for both, 8:2 and 10:2 compounds. (Myers and Mabury 2010; Butt et al., 2014**).**

55. Environment Canada and Health Canada (2012) and ECHA (2015a) compile scientific evidence on the degradation/transformation of PFOA related substances based on different sources (the information from both sources is compiled in section 2.1.3 of document UNEP/POPS/POPRC.12/INF/5).

56. ECHA (2015a) provides further details on the role of PFOA-related compounds to degrade and contribute to environmental concentrations of PFOA: *"The yields of PFOA are in most studies in the range 1.7 – 20%. The duration of the studies varies from 28 days to 90 days. One study was performed with a longer time scale of 7 months. The yield of PFOA in this study was in the range of 10 — 40% (Wang et al., 2009).This indicates that some of the degradation steps may take some time although the estimated half-life of the PFOA-related compounds is in the range of days. Thus, it can be hypothesized that in the environment PFOA yields from PFOA-related compounds are much higher than measured in the short time degradation experiments. We further hypothesize that over a long time frame of 5 — 10 years PFOA yields from PFOA-related compounds degradation are around 80%".*

57. In conclusion, PFOA-related compounds have the capacity to degrade to PFOA in the natural environment contributing to the environmental concentrations of PFOA. The quantities of PFOA generated via degradation from PFOA-related compounds are more debatable with values of between 1.7% - 40% quoted. However, as noted by ECHA (2015a), these results are based on shorter term tests and over longer periods of time the quantity of PFOA may be much higher (around 80%).

2.2 Environmental fate

2.2.1 Persistence

58. PFOA is extremely stable within the natural environment due to its chemical properties and does not degrade under environmentally relevant conditions. This fact is corroborated by the US EPA (2014), Australian NICNAS (2015a and 2015b), Environment Canada and Health Canada (2012) and OECD (2006). In particular, both assessments conducted by Environment Canada and Health Canada and OECD noted that there was no clear degradation of PFOA under abiotic or biotic conditions.

59. Within the aquatic compartment under natural environmental conditions, PFOA has a half-life of greater than 92 years with the most likely value of 235 years and shows no obvious decay from photodegradation (Todd, 1979; Hatfield, 2001; 3M, 2001). In aquatic environments where PFOA undergoes indirect photolysis, the half-life was estimated to be longer than 349 days (Hatfield, 2001; ECHA, 2013a, 2013b). A review of half-life data and mechanisms of decay is presented in Table 6.

Table 6: Reported findings on the persistence of PFOA (adapted from Environment Canada and Health Canada, 2012)

Medium	Mechanism	Degradation Half-life	References
Water	Photolysis	No photodegradation	Todd 1979; Hatfield, 2001
Water	Indirect photolysis	> 349 days	Hatfield, 2001
Water	Hydrolysis	~ 235 years	3M, 2001
Air	Hydroxyl reaction	~ 130 days	Hurley et al., 2004
Sludge	Biodegradation	> 2.5 months	Pace Analytical , 2001
Soil/sludge	Biodegradation	> 259 days	Liou et al., 2010

60. On the basis of the available data, abiotic degradation of PFOA in the atmosphere is expected to be slow. The atmospheric lifetime of PFOA has been predicted to be 130 days (conclusion by analogy from short-chain perfluorinated acids; see OECD, 2006; Hurley et al., 2004).

61. Persistence within the terrestrial environment mirrors the position seen in the aquatic environment, with high persistence, slow degradation and long half-lives. Both the REACH Annex XV restriction dossier (ECHA, 2015a) and REACH proposal for identification of PFOA as an SVHC (ECHA 2013a) state that PFOA was not biodegradable and that, based on high persistence, it was not possible to calculate half-lives in soil or sediment. This was the same conclusion presented within the screening dossier (UNEP/POPS/POPRC.11.5).

62. More detailed information on persistence is provided in section 2.2.1 of document UNEP/POPS/POPRC.12/INF/5.

Summary on persistence

63. Based on the available experimental evidence it is concluded that PFOA is highly persistent in all environmental compartments, with a strong resistance to all conventional mechanisms of degradation under relevant environmental conditions.

2.2.2 Bioaccumulation

Screening assessment based on physical-chemical properties

64. Due to the high surfactant capacity of PFOA and its ability to form multiple layers in octanol/water, it is not possible to analyze log K_{ow} directly (US EPA, 2002). As quoted in Annex D of the Stockholm Convention and reported in Table 2, the derived estimates vary from above to below the critical log K_{ow} value of 5. Studies for BCF and BAF also highlight values below the critical value of 5,000 quoted by Annex D. However, based on the physical properties, PFOA is known to undergo a protein bioaccumulation mechanism rather than lipid partitioning (UNEP/POPS/POPRC.3/INF/8/2003), which makes standard BCF/BAF analysis less meaningful. Thus the use of log K_{ow}, BCF and BAF have been demonstrated to be inappropriate measures of bioaccumulation of PFOA (ECHA, 2013a).

65. To assess whether PFOA meets the bioaccumulation criterion, the focus is placed on the Annex D paragraph c) ii and iii; the evidence for concern within species as a part of monitoring. This includes an approach utilising biomagnification factors (BMF) and trophic magnification factors (TMF), which has been adopted alongside monitoring of higher trophic tier species to substantiate that bioaccumulation occurs in the natural environment. BMF and TMF approaches assess predator-prey relations and the whole food chain, respectively, to evaluate the flow of material and substantiate

whether biomagnification might take place across trophic levels. A number of studies have assessed both BMF and TMF within ecosystems spanning the Arctic, Canada, USA, Netherlands and Brazil with reported values of >1 (critical value), suggesting that bioaccumulation of PFOA is taking place across trophic levels (Houde et al., 2006; Kelly et al., 2009; Martin et al., 2004; Tomy et al., 2004, 2009; Butt et al., 2008).

66. A literature review of studies reporting the BMF and TMF of PFOA indicated wide ranges of BMF (min=0.04; max=125) and TMF (min=0.58; max=13), raising the concern of the reliability of these values as indicators of bioaccumulation potential. This might be a result of several factors such as nonachievement of steady-state conditions, uncertainties in the feeding ecology and the impact of metabolism of precursor compounds. It is suggested that BMFs and TMFs to be determined in dietary studies performed under strictly controlled conditions with consideration of measured elimination half-lives (Franklin, 2016).

Bioconcentration studies in aquatic organisms

67. Because of the high surfactant capacity and solubility of PFOA, fish might excrete PFOA through the gills leading to reduce uptake and bioaccumulation. This explains the often low values seen in BMF/BAF tests using fish. Equally for BMF/TMF analysis where the higher predators within the food chain are fish species it can be seen that the critical values fall below 1. BCF values within the aquatic environment tend to be low. Studies based on water breathing animals provide evidence that the bioaccumulation criterion in the aquatic environment is not met (OECD, 2006; Kelly et al., 2009). There are several studies investigating the isomer profile of PFOA in the aquatic organisms. In a marine food web, the linear isomer of PFOA is the dominant form found in biota. In another study, branched PFOA isomers accumulated in rainbow trout tissue (Fang et al., 2014; De Silva et al., 2009).

68. Studies for air breathing aquatic species are scarce. However, the potential for bioaccumulation with marine mammals is confirmed. There is evidence that PFOA biomagnifies in air-breathing mammals because BMFs range from 1.3 – 125 for selected predator prey relationships and TMFs range from 1.1 to 13 for selected food chains. For non-fish species, particularly air-breathing terrestrial and avian species, bioaccumulation is shown to occur (Houde et al., 2006; Butt et al., 2008; van den Heuvel-Greve et al., 2009; Müller et al., 2011).

69. More detailed information on bioconcentration in aquatic organisms is provided in section 2.2.2 of document UNEP/POPS/POPRC.12/INF/5.

Bioaccumulation studies in terrestrial organisms

70. A number of studies have been completed highlighting the presence of PFOA in higher-tier terrestrial species. Studies include an overview of the presence of perfluorinated chemicals in marine, limnetic and terrestrial biota in Germany (Rüdel et al., 2011). PFOA was detected in liver samples from Canadian bears, and ecosystem studies in Canada highlighted the presence of PFOA above detectable limits in lichen, caribou and wolves. Trophic magnification factors for wolf/caribou/lichen (or vegetation) ranged from 1.1 to 2.4. (Martin et al., 2004; Müller et al., 2011). In these three studies, the potential for PFOA to bioaccumulate within terrestrial species was confirmed. A feeding study with fattening pigs showed that PFAAs accumulated in their tissues. The authors modeled related toxicokinetics and concluded that pigs exhibit longer elimination half-lives (236 days for PFOA) than reported for most organisms (Numata et al., 2014).

71. More detailed information on bioconcentration in terrestrial organisms is provided in section 2.2.2 of document UNEP/POPS/POPRC.12/INF/5.

Summary on bioaccumulation

72. The assessment of bioaccumulation for PFOA is complicated by its physical properties, which make assessment of log K_{ow}, BCF and BAF approaches challenging. PFOA does not accumulate in water-breathing animals according to the criteria of the Stockholm Convention. This can be explained by the way that fish process and excrete PFOA through their gills.

73. PFOA biomagnifies in air breathing mammals. PFOA has been detected within the body tissues of air-breathing aquatic species. For terrestrial species, the presence of PFOA is readily detected, with a number of studies indicating BMF and TMF scores of greater than 1. There is evidence that PFOA bioaccumulates in air-breathing mammals and other terrestrial species, including humans (see specific section 2.3.2 on human exposure).

2.2.3 Potential for long-range environmental transport

74. The screening dossier (UNEP/POPS/POPRC.11/5) highlights the high persistence and stability of PFOA, its salts and PFOA-related compounds, particularly within the air compartment. Hurley et al. (2004) quote that the atmospheric lifetime of PFOA with respect to hydroxyl radicals has been predicted to be 130 days (see Table 6). This would be sufficient amount of time to allow PFOA to travel considerable distances from the point of emission.

75. Franklin (2002) calculated an atmospheric lifetime of PFOA to be in the order of days if PFOA is emitted from a ground source, and therefore, PFOA is likely not subject to long-range transport. However, if PFOA is produced from an atmospheric source (i.e. via precursors) and if the major loss mechanism is wet or dry deposition, then it may have a lifetime of 20-30 days before deposition (Ellis et al, 2004b). This would be sufficient amount of time to allow PFOA transport over many thousands of kilometres.

76. Modeling studies have reported oceanic transport as the dominant pathway for distributing PFOA (primarily from direct sources) to the Arctic. It is believed that ocean circulation and its variations are factors that determine the long-range distribution and fate of PFOA (Stemmler and Lammel, 2010; Armitage et al., 2009).

Presence of PFOA, its salts and PFOA-related compounds in remote areas

77. Alongside the persistent characteristics of PFOA and environmental modeling data to suggest the capacity for long-range transport, environmental monitoring data from a number of studies also exist to help corroborate the model estimates. Table 7 provides details of monitoring for PFOA within surface water, ice, sediment and biota from remote locations far from the point of use and emission.

Table 7: Examples of presence of PFOA in remote areas

Sample	Value	Remarks	Reference
Surface Water			
Canadian Arctic lakes (Meretta, Resolute, Char, Small, North, and 9 Mile)	0.6 – 17 ng/L (range)	2010-2011	(Lescord et al., 2015)
Sea Water / Ice			
Baydaratskaya Bay (Russian Federation)	0.1307 (±0.077.2) ng/L (average ± std dev.)	2007	(Saez et al., 2008)
Greenland Sea	0.020 – 0.111 ng/L (range)		(Theobald et al., 2007; ECHA, 2015a)
Sediment			
Canadian Arctic lakes (Char Lake and Resolute Lake)	1.7 and 7.5 ng/g dw <1.1 and 2.3 ng/g dw 1.2 and <1.8 ng/g dw (range)	0-1 cm (depth) 1-2 cm 2-3 cm	(Stock et al., 2007)
Air			
High volume air samples collected from vessels on Atlantic Ocean, Southern Ocean and Baltic Sea High volume air samples from a land-based site close to Hamburg, Germany	0.7 pg/m^3 (average) 0.3 pg/m^3 (average)	2007-2008	(Dreyer et al., 2009)
Birkenes Zeppelin Andøya (Norway)	0.32 pg/m^3 0.22 pg/m^3 0.19 pg/m^3 (average)	2014	(NILU, 2015)
Cornwallis Island (Canada)	1.4 pg/m^3 (average)	2004	(Stock et al., 2007)
Biota			
Polar bear (liver) (East Greenland)	0.6 – 14 ng/g ww 6.8 – 15.8 ng/g ww 11.8 – 17.6 ng/g ww (range) 14 ng/g ww 12.3 ng/g ww 4.8 ng/g ww (annual average)	1990 (year) 1995 2006 2006 2010 2011	(Dietz et al., 2007) (Rigét et al., 2013)

Sample	Value	Remarks	Reference
Polar bear (liver) (North American Arctic, European Arctic)	2.4 – 36 ng/g ww (range of geometric means)		(Smithwick et al., 2005)
Ringed seal (liver) (Arviat – Canadian Arctic)	<0.85 – 3.6 ng/g ww (range)		(Butt et al., 2007)
Ringed seal (liver) (East Greenland)	1.6 ng/g ww 2.2 ng/g ww <Limit of detection (annual average)	2006 2008 2010	(Rigét et al., 2013)

78. There is evidence of PFOA present in the remotes regions of the Arctic ice cap (US EPA, 2014), surface and sea water in Arctic regions (Butt et al., 2010b; AMAP, 2014; Benskin et al., 2012a, 2012b; Veillette et al., 2012; Kwok et al., 2013; Cai et al., 2012; Zhao et al., 2012a) snow and ice cores from China (e.g. northern China and Tibetan Plateau) (Wang et al., 2014b; Shan et al., 2015), air, snow/ice cores, water, sediment and biota samples from Norway (Xie et al., 2015; NILU, 2015; Kwok et al., 2013), snow samples from Slovakia, Switzerland and Italy (Cobbing, 2015) as well as air, water and fauna samples from Antarctica and the Southern Hemisphere (Zhao et al., 2012a; Tao et al., 2006; Danish Ministry of Environment, 2013; Wang et al., 2015).

79. Lescord et al. (2015) report evidence of PFOA in lake food webs from the Canadian high Arctic. Evidence is also reported to show the contamination in eggs of the high-artic ivory gull (*Pagophila eburnea*) (Lucia et al., 2015) and other Arctic and North Atlantic mammals (Bytingsvik et al., 2012; Rotander et al., 2012; Rigét et al., 2013). Different PFOA isomers were detected in liver samples of polar bears from the Canadian Arctic and eastern Greenland such that Greenland polar bear samples showed a variety of branched isomers while only the linear PFOA isomer was determined in Canadian samples (de Silva and Mabury, 2004). Regarding the Arctic, PFOA was detected in liver samples of killer whales, seals, and polar bears from East Greenland (Gebbink et al., 2016).

80. Fluorotelomer alcohols such as n-$C_8F_{17}CH_2CH_2OH$ appear to be a significant global source of persistent bioaccumulative perfluorocarboxylic acid pollution, and present modeling results show that with current estimates of chemistry and fluxes the atmospheric oxidation of 8:2 FTOH can provide a quantitative explanation for the presence of PFCAs including PFOA in remote regions (Wallington et al., 2006; Young et al., 2007). Besides, biotransformation of 8:2 FTOH to PFOA has been shown in laboratory experiments (Butt et al., 2014).

Potential mechanisms for long range transport

81. Bengtson Nash et al. (2010) and Prevedouros et al. (2006) discuss two key mechanisms to aid the long range transport of PFOA to remote regions. The first mechanism involves a release to environment either as air-borne dust particles contaminated directly by PFOA or salts of PFOA, or a direct release to surface waters. These releases then undergo long range transport through a cycle of deposition and volatization from marine waters, with the transport in water via the marine environment likely to be the dominant delivery method to the Arctic regions. It has been suggested that hydrospheric transport will form a slow but primary input pathway of PFCs to the Antarctic region (Bengtson Nash et al., 2010). The second mechanism involves a delivery through air-borne precursors (such as FTOHs) again through contaminated dust particles and then the degradation of these materials to form PFOA *in situ* on arrival.

82. ECHA discusses the mechanism of atmospheric transport. Due to the relative vapor pressures of APFO, PFOA, and perfluorooctanoate (PFO), the chemical form potentially most subject to gas-phase atmospheric transport is PFOA (ECHA, 2015a). Franklin (2002) suggested that in the presence of water in air, gaseous PFOA condenses to aerosol particles and dissociates to corresponding PFO. This would suggest that cycling between atmosphere and ground through wet/dry deposition and resuspension is possible and would aid the long range transport of PFOA. Climate change leading to melting snow and ice has also been proposed as a potential mechanism (Zhao et al., 2012a).

83. More detailed information on long-range transport is provided in section 2.2.3 of document UNEP/POPS/POPRC.12/INF/5.

Summary on long-range environmental transport

84. PFOA is highly stable and resistant to degradation. Monitoring of water, air, sediment and biota at remote locations all detect the presence of PFOA. Equally, environmental modeling data suggest that the capacity for long range transport (e.g. oceanic transport) does exist while others have identified key mechanisms involving precursors that would make long range transport plausible. On this basis, it can be concluded that PFOA meets the Annex D criterion for long range transport.

2.3 Exposure

2.3.1 Environmental monitoring data

85. Various studies demonstrate that PFOA is ubiquitously present in the environment. ECHA (2015a) contains a selection of studies, which report detections of PFOA and related compounds in several compartments (surface water, deep-sea water, drinking water, wastewater treatment plant, sediment, groundwater, soil, atmosphere, dust, biota, and human) at worldwide sampling locations (see ECHA, 2015a, Table A.B.4-8 in Appendix B; see also section 2.3.1 of document UNEP/POPS/POPRC.12/INF/5). No large-scale monitoring program has been conducted for PFOA and only limited time trend studies are available. There is not sufficient information available to conclude on the trend of environmental concentrations. The available time trends studies indicate both decreasing and increasing trends in biota in Europe as well as in arctic regions (ECHA 2015a, Roos and Benson, 2016, Faxneld et al., 2014; Rigét et al., 2013).As PFOA is not degradable this decreasing trend is not proven by water and sediment samples suggesting that oceans and sediments are sinks of PFOA (ECHA 2015a).

86. Environmental monitoring data has been gathered for a number of sites still producing PFOA and its related compounds in China. PFOA has been found in sediment, river water, surface and groundwater as well as drinking water, primarily near PTFE and perfluorobutane sulfonate production facility or fluorine industry parks (Bao et al., 2011; Chen et al., 2015; Shi et al., 2015, Yao et al., 2014). Although it is widely accepted that telomerization is currently the predominant manufacturing method for PFOA, yielding an isomerically pure and linear product, electrochemical fluorination is still used by some manufacturers in China (Jiang et al., 2015). This is confirmed with the analysis of isomer profiles of PFOA in fresh snow samples collected in northern China, which were in agreement with the signature of the historical 3M electrochemical fluorination products, suggesting that these products were still produced and used in China (Shan et al., 2015).

87. PFOA was found in the majority of ground water samples in the EU and of public drinking water systems in the U.S. (Loos et al., 2010; Post et al., 2009). Reasons for groundwater contamination are e.g. release to surface soils, general atmospheric deposition, landfill leachate, historical use of AFFF e.g. in the vicinity of airports and fire-fighting training sites (Xiao et al., 2015; Eschauzier et al., 2013; Yan et al., 2015; Filipovic et al., 2015; KemI, 2016). Currently, there is a large-scale drinking water monitoring program funded by the U.S. EPA under the Safe Drinking Water Act called the Unregulated Contaminant Monitoring Rule (UCMR), where over 4800 public water systems are being monitored for 30 contaminants including PFOA (US EPA, 2016).

88. An assessment of the relative contribution of historic (i.e. electronically fluorinated) and contemporary (i.e. telomer) sources of PFOA in various seawater samples indicated that the dominant PFOA source(s) to the Pacific and Canadian Arctic Archipelago are either from (1) direct emissions of contemporary PFOA via manufacturing or use in Asia or (2) from atmospheric transport and oxidation of contemporary PFOA-precursors (Benskin et al., 2012c).

89. Environmental monitoring data are available for surface water and sediment in Japan (Japan, 2015), for the river Po in Italy (ECHA, 2014b), landfill leachate, water and gull eggs and sediment in Australia (Gallen et al., 2016; Thompson et al., 2011a) and for river sediments from South Africa PFOA with higher concentrations than those found in other countries (Mudumbi et al. 2014).

90. There is abundant evidence to show detected levels of PFOA in marine, limnetic and terrestrial biota worldwide (de Silva and Mabury, 2004; Martin et al., 2004; Smithwick et al., 2005; Houde et al., 2006; Butt et al., 2007; Dietz et al., 2007; Ishibashi et al., 2008; Sonne et al., 2008; de Silva et al., 2009; Müller et al., 2011; Rüdel et al., 2011; Bytingsvik et al., 2012; Rotander et al., 2012; NILU, 2013; Fang et al., 2014; Lescord et al., 2015; Lucia et al., 2015). As previously discussed in Sections 2.2.2 and 2.2.3, bioaccumulation of PFOA occurs across trophic levels, and the detection of PFOA in biota at remote locations suggest the capacity of PFOA for long range transport, respectively.

91. A previous study reported higher levels of PFOA in pine needles (Pinus mugo) near ski areas (Chropeňová et al. 2016a). PFOA application as stain repellents in modern outdoor clothes and in ski waxes is assumed to be a potential important source in ski resorts for releases to the high mountains environment and potential for human exposure (Chropeňová et al. 2016b).

92. More detailed information on environmental monitoring is provided in section 2.3.1 of document UNEP/POPS/POPRC.12/INF/5.

2.3.2 Human Exposure

93. A large number of studies have been conducted to determine human exposure to PFOA. Among other things, findings identify common routes to exposure and vulnerable groups to exposure as well as reporting concentration levels found in samples.

94. Human exposure typically takes place "human via environment"[5] by consumption of drinking water and food, via uptake of contaminated indoor dust or from consumer products containing PFOA and its related substances and, to a lesser degree, through dermal contact. (ECHA, 2013a ; Post et al., 2009 ; Shoeib et al., 2015 ; Wilhelm et al., 2010 ; Schwanz et al., 2015 ; D'Hollander et al., 2015 ; Eriksson et al., 2013 ; Carlsson et al., 2014 ; Yamada et al., 2014). Indoor air and dust are also important sources of human PFOA exposure (Haug et al., 2011; Gebbink et al., 2015). PFOA then concentrates within the blood, liver, kidney and lungs (ECHA, 2013a).

95. Several studies have suggested that PFOA levels increase with age (Haug et al., 2010, 2011; Christensen et al., 2016) and that breast feeding, diet and indoor environment are important factors for PFOA exposure that need to be addressed in the evaluation of human exposure and accumulation of PFOA (Haug et al., 2010, 2011; Brantsater et al. 2013; ECHA, 2013a).

96. Dietary intake including water is considered as the most important route of human exposure to PFOA based on studies from various countries. There is evidence that for children, the intake is higher (Vestergren et al., 2008; Haug et al., 2010, 2011; Thompson et al., 2011b; Cornelis et al., 2012, Shan et al., 2016). Taking this into consideration, among others, the U.S. EPA has issued a lifetime drinking water Health Advisory for combined PFOA/PFOS of 0.07 micrograms per liter (µg/L) based on a reference dose (RfD) derived from a developmental toxicity study in mice (US EPA, 2016b).

97. The issue of human exposure via consumer products was examined by Vestergren et al. (2015), who modeled emissions from consumer products imported from China and finds that 1.5% of PFOA discharged to wastewater and 0.3% of 8:2 FTOH emissions to air in Norway can be attributed to these products imported to Norway.

98. Analysis of serum samples demonstrate that PFOA is detectable across the general population in various countries (Emmett et al. 2006; Vestergren and Cousins, 2009; Fromme et al., 2009; Health Canada, 2013; CDC, 2015; Cho et al., 2015; Góralczyk et al., 2015; Wuttke et al., 2013; Vorkamp et al., 2014).

99. Based on the existing studies of serum/plasma PFOA concentrations in the general European adult population and in children worldwide, the average median (and maximum) PFOA serum levels were calculated to be 3.5 (21) ng/mL and 6.4 (108) ng/mL for European adults and children worldwide, respectively (ECHA, 2015a; also see UNEP/POPS/POPRC.12/INF/5 for list of studies).[6]

100. It has been estimated that serum and plasma PFOA concentrations in the European populations ranged from <0.5 – 40 µg/mL (Fromme et al., 2009; Vestergren and Cousins, 2009). PFOA was also detected in the general American population and Canadian population including children in Nunavik as well as Canadians living on reserve with geometric mean concentrations ranging from 1.39 – 2.5 µg/L (Health Canada, 2013; Wuttke et al., 2013 AMAP, 2015; CDC, 2015). Levels of PFOA were also found in people throughout the circumpolar Arctic, and in some countries such as Iceland and Norway, PFOA levels within the sampled populations were among the highest compared to other POPs (AMAP, 2015). A US study of older male anglers found PFOA serum levels similar to those of the US general population, and increasing age as well as alcohol consumption were observed to be predictors of PFOA levels (Christensen et al., 2016). Several studies indicated that human PFOA concentrations in Australian adults and Danish pregnant women decreased over time (Toms et al., 2014; Bjerregaard-Olesen et al., 2016) and that concentrations of PFOA in Australian women of child-bearing age are higher compared to Germany and the USA (Toms et al., 2014).

101. There are a few reports of detected PFOA serum levels in the occupationally exposed workers, (Guruge et al., 2005; Fromme et al., 2009; Freberg et al., 2010; Nilsson et al., 2010b). Indoor dust and total suspended particles seem to be important occupational exposure routes in fluorochemical manufacturing and is also considered relevant in domestic settings (Gao et al., 2015; Eriksson and Kärrman, 2015; Tian et al., 2016). In some cases, elevated serum PFOA levels can be largely

[5] Indirect exposure of humans via the environment may occur by consumption of food (fish, crops, meat and milk) and drinking water as well as inhalation of air (ECHA, 2012).

[6] It should be mentioned that for the calculation of average median (and maximum) PFOA serum levels reported in ECHA, 2015a, one outlying value from the study by Mondal et al., (2012) was included in the calculation. By removing this outlying value, the average median (and maximum) PFOA serum levels in children is 2.52 ng/mL (15.9 ng/mL)

attributed to exposure to PFOA-related compounds such as 8:2 FTOH (Nilsson et al., 2010a, 2010b). Persons living in the vicinity of fluorochemical manufacturing plants have higher PFOA levels than the general population (Emmett et al., 2006; Oliaei et al., 2013; Hoffman et al., 2011).

102. Mothers excrete PFOA via breast milk, which is considered an important source of exposure to breast-fed infants, whose PFOA exposure level is considerably higher than adults (Haug et al., 2011). PFOA is also transferred to the fetus through the placenta, and it has been reported that total branched PFOA isomers cross the placenta more efficiently than linear isomers (Beeson et al. 2011). Time interval between pregnancies has been shown to be strongly correlated with increased concentrations of PFOA in pregnant women, possibly reflecting the re-accumulation of PFOA in maternal blood with increasing time between pregnancies (Brantsæter et al., 2013). Due to *in utero* exposure and exposure from breast milk and drinking water, children up to about 12 years of age have higher serum PFOA concentrations than their mothers (Mondal et al., 2012). Breastfeeding is an important exposure pathway to PFOA as well as trans-placental passage (Umweltbundesamt AT, 2012, 2013; Carious et al., 2015; Forns et al., 2015; Papadopoulou et al., 2015; Hanssen et al., 2013; Mogensen et al., 2015, Brantsæter et al., 2013).

103. Studies related to breastfeeding from Jordan, Spain and Italy indicate that PFOA levels are higher in older women and that there is a greater transfer of PFC during breastfeeding by primiparous and thus a higher exposure to these contaminants for the first child (Al-sheyab et al., 2015; Motas Guzmàn et al., 2016; Barbarossa et al., 2013).

104. A recent study reported the detection of PFOA in 27 out of 30 human hair samples with a PFOA concentration range of 25-74 pg/g hair and an average of 46 pg/g hair (Alves et al., 2015).

105. Humans are very slow eliminators of PFOA compared with other species such as rodents, pigs and monkeys (Olsen et al., 2007; Numata et al., 2014) with a half-life ranging between 2 and 4 years (ECHA, 2014a; Olsen et al., 2007; Russell et al., 2015; Bartell et al., 2010; Han et al., 2012).

106. More detailed information on human exposure is provided in section 2.3.2 of document UNEP/POPS/POPRC.12/INF/5.

Summary of human exposure

107. Human exposure typically takes place “human via environment” by consumption of drinking water and food, via uptake of contaminated indoor dust or from consumer products containing PFOA and its related substances. PFOA has been detected in humans in blood and breast milk from various countries. Babies are susceptible to PFOA exposure via breastfeeding or trans-placental passage, and people who live near fluoropolymer manufacturing facilities have been shown to have higher levels of serum PFOA than those from the general population. There is evidence that PFOA levels in humans accumulate and increase with age. Humans are very slow eliminators of PFOA compared with other species with an average half-life of 2-4 years.

2.4 Hazard assessment for endpoints of concern

Adverse effects on aquatic organisms

108. According to several information sources, data currently available for PFOA indicate some adverse effects on a number of aquatic organisms. Generally, acute aquatic toxicity is low in standard ecotoxicity tests (NICNAS, 2015a); moderate to low acute toxicities are seen in pelagic organisms including fish, and low chronic toxicities in benthic organisms (Environment Canada and Health Canada, 2012). Adverse effects include intergenerational toxicity in the first offspring generation (Ji et al., 2008) and some PFOA-mediated toxicity in freshwater algae (Elnabarawy et al., 1981; Ward et al., 1995a, 1995b, 1996a, 1996b, 1996c; Boudreau, 2002; Thompson et al., 2004 as cited in Environment Canada and Health Canada, 2012; Latała et al., 2009) and other aquatic organisms (3M Company 1987a, 1990a, 1996a, b, c; Beach 1995a cited in Environment and Health Canada 2012). Further, PFOA-mediated effects on fish development, particularly in reproduction, have been observed (Ulhaq et al. 2015; Wei et al., 2007; Wei et al., 2008). Studies with other aquatic organisms such as freshwater male tilapia, marine mussels and Baikal seals showed estrogenic effects, hepatotoxicity, inflammation, and chemosensitivity (Liu et al., 2007; Stevenson et al., 2006; Ishibashi et al., 2008). Field studies related to effects of PFOA on immune function and clinical blood parameters in dolphins and sea turtles revealed increases in indicators of inflammation and immunity (Peden-Adams et al., 2004a, 2004b). Increased pro-inflammatory responses in male Japanese medaka were also observed (Yang, 2010). Activation of peroxisome proliferator–activated receptor α were shown in Baikal seals (Ishibashi et al., 2008b). Evidence indicates that PFOA could exacerbate the adverse effects triggered by certain types of pesticides (Rodea-Palomares et al., 2015).

Adverse effects on terrestrial organisms

109. The effects of repeated oral exposure to PFOA have been evaluated in mice (Loveless et al., 2006; Christopher and Marisa, 1977; Griffith and Long, 1980; Lau et al., 2006; Macon et al., 2011; Abbott et al., 2007; Wolf et al., 2007), rats (Metrick and Marisa, 1977; Griffith and Long, 1980; Goldenthal, 1978; Palazzolo, 1993; Biegel et al., 2001; Perkins et al., 2004) and monkeys (Goldenthal, 1978b; Griffith and Long, 1980; Thomford, 2001; Butenhoff et al., 2002). Hepatocellular hypertrophy was observed in all species. At lower doses, reduced body weight as well as increased kidney and liver weight were noted. Also, degeneration and/or focal to multifocal necrosis were reported with increased severity at doses between 1.5 to 15 mg/kg bw/day in rats and mice. Mortality was observed at high doses (ECHA, 2015a).

110. No-observed- and lowest-observed-adverse-effect-levels (NOAELs and LOAELs respectively) were identified from critical and relevant studies for the observed effects. The NOAEL and LOAEL for increased liver weight and hepatocellular hypertrophy based on subchronic toxicity studies in rats are 0.056 mg/kg bw/day and 0.64 mg/kg bw/day, respectively (ECHA, 2015a; Perkins et al., 2004). The LOAEL of maternal toxicity was 1 mg/kg bw/day based on increased liver weight based on a developmental toxicity study in CD-1 mice (Macon et al. 2011). White et al. (2009) identified a LOAEL of 1.0 mg/kg bw/day for delayed mammary gland development in F1 (the first offspring generation). Abbott et al. (2007) calculated a NOAEL of 0.3 mg/kg bw/day for neonatal survival based on developmental exposure of mice.

111. Toxicological studies in rats have shown that PFOA reduces serum lipids while it increases hepatic triglycerides, probably through the activation of the peroxisome proliferator-activated receptor α (PPARα) (Haugom and Spydevold, 1992; Bjork et al., 2011). A study by Butenhoff et al. reported a dose-dependent increase in serum triglycerides in monkeys and only a moderate and non-significant reduction in cholesterol with increasing PFOA (Butenhoff et al., 2002).

112. The induction of tumours has been demonstrated in rats exposed to PFOA. Rats chronically exposed to PFOA resulted in increased incidences of liver adenomas, Leydig cell hyperplasia/adenomas and pancreatic acinar cell tumours (PACT) in male Sprague-Dawley rats (Biegel et al., 2001). Mammary fibroadenoma in the female rats was observed in another chronic PFOA exposure study although this observation has since been disputed after an independent group of pathologists (Pathology Working Group) re-examined the tissue and reached a consensus that incidence of mammary gland neoplasms were not affected by chronic PFOA exposure (Hardisty et al., 2010; Butenhoff et al., 2012).

113. Animal studies show that PFOA increases the incidence of complete litter loss, postnatal mortality, decreases foetal body weight, delays ossification, changes mammary gland development and delays maturation in several developmental studies in mice (and some in rat) depending on strain, dose, time and length of exposure (Lau et al., 2006; Abbott et al., 2007; Macon et al., 2011; White et al., 2007, 2009, 2011; Wolf et al., 2007; Yang et al., 2009; Zhao et al., 2012b; Dixon et al., 2012, Suh et al., 2011; Albrecht et al., 2013). The LOAEL of maternal toxicity was determined as 1 mg/kg bw/day, and the NOAEL for neonatal survival was 0.3 mg/kg bw/day (Lau et al., 2006; Abbott et al., 2007). The National Institute of Environmental Health Sciences (US) reviewed the evidence for the effects of PFOA on foetal growth in animals, and the authors concluded that there is sufficient evidence of decreased foetal growth in non-human mammalian species (Koustas et al., 2014).

114. Effects of gestational exposure to PFOA on the development of the mammary gland from lactating dams and female pups have been demonstrated (White et al., 2007, 2009). PFOA, when exposed in a critical window of susceptibility (GD 10-17), was shown to induce changes in offspring mammary gland development in CD-1 mice (Macon et al., 2011). In addition, chronic low dose exposure of PFOA reduced mammary gland development in F_1 as well as F_2 (Yang et al. 2009). Zhao et al. (2010) observed that PFOA stimulates mammary gland development in C57BL/6 mice. Some of observed PFOA-induced developmental/reproductive effects might be mediated by PPARα (Zhao et al., 2012b; Albrecht et al., 2013). However, it has been mentioned that PFOA-induced alterations in mammary gland development might be to be dependent on steroid production in ovaries and independent of PPARα (Zhao et al., 2010).

115. There are studies suggesting that PFOA may alter steroid hormone production or act indirectly via ovarian effects as a mean of endocrine disruption (Zhao et al., 2010, 2012b; York, 2002; Butenhoff et al., 2004; Suh et al., 2011; Hines et al., 2009). PFOA has been reported to alter sexual maturation and pubertal timing in female and male offspring of rats and in multiple strains of mice (York, 2002; Butenhoff et al., 2004, Yang et al., 2009; Dixon et al. 2012), indicating a disruption of the normal steroid hormone regulation. Also, inhibited expression of the placental prolactin-family hormone genes was observed in the placenta of mice exposed to PFOA during gestation (Suh et al., 2011).

116. There are indications of immune effects mediated by PFOA. Short-term dietary exposure to PFOA resulted in a reduction in thymus weight, decreased number of thymocytes and splenocytes and suppressed IgM antibody synthesis in C57BL/6 mice (DeWitt et al., 2008; DeWitt et al., 2009; Qazi et al., 2009). Adult offspring exposed to PFOA given to dams from gestation through lactation exhibited altered immune responses such as reduced splenic T cells and IL-10 production from these cells (Hu et al., 2012). PFOA was also shown to increase histamine release from mast cells as well as exacerbate the IgE-dependent local allergic reaction in mice (Singh et al., 2012). Lastly, suppressed T-cell-mediated immunity in Japanese quails was observed after exposure to PFOA via drinking water for 8 weeks (Smits and Nain, 2013).

117. The authors of the background document for the restriction of PFOA (ECHA, 2015a) emphasize the importance of assessing mice studies instead of rat studies as basis for DNEL-setting when this is based on animal studies due to the longer half-life of PFOA in mice compared to rats.

118. Studies with chicken showed no significant outcomes such as alterations in embryonic pipping success or in biochemical parameters at concentrations up to 10 µg/g ww of embryo and doses up to 1.0 mg/kg body weight for 3 weeks (O'Brien et al., 2009; Yeung et al., 2009). However, a recent study observed developmental toxicity (namely reduced embryo survival) of PFOA in cormorant (*Phalacrocorax carbo sinensis*), herring gull (*Larus argentatus*) and the domestic White Leghorn chicken (*Gallus gallus domesticus*), with chicken being the most sensitive species (Nordén et al., 2016).

119. The soil-dwelling nematode *Caenorhabditis elegans* showed lethal effects with EC_{50} concentrations of 3.85 mM after 1 hour of exposure and 2.35 mM after 48 hours of exposure (Tominaga et al., 2004).

120. Studies with terrestrial plants such as lettuce (*Lactuca sativa*), cucumber (*Cucumis sativus*) and pakchoi (*Brassica rapa chinensis*), spring wheat, oats, potatoes, maize, and perennial ryegrass showed species-dependent adverse effects (e.g. root growth and necrosis) mediated by PFOA (Li, 2008; Stahl et al., 2009).

121. PFOA is primarily detected in the livers of biota such as polar bears and seals (Martin et al., 2004; Smithwick et al., 2005; Dietz et al., 2007; Sonne et al., 2008; Butt et al., 2007; Ishibashi et al., 2008), but the adverse effects of PFOA in such biota have not yet been elucidated. Ishibashi et al., (2008) showed activation of PPARα in the livers of Baikal seals, but no PFOA-mediated adverse effect in the livers was reported. Also, Sonne et al., (2008) concluded that it is not clear whether chronic exposure to PFOA is associated with liver lesions in polar bears, but it is possible that at sufficient concentrations in polar bears, PFOA might induce hepatic alterations.

122. Environment Canada and Health Canada (2012) concluded that the risk quotients (PEC/PNEC) indicate low likelihood of risk to pelagic organisms, mammalian wildlife from exposures at current concentrations in the environment. However, according to the ECHA (2014), the properties of persistent, bioaccumulative, and toxic (PBT) chemicals create uncertainty in the risk estimation to the environment and human health when performing quantitative risk assessment. ECHA stated that using the currently available methods, a "safe" concentration in the environment cannot be established quantitatively with sufficient reliability for an acceptable risk. Furthermore, due to the persistence of the substance, its tendency to accumulate and biomagnify in a variety of terrestrial and marine mammals, its hepatotoxicity and the upward temporal trend of PFOA concentrations in polar bears and some other species, PFOA concentrations in polar bears may approach exposures resulting in harm. Indeed, a temporal trend analysis indicated an annual increase of 2.3% in PFOA levels in East Greenland polar bears from 1984 to 2006 (Dietz et al., 2007).

123. Detailed information on adverse effects on aquatic and terrestrial organisms is presented in the background document (see section 2.4 of document UNEP/POPS/POPRC.12/INF/5).

Summary of ecotoxicological effects

124. Acute aquatic toxicity is low in standard ecotoxicity tests; moderate to low acute toxicities are seen in pelagic organisms including fish and low chronic toxicities in benthic organisms. Adverse effects include intergenerational toxicity in the first offspring generation and some PFOA-mediated toxicity in freshwater algae and other aquatic organisms.

125. There is experimental evidence in terrestrial organisms showing the potential for PFOA to induce alterations to the liver, endocrine dysfunction, developmental toxicity and tumour formation. Adverse effects include alterations in sexual maturation and pubertal timing, changes in mammary gland development as well as induction of a variety of tumours. There are some indications of PFOA-mediated immunomodulation. In plants, PFOA can cause visible abnormalities and alter root

growth. Because of the tendency of PFOA to bioaccumulate, PFOA concentrations in polar bears might increase over time and approach exposures resulting in harm.

Adverse effects on human health

126. The toxicity of PFOA has been evaluated by ECHA, US EPA, the Canadian ministries and EFSA (ECHA, 2011, 2015a; Environment Canada and Health Canada, 2012; US EPA, 2006, 2016b; EFSA, 2008). In the European Union, PFOA has a legally-binding harmonized classification as Carc. 2, Repr. 1B and STOT RE 1 (liver) according to Regulation (EU) No 944/2013.

127. PFOA is readily absorbed after exposure (ingestion) and accumulates in serum and highly perfused organs, mainly in the liver and kidney, due to PFOA primarily binding to albumin proteins in the blood. PFOA does not undergo metabolism or biotransformation in the body (Environment Canada and Health Canada, 2012; Post et al., 2012). As mentioned earlier, the half-life of PFOA elimination in humans is long, ranging between 2 and 4 years (Olsen et al., 2007; Russell et al., 2015).

128. Animal studies have demonstrated the induction of tumours mediated by PFOA or APFO, and hepatic activation of PPARα has been proposed as a mechanism of induction of hepatic tumours (Klaunig et al., 2003). However, the PPAR-agonist mode of action proposed for rat liver, testes and pancreatic tumours may not be relevant for humans. However, human relevance had not been definitively determined according to established frameworks a decade ago (Meek et al., 2003; Boobis et al., 2006), and PFOA compounds have also not been tested for carcinogenic potential in any laboratory animal species other than rats (Environment Canada and Health Canada, 2012). Therefore, the ECHA's Risk Assessment Committee (RAC) came to the conclusion that data on the mode of action are insufficient to conclude that APFO-induced tumours in animals are not relevant for humans, and therefore, PFOA is classified as Carc 2. Based on limited evidence in humans that PFOA causes testicular and renal cancer as well as limited evidence in experimental animals, IARC has classified PFOA as a Group 2B substance (possibly carcinogenic to humans) (Benbrahim-Tallaa et al., 2014; IARC, 2016).

129. PFOA is known to be transmitted to the fetus in cord blood and to the newborn in breast milk. Developing fetuses and newborns are particularly sensitive to PFOA-induced toxicity (US EPA 2016b). Positive correlation in PFOA level between maternal and cord blood samples has been reported in several birth cohort studies in Spain and Norway (Manzano-Salgado et al., 2015; Gutzkow et al., 2012). As APFO can be transferred to infants through breast-feeding, the RAC agreed on an additional classification of PFOA on lactation effects (CLP: Lact. H362: May cause harm to breast-fed children) (ECHA, 2011).

Epidemiological studies

130. Several epidemiological studies investigated exposure and related health effects in workers and different population groups. One of the most extensive epidemiological studies regarding PFOA in humans is the C8 Health Project, a population-wide health study to assess whether or not there is a probable link between C8 exposure and disease in the community. The background behind the C8 Health Project can be found online (C8 Science Panel, 2013).

131. Exposure of PFOA and elevated cholesterol levels (e.g. hypercholesterolemia) as well as other lipid parameters (e.g. uric acid, serum lipid) have been positively correlated in studies involving occupationally-exposed workers (Sakr et al., 2007), highly exposed community residents (Steenland et al., 2009; Steenland et al., 2010a; Frisbee et al., 2010; Fitz-Simon et al., 2013), the general population (Eriksen et al., 2013; Nelson et al., 2010) and children especially boys (Qin et al., 2016).

132. There is also evidence from the C8 Health Project to suggest potential association between PFOA exposure and increased risk of testicular and/or kidney cancers (Barry et al., 2013; Vieira et al., 2013; Steenland, 2012). There are a few reports where no significant association between PFOA exposure and human cancer risk was observed (Chang et al., 2014; Leonard et al., 2008). The Eriksen study acknowledges the possibility of information bias regarding the exposure related to effect (Eriksen et al., 2009). According to IARC (2016) there is limited evidence in humans for the carcinogenicity of PFOA. A positive association was observed for cancers of the testis and kidney.

133. Ulcerative colitis and rheumatoid arthritis have been positively associated with PFOA exposure among workers (Steenland et al., 2015).

134. Adverse reproductive effects have been reported in some epidemiological studies. A positive association between serum PFOA levels and the rate of menopause has been reported in several studies such that women in the highest quintile of PFOA exposure have higher chances of experiencing earlier menopause (Taylor et al., 2013; Knox et al., 2011a), but reverse causation,

i.e. earlier menopause leading to increased PFOA, has been suggested (Dhingra et al. 2016a, 2016b). This would suggest that women who experience earlier menopause might be at risk of higher body burden of PFOA. Another study in Canada involving more than 1,700 women showed possible reduction in fecundity in women with higher plasma levels of PFOA (Velez et al., 2015). Serum PFOA is positively associated with pregnancy-induced hypertension (Darrow et al., 2013), and preeclampsia is weakly associated with PFOA level (Savitz et al., 2012; Stein et al., 2009). Higher serum PFOA levels have been found in patients with polycystic ovary syndrome (Vagi et al., 2014).

135. Developmental effects in humans may be associated with PFOA exposure. On one hand, an inverse correlation between PFOA and birth weight, ponderal index and head circumference has been reported in several mother-child cohort studies (Fei et al., 2007; Apelberg et al., 2007; Maisonet et al., 2012; Chen et al., 2012, Wu et al., 2012; Whitworth et al., 2012a). A novel meta-analysis methodology was applied to review the evidence of 9 human studies, and the outcomes of this meta-analysis indicated that there was sufficient evidence to suggest that developmental exposure to PFOA reduces foetal growth (Johnson et al., 2014; Lam et al., 2014). On the other hand, mothers of low birth weight babies might have altered renal function such as less plasma volume expansion, therefore leading to reduced clearance of PFOA through glomerular filtration (Whitworth et al., 2012b; Verner et al., 2015; Sagiv et al., 2015). Furthermore, there are other studies that reported no significant association between maternal serum PFOA levels and birth weight (Washino et al., 2009; Stein et al., 2009; Monroy et al., 2008; Hamm et al., 2010).

136. Other reported adverse effects observed in children and adolescents associated with higher levels of serum PFOA include impaired neurodevelopment (see below), adiposity (Halldorsson et al., 2012 ; Braun et al., 2016), dyslipidemia (Geiger et al., 2014), altered renal function (Kataria et al., 2015), reduced humoral immune response (Grandjean et al., 2012; Grandjean and Budtz-Jørgensen, 2013), lower levels of insulin-like growth factor-1 and sex hormones (Lopez-Espinosa et al., 2016), higher odds of self-reported food allergies (Buser and Scinicariello, 2016) and later age of puberty in girls (Lopez-Espinosa et al., 2011; Holtcamp, 2012).

Neurotoxicity in humans

137. Impaired neurodevelopment has been associated with PFOA. An inverse relationship between prenatal PFOA concentrations in mothers and neurodevelopment as determined with the mental development index (MDI) in female (not male) offspring at 6 months of age was observed in a Japanese birth cohort (Hokkaido) study. However, this relationship was not observed with offspring at 18 months of age (Goudarzi et al., 2016). Also, no correlation between PFOA levels and birth weight was observed in the same cohort study (Washino et al., 2009). Statistically significant inverse associations between PFOA and memory impairment has been reported (Gallo et al., 2013). On the other hand, there are studies that reported no association between PFOA exposure and impaired neurodevelopment or behavior (Chen et al., 2013; Stein et al., 2013).

Immunotoxicity

138. The U.S. National Institute of Environmental Health Sciences' National Toxicology Program (NTP) systematically reviewed and evaluated evidence on exposure to PFOS or PFOA and immune-related health effects to determine whether exposure to either chemical is associated with immunotoxicity for humans. Based on the health effects data from 33 human studies, 93 animal studies, and 27 in vitro/mechanistic studies relevant for addressing the objective, NTP published its draft findings in June of 2016 concluding that PFOA is presumed to be an immune hazard to humans. The NTP based this conclusion primarily on evidence of suppression of the antibody response and increased hypersensitivity, as well as additional evidence that is primarily from epidemiological studies that PFOA reduced infectious disease resistance and increased autoimmune disease (US NIEHS, 2016).

139. Reduced humoral immune response has been observed in a few studies (Grandjean et al., 2012; Looker et al., 2014; Kielsen et al., 2015). In particular, elevated PFOA serum levels are associated with reduced antibody titer rise, especially to A/H3N2 influenza virus and an increased risk of not attaining a protection threshold antibody concentration (Looker et al., 2014). In the Danish National Birth Cohort study, it was reported that prenatal exposure to PFOA is not associated with increased risk of infectious diseases leading to hospitalisation in early childhood; however, when the analysis was stratified by gender, girls showed a slightly higher risk of hospitalisation for infections associated with higher maternal PFOA levels (incidence rate ratio of 1.74 at the highest quartile compared with the lowest) (Fei et al., 2010).

140. Using data from a study of immunotoxicity in children (Grandjean et al., 2012), BMDLs were calculated to be approximately 0.3 ng/mL for PFOA, in terms of the serum concentration decrease of specific antibodies. Using an uncertainty factor of ten to take into account individual susceptibility, the BMDLs would result in a reference dose serum concentration of about or below 0.1 ng/mL.

Endocrine Disruption

141. Findings from studies seem to indicate a PFOA-mediated effect on the endocrine system. Prenatal exposure of PFOA may alter testosterone concentrations in females (Maisonet et al., 2015), and an inverse correlation between parathyroid hormone 2 receptor (PTH2R) and PFOA exposure was also reported in a study of 189 women (Galloway et al., 2015). As for men, a study by La Rocca et al. (2015) reported an inverse relationship between PFOA serum level in men and expression of nuclear receptors such as estrogen and androgen receptors. Also, early menopause in women with high PFOA levels have been observed in the C8 Health Project (Knox et al., 2011a, 2011b).

142. PFOA has been implicated to act as a so-called obesogene similar to other endocrine disruptive compounds that can act directly on ligands for nuclear hormone receptors or affect components in metabolic signaling pathways. A human prospective cohort study showed a correlation between low dose PFOA exposure of 655 Danish pregnant women and obesogenic effects in their offspring at 20 years of age. Maternal PFOA concentrations were positively associated with serum insulin and leptin levels and inversely associated with adiponectin levels in female offspring (Halldorsson et al., 2012). On the other hand, the C8 Health Project concluded that PFOA exposure in early life was not associated with overweight and obesity risk in adulthood (Barry et al., 2014).

143. Evidence from several epidemiological studies seems to suggest an association between exposure to PFOA and changes in different thyroid hormones leading to altered thyroid function inducing thyroid disease such as hypothyroidism or hyperthyroidism (Shrestha et al., 2015; Lopez-Espinosa et al., 2012; Knox et al., 2011b; Kim et al., 2011; Melzer et al., 2010; C8 Science Panel, 2013; Yang et al., 2016). However, there have also been studies that reported inconsistent findings between PFOA exposure and thyroid diseases (i.e. inverse relation between subclinical hyperthyroidism and PFOA or no association between hypothyroidism and PFOA) (as summarised in Steenland et al., 2010b and C8 Science Panel, 2013).

144. The potential of PFOA to affect estrogen receptor (ER) and androgen receptor (AR) transactivity as well as aromatase enzyme activity was analysed in an *in vitro* study, and it was shown that PFOA significantly induced ER transactivity yet antagonized AR activity in a concentration-dependent manner. In addition, when PFOA was mixed with 6 other PFCs, a mixture effect more than additive was observed on AR function, emphasizing the importance of considering the combined action of PFCs in assessing related health risks (Kjeldsen and Bonefeld-Jørgensen, 2013).

145. According to the study of Su et al., (2016), PFOA showed a potential protective effect against glucose intolerance and the risk of diabetes.

146. Detailed information on adverse effects on human health is presented in the background document (see section 2.4 of document UNEP/POPS/POPRC.12/INF/5).

Summary of adverse effects on human health

147. PFOA is classified as Carc. 2, Repr. 1B and STOT RE 1 (liver) according to Regulation (EU) No 944/2013. IARC also categorised PFOA as a Group 2B substance (possibly carcinogenic to humans). There have been reported adverse health effects such as elevated cholesterol levels, altered reproductive/developmental effects, endocrine disruption, impaired neurodevelopment, as well as increased risk of cancer associated with PFOA exposure in humans. Scientific data have demonstrated PFOA-mediated immunotoxicity, primarily suppression of antibody response, in humans. Although the findings are limited, the reported adverse health effects suggest additional public health concerns.

3. Synthesis of information

148. PFOA has been manufactured since 1947 and is currently manufactured mainly as the salt APFO. The global volume of production has gradually increased over time with ongoing production, for example, in China.

149. PFOA-related compounds have the capacity to degrade to PFOA and hence to contribute to environmental concentrations of PFOA. It is unlikely that actions against PFOA and APFO alone can fully minimize and eliminate environmental concentrations. In particular, fluorotelomer alcohols (FTOHs) have been identified as a potential source of PFOA. Numerous direct and indirect sources of

PFOA, its salts and PFOA-related compounds contribute to the overall release of PFOA to the environment. Main emission vectors are water, wastewater, dust particles and air.

150. Fluoropolymers and fluorotelomer-based polymers (FTPs) are used across many sectors for different purposes, including the manufacture of stain- and water-resistant coatings on textiles and carpets; hoses, cable and gaskets; non-stick coatings on cookware; and personal care products. Traces of PFOA can also be found in certain aqueous fire-fighting foams.

151. Based on the available experimental evidence, it is concluded that PFOA is highly stable and persistent within the natural environment. PFOA is unlikely to degrade under conditions present in the natural environment and has been shown to have long half-lives within the environment. Monitoring data show that PFOA in soil leaches over time and can be a long term contamination source to underlying groundwater.

152. PFOA has been found in marine, limnetic and terrestrial biota worldwide, and bioaccumulation of PFOA occurs across trophic levels. Assessment of bioaccumulation for PFOA is complicated by its physical properties as a surfactant, which make analysis for development of log K_{ow} values not directly possible. PFOA accumulates and biomagnifies in air breathing animals and other terrestrial species including humans but not in water breathing animals as fish excrete PFOA through their gills.

153. Monitoring of water, snow, air, sediment and biota at remote locations all detect the presence of PFOA. Equally, environmental modeling data and other information enable to conclude that PFOA meets the criterion for long range transport.

154. Human PFOA exposure occurs via dietary intake of food and drinking water, exposure to contaminated indoor dust or consumer products containing PFOA and its related substances. Studies have demonstrated the presence of PFOA within humans, mainly in blood and breast milk samples. Fetuses and newborns are susceptible to PFOA exposure via breastfeeding or trans-placental passage. Occupational exposure or exposure near sites of production resulted in higher serum PFOA levels than exposure of general population. Humans are very slow eliminators of PFOA compared with other species. The half-life of PFOA elimination in human blood is long, ranging from 2-4 years.

155. PFOA exhibits adverse effects for both terrestrial and aquatic species. Ecotoxicity data indicate a low acute toxicity for aquatic organisms. There is also experimental evidence in terrestrial organisms showing the potential for PFOA to induce changes in liver function, endocrine function, development as well as immune responses, and induction of tumours has been shown in rats exposed to PFOA. The adverse effects of PFOA in biota have not yet been elucidated, but because of the tendency of PFOA to bioaccumulate, PFOA concentrations in biota, especially polar bears, might increase over time and approach exposures resulting in harm.

156. PFOA is classified in line with the EU GHS criteria as Carc. 2, Repr. 1B and STOT RE 1 (liver) (Regulation (EU) No 944/2013). IARC has also categorized PFOA a Class 2B carcinogen with particular regard to testicular and kidney cancers. High cholesterol, inflammatory diseases, ulcerative colitis, thyroid disease, immune effects, pregnancy-induced hypertension, endocrine disruption and impaired neuro- as well as reproductive development have been found to be associated with PFOA exposure in humans in epidemiological studies, but more evidence is needed to determine the relationship between PFOA and the observed health effects.

4. Concluding statement

157. PFOA, its isomers, salts (since the late 1940s) and PFOA-related compounds (since the 1960s) have been widely used on a global basis. However, growing evidence of health and environmental effects has meant that concerns regarding the use of PFOA have existed for a number of decades. Stricter regulatory control and voluntary action by industry to phase-out the production and use of PFOA have been in place since 2006.

158. PFOA has been demonstrated to be highly persistent with the capacity to undergo long range transport far from the point of use. This is evidenced by monitoring data of PFOA in air, water, soil/sediment and biota in both local and remote locations like the Arctic. Additionally, PFOA-related compounds exist and have the capacity within the natural environment to degrade and form PFOA, further aiding the long range transport of these substances. PFOA can bioaccumulate in air-breathing mammals and other terrestrial species including humans. Evidence also exists to highlight the potential adverse effects of PFOA upon both environmental species and humans.

159. Based on the persistence, bioaccumulation, toxicity in mammals including humans and widespread occurrence in environmental compartments, it is concluded that PFOA, its isomers, salts and related compounds that degrade to PFOA, as a result of their long-range environmental transport,

are likely to lead to significant adverse human health and environmental effects such that global action is warranted.

EXECUTIVE SUMMARY

1 INTRODUCTION

1.1 Chemical Identity of the proposed substance

On July 14, 2005, the government of Sweden made a proposal for listing perfluorooctane sulfonate (PFOS) and 96 PFOS-related substances in Annex A of the Stockholm Convention on Persistent Organic Pollutants (POPs).

Chemical name: Perfluorooctane Sulfonate (PFOS)

Molecular formula: $C_8F_{17}SO_3^-$

PFOS, as an anion, does not have a specific CAS number. The parent sulfonic acid has a recognised CAS number (CAS No. 1763-23-1). Some examples of its commercially important salts are listed below:

Potassium salt (CAS No. 2795-39-3)

Diethanolamine salt (CAS No. 70225-14-8)

Ammonium salt (CAS No. 29081-56-9)

Lithium salt (CAS No. 29457-72-5)

Structural formula:

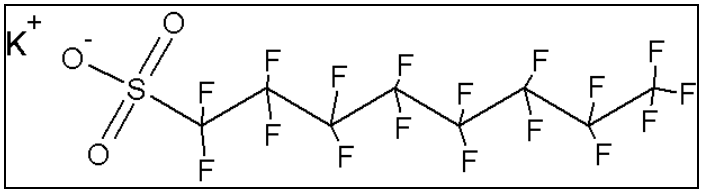

Figure 1. Structural formula of PFOS shown as its potassium salt

PFOS is a fully fluorinated anion, which is commonly used as a salt or incorporated into larger polymers. PFOS and its closely related compounds, which contain PFOS impurities or substances which can give rise to PFOS, are members of the large family of perfluoroalkyl sulfonate substances. In its regulatory measures on PFOS, the EU has addressed all molecules having the following molecular formula: $C_8F_{17}SO_2Y$, where Y = OH, metal or other salt, halide, amide and other derivatives including polymers (European Union 2006).

The physical and chemical properties of the potassium salt of PFOS are listed in Table 2.

Table 2. Physical and chemical properties of PFOS potassium salt.

(Data from OECD, 2002, unless otherwise noted).

Property	Value
Appearance at normal temperature and pressure	White powder
Molecular weight	538 g/mol
Vapour Pressure	3,31 x 10^{-4} Pa
Water solubility in pure water	519 mg/L (20 ± 0,5ºC) 680 mg/L (24 - 25ºC)
Melting point	> 400 ºC
Boiling point	Not measurable
Log K_{OW}	Not measurable
Air-water partition coefficient	< 2 x 10^{-6} (3M, 2003a)
Henry's Law Constant	3,09 x 10^{-9} atm m^3/mol pure water

PFOS can be formed (by environmental microbial degradation or by metabolism in larger organisms) from PFOS-related substances, i.e., molecules containing the PFOS-moiety depicted in Figure 1. Although the ultimate net contribution of individual PFOS-related substances to the environmental loadings of PFOS cannot be predicted readily, there is a potential that any molecule containing the PFOS moiety could be a precursor to PFOS.

The majority of PFOS-related substances are polymers of high molecular weights in which PFOS is only a fraction of the polymer and final product (OECD, 2002). PFOS-related substances have been defined somewhat differently in different contexts and there are currently a number of lists of PFOS-related substances (Table 3). The lists contain varying numbers of PFOS-related substances that are thought to have the potential to break down to PFOS. The lists overlap to varying extents depending on the substances under consideration and the overlap between national lists of existing chemicals.

Table 3. Number of PFOS-related substances as proposed by UK – DEFRA, US – EPA, OECD, OSPAR, and Canada

Source	Number of PFOS-related substances
RPA and BRE (2004)	96
US - EPA (2002, 2006)	88[1] + 183[1]
OECD (2002)	172[1] (22 classes of perfluoroalkyl sulfonate substances)
OSPAR (2002)	48
Environment Canada (2006)	57

[1] Perfluorinated substances with different carbon chain lengths are included in the list.

A large number of substances may give rise to PFOS and thus contribute to the contamination problem. DEFRA in the United Kingdom (RPA and BRE, 2004) has recently proposed a list of 96 PFOS-related substances. However, the properties of the 96 substances have not generally been determined. According to 3M (submission to the secretariat of Stockholm Convention (SC), 2006), they may have very different environmental characteristics such as solubility, stability and ability to be absorbed or metabolised. Nevertheless, the document by the United Kingdom infers that all of these substances would give rise to the final degradation product of PFOS (RPA and BRE, 2004).

Environment Canada's ecological risk assessment defines PFOS precursors as substances containing the perfluorooctylsulfonyl ($C_8F_{17}SO_2$, $C_8F_{17}SO_3$,, or $C_8F_{17}SO_2N$) moiety that have the potential to transform or degrade to PFOS (Environment Canada, 2006). The term "precursor" applies to, but is not limited to, some 51 substances identified in the ecological assessment. However, this list is not considered exhaustive, as there may be other perfluorinated alkyl compounds that are also PFOS precursors. This information was compiled based on a survey to industry, expert judgement and CATABOL modelling, in which 256 perfluorinated alkyl compounds were examined to determine whether non-fluorinated components of each substance were expected to degrade chemically and/or biochemically and whether the final perfluorinated degradation product was predicted to be PFOS. While the assessment did not consider the additive effects of PFOS and its precursors, it is recognized that the precursors to PFOS contribute to the ultimate environmental loading of PFOS. Precursors may also play a key role in the long-range transport and subsequent degradation to PFOS in remote areas, such as the Canadian Arctic.

1.2 Conclusion of the POP Review Committee on Annex D information

The Persistent Organic Pollutants Review Committee (POPRC) evaluated Annex D information at the First meeting of the POPRC, Geneva, 7-11 November 2005, and concluded that PFOS information meets the screening criteria specified in Annex D (decision POPRC-1/7: Perfluorooctane sulfonate).

1.3 Data sources

This document on PFOS mainly builds on information that has been gathered in the hazard assessment report prepared by the UK and the USA for the OECD, and in the UK risk reduction strategy:

OECD (2002) Co-operation on Existing Chemicals - Hazard Assessment of Perfluorooctane Sulfonate and its Salts, Environment Directorate Joint Meeting of the Chemicals Committee and the Working Party on Chemicals, Pesticides and Biotechnology, Organisation for Economic Co-operation and Development, Paris, 21 November 2002.

RPA AND BRE (2004) Perfluorooctane Sulfonate – Risk reduction strategy and analysis of advantages and drawbacks, Final Report prepared for Department for Environment, Food and Rural Affairs and the Environment Agency for England and Wales.

Recent relevant information from the open scientific literature (up to May 2006) is also included. Data submitted by Parties and observers, which have been considered, are also included in this report when they add new information.

1.4 Summary of assessment and management under other programs

The hazard assessment of PFOS, prepared by the OECD in 2002, concluded that the presence and the persistence of PFOS in the environment, as well as its toxicity and bioaccumulation potential, indicate a cause of concern for the environment and human health.

An environmental risk assessment, prepared by the UK-Environment Agency, and discussed by the EU member states under the umbrella of the existing substances regulation (ESR DIR 793/93) shows that PFOS is of concern.

The final Environment Canada/Health Canada assessments of PFOS, its salts and its precursors were released in July 2006. The ecological risk assessment has concluded that PFOS and its salts are persistent and bioaccumulative, and that PFOS, its salts and its precursors have immediate or long-term harmful effects on the environment (Environment Canada, 2006).

The EU has recently decided on restrictions on the marketing and use of PFOS (European Union, 2006). The measures cover PFOS acid, its salts and PFOS derivatives, including PFOS polymers. The decision prohibits the placing on the market and use of these compounds as a substance or constituent of preparations in a concentration equal to or higher than 0,005% by mass. Furthermore, semi-finished products and articles, containing PFOS more than 0,1% by mass are prohibited. Some derogations are, however, granted in the decision. These include certain uses in photolithography processes, in photographic coatings and in metal plating, hydraulic fluids for aviation and fire fighting foams that have already been placed on the market.

The UK and Sweden have proposed the following classification for PFOS in EU (2005):

T Toxic

R40 Carcinogen category 3; limited evidence of carcinogenic effect

R48/25 Toxic; danger of serious damage to health by prolonged exposure if swallowed

R61 May cause harm to the unborn child

R51/53 Toxic to aquatic organisms, may cause long-term adverse effects in the aquatic environment has.

Norway is now considering a proposal to prohibit the use of fire fighting foams containing PFOS and PFOS-related compounds, which is the major use of these compounds today in Norway.

The Environmental Protection Agency (EPA) in the USA finalized two Significant New Use Rules (SNURs) in 2002, requiring companies to inform the EPA before manufacturing or importing 88 listed PFOS-related substances. The EPA proposed an additional SNUR under section 5(a)(2) of the Toxic Substances Control Act (TSCA) in March 2006 to include within the scope of this regulation another 183 perfluoroalkyl sulfonates with carbon chain lengths of five carbons and higher. The EPA further proposed an amendment to the Polymer Exemption rule in March 2006 which would remove from exemption polymers containing certain perfluoroalkyl moieties consisting of CF3- or longer chains, and would require that new chemical notifications be submitted on such polymers.

1.5 Status of the chemical under international conventions

OSPAR: PFOS was added to the list of Chemicals for Priority Action in June 2003.

Persistent Organic Pollutants Protocol to the Long-Range Transboundary Air Pollution Convention ("LRTAP"): The Executive Body of the UNECE LRTAP Convention agreed that PFOS be considered a POP as defined under the Protocol on POPs and requested that the UNECE Task Force on POPs continue with the review of the substance and exploring management strategies.

2 SUMMARY INFORMATION RELEVANT FOR THE RISK PROFILE

2.1 Sources

2.1.1 Production and trade

The main production process of PFOS and PFOS-related substances is electro-chemical fluorination (ECF), utilized by 3M, the major global producer of PFOS and PFOS-related substances prior to 2000.

Direct fluorination, electro-chemical fluorination (ECF):

$$C_8H_{17}SO_2Cl + 18\ HF \rightarrow C_8F_{17}SO_2F + HCl + \text{by products}$$

The reaction product, perfluorooctanesulfonyl fluoride (PFOSF)[1] is the primary intermediate for synthesis of PFOS and PFOS-related substances. The ECF method results in a mixture of isomers and homologues with about 35-40% 8-carbon straight chain PFOSF. However, the commercial PFOSF products were a mixture of approximately 70% linear and 30% branched PFOSF derivate impurities. The global production of PFOSF by 3M until the production ceased is estimated to have been 13,670 metric tonnes (1985 to 2002), with the largest yearly production volume, 3700 metric tonnes of PFOS and PFOS related substances, in 2000 (3M, Submission to SC, 2006). PFOSF may be further reacted with methyl- or ethylamine to form *N*-ethyl- and *N*-methyl perfluorooctane sulfamide and subsequently with ethylene carbonate resulting in *N*-ethyl- and -methyl-perfluorooctane sulfamidoethanol (*N*-EtFOSE and *N*-MeFOSE). *N*-EtFOSE and *N*-MeFOSE were the principal building blocks of 3M's product lines. PFOS is formed after the chemical or enzymatic hydrolysis of PFOSF (3M, 1999).

Other production methods for perfluoroalkylated substances are telomerisation and oligomerisation. However, to which extent these methods are applied for production of PFOS and PFOS-related substances is not evident.

[1] In the OECD report, 2002, perfluorooctanesulfonyl fluoride is abbreviated POSF.

On 16 May 2000, 3M announced that the company would phase-out the manufacture of PFOS and PFOS-related substances voluntarily from 2001 onwards. By the end of 2000, about 90 % of 3M's production of these substances had stopped and in the beginning of 2003 the production ceased completely.

3M´s voluntary phase-out of PFOS production has led to a reduction in the use of PFOS-related substances. This is due not only to the limited availability of these substances (3M had at the time the greatest production capacity of PFOS-related substances in the world), but also to action within the relevant industry sectors to decrease companies´ dependence on these substances.

The US Environmental Protection Agency (US EPA) compiled a list of non-US companies which are believed to supply PFOS-related substances to the global market. Of these (and excluding the plant of 3M in Belgium), six plants are located in Europe, six are located in Asia (of which four are in Japan) and one in Latin America (OECD, 2002). However, this list may not be exhaustive or current.

According to the recent submission from Japan to the secretariat of the Stockholm Convention, 2006, there is one manufacturer in Japan still producing PFOS and with a production amount of 1-10 tonnes (2005). The submission from Brazil states that lithium salt of PFOS is produced but that no quantitative data is available.

2.1.2 Uses

Perfluorinated substances with long carbon chains, including PFOS, are both lipid-repellent and water-repellent. Therefore, the PFOS-related substances are used as surface-active agents in different applications. The extreme persistence of these substances makes them suitable for high temperature applications and for applications in contact with strong acids or bases. It is the very strong carbon-fluorine binding property that causes the persistence of perfluorinated substances.

The historical use of PFOS-related substances in the following applications has been confirmed in the US and the EU.

- Fire fighting foams
- Carpets
- Leather/apparel
- Textiles/upholstery
- Paper and packaging
- Coatings and coating additives
- Industrial and household cleaning products
- Pesticides and insecticides

In the UK study (RPA and BRE, 2004), detailed information has been received from the following sectors that currently use PFOS-related substances:

- Use of existing fire fighting foam stock
- Photographic industry
- Photolithography and semiconductor
- Hydraulic fluids
- Metal plating

The sectors presented above account for the UK but are considered to be representative for EU. However, deviation in the current use pattern between EU countries cannot be excluded.

PFOS and its precursors are not manufactured in Canada but rather are imported as chemicals or products for Canadian uses. They may also be components in imported manufactured articles. It is estimated that the majority of PFOS has been used as water, oil, soil and grease repellents (e.g. on fabric, leather, paper, packaging, rugs and carpets) and as surfactants (e.g. in fire fighting foams and coating additives) (Environment Canada, 2006).

PFOS and its precursors are not manufactured in the US, but can be imported either as chemicals or in products for the specific limited uses that were excluded from regulation. These comprise use as an anti-erosion additive in aviation hydraulic fluids; use as a component of a photoresist substance, including a photo acid generator or surfactant, or as a component of an anti-reflective coating, used in a photomicrolithography process to produce semiconductors or similar components of electronic or other miniaturized devices; use in coatings for surface tension, static discharge, and adhesion control for analog and digital imaging films, papers, and printing plates, or as a surfactant in mixtures used to process imaging films; and use as an intermediate only to produce other chemical substances to be used solely for these uses. Historically, PFOS and its precursors were also used as surfactants in fire fighting foams and in industrial and household cleaning products; in carpet, textile, leather, and paper coatings; and in termite and ant bait insecticide products. Stocks of PFOS and PFOS-containing products that were in existence at the time the US regulations were promulgated in 2002 could continue to be used in any application until they were consumed without violating the regulation, except that the PFOS-related insecticide products are subject to a phase-out agreement prohibiting their use after 2015.

The table below outlines the estimated current demand for PFOS-related substances in these applications in the EU (RPA and BRE, 2004).

Estimated Current (2004) Demand for PFOS Related Substances in the EU	
Industry Sector	Quantity (kg/year)
Photographic industry	1,000
Photolithographic and semi-conductors	470
Hydraulic fluids	730
Metal plating	10,000

In the survey on production and use of PFOS and related substances performed by OECD in 2004 (published 2005), data concerning PFOS were difficult to separate from data on other perfluoroalkyl sulfonates.

Fire Fighting Foams

The fire fighting foams can be grouped in two main categories:

- Fluorine-containing foam types (some of them consist of PFOS-related substances)
- Fluorine-free foam types

Since the announcement of the voluntary cessation of production of PFOS-related substances by 3M, the presence of PFOS in fire fighting foams has gradually decreased (RPA and BRE, 2004).

Historically, in Canada, the most significant imports of PFOS, itself, were in the form of the potassium salt, used for fire-fighting foams (Environment Canada, 2006). Canada has also identified that existing stocks of PFOS-containing fire fighting foams could be a continued significant source of releases.

An industry survey conducted in the US by the Fire Fighting Foam Coalition in 2004 reported that the total inventory of aqueous film-forming foam in the US was approximately 9.9 million gallons, of which about 45% was PFOS-based stocks produced before 2003, with the other 55% comprised of telomer-based foams.

Textile, Carpet and Leather Protection

PFOS-related substances have been used to provide soil, oil and water resistance to textiles, apparels, home furnishings and upholstery, carpets, and leather products. Since 3M´s withdrawal from the market, PFOS-related substances are used to a much smaller extent for these applications (RPA AND BRE, 2004).

Paper and Packaging Protection

PFOS-related substances have been used in the packaging and paper industries in both food packaging and commercial applications to impart grease, oil and water resistance to paper, paperboard and packaging substrates. According to 3M, fluorochemicals were used for both food contact applications (plates, food containers, bags and wraps) and non-food applications (folding cartons, containers and carbonless forms and masking papers). Since 3M´s withdrawal from the market, PFOS related substances are used to a much smaller extent for these applications (RPA and BRE, 2004).

Coatings and Coating Additives

3M indicates that prior to its voluntary phase-out of PFOS production, the company would sell fluorochemical polymer coatings and coating additives which were used undiluted or diluted with water or butyl acetate to impart soil or water repellence to surfaces (including printing circuit boards and photographic film) (RPA and BRE, 2004).These polymers contained fluorocarbon residuals at a concentration of 4% or less. Other applications for aqueous coatings are to protect tile, marble and concrete. It is unclear which of these products were actually based on PFOS-related substances.

A survey in the UK among members of the British Coatings Federation (BCF) showed that the use of PFOS-related substances for these purposes is very limited (RPA and BRE, 2004).

Industrial and Household Cleaning Products (Surfactants)

3M PFOS-based products were sold in the past to a variety of formulators to improve the wetting of water-based products marketed as alkaline cleaners, floor polishes (to improve wetting and levelling), denture cleansers and shampoos. Several of these products (alkaline cleaners, floor polishes, shampoos) were marketed to consumers; some products were also sold to janitorial and commercial services. A number of the alkaline cleaners were spray-applied.

With regard to the UK cleaning products industry, the responses received do not indicate the use of PFOS-related substances in industrial and household cleaning products. Based on information provided in product registers, the Swedish National Chemicals Inspectorate (KemI) has indicated that PFOS-related substances are still being used in Sweden for both industrial and household use (RPA and BRE, 2004).

Photographic Industry

PFOS-based chemicals are used for the following purposes in mixtures, in coatings applied to photographic films, papers, and printing plates (RPA and BRE, 2004):

- Surfactants
- Electrostatic charge control agents;

- Friction control agents;
- Dirt repellent agents; and
- Adhesion control agents

Photolithography and Semiconductors

Photoresist

Semiconductor manufacturing comprises up to 500 steps, of which there are four fundamental physical processes:

- Implant
- Deposition
- Etch
- Photolithography

Photolithography is the most important step towards the successful implementation of each of the other steps and, indeed, the overall process. It shapes and isolates the junctions and transistors; it defines the metallic interconnects; it delineates the electrical paths that form the transistors; and joins them together. Photolithography reportedly represents 150 of the total of 500 steps mentioned above. Photolithography is also integral to the miniaturization of semiconductors (RPA and BRE, 2004).

PFOS is used as a photoacid generator (PAG) in a mechanism called chemical amplification that increases the sensitivity of photoresist to allow etching images smaller than wavelength of light.

Antireflective Coatings

A number of resist suppliers sell antireflective coatings (ARC), subdivided into Top (TARC) and Bottom (BARC) coatings and used in combination with deep ultra violet (DUV) photoresist. The process involves placing a thin, top coating on the resist to reduce reflective light, in much the same way and for the same purposes that eyeglasses and camera lenses are coated.

Hydraulic Fluids for the Aviation Industry

Hydraulic fluids were initially used in aircraft to apply brake pressure. As larger and faster aircraft were designed, greater use of hydraulic fluids became necessary. An increase in the number of hydraulic fluid fires in the 1940s necessitated work towards developing fire resistant fluids. The first of these fluids was developed around 1948, when fire resistant hydraulic fluids based on phosphate ester chemistry were developed.

Perfluorinated anions act by altering the electrical potential at the metal surface, thereby preventing the electrochemical oxidation of the metal surface under high fluid flow conditions (RPA and BRE, 2004). As a result, hydraulic fluids based on phosphate ester technology and incorporating additives based on perfluorinated anions are used in all commercial aircraft, and in many military and general aviation aircraft throughout the world, as well as by every airframe manufacturer (RPA and BRE, 2004).

Metal Plating

The main uses of PFOS-related substances in metal plating are for chromium plating, and anodising and acid pickling. PFOS related substances lower the surface tension of the plating solution so that mist containing chromic acid from the plating activity is trapped in solution and is not released to air (RPA and BRE, 2004).

Other

There is information on other historical or current PFOS applications such as in pesticides, medical applications, mining and oil surfactants, flame retardants and in adhesives. Based on current understanding, these applications represent a minor part of known PFOS applications and are therefore not further elaborated in this profile.

2.1.3 Releases to the environment

There is to date very limited information regarding the emissions and pathways of PFOS to the environment. The occurrence of PFOS in the environment is a result of anthropogenic manufacturing and use, since PFOS is not a naturally occurring substance.

Releases of PFOS and its related substances are likely to occur during their whole life cycle. They can be released at their production, at their assembly into a commercial product, during the distribution and industrial or consumer use as well as from landfills and sewage treatment plants after the use of the products (3M, 2000).

Manufacturing processes constitute a major source of PFOS to the local environment. During these processes, volatile PFOS-related substances may be released to the atmosphere. PFOS and PFOS-related substances could also be released via sewage effluents (3M, 2000). High local emissions are indicated by one study that showed extremely high concentrations of PFOS in wood mice collected in the immediate vicinity to 3M's fluorochemical plant in Antwerpen, Belgium (Hoff et al., 2004). High concentrations of PFOS were also found in liver and blood from fish collected in the Mississippi River at the immediate vicinity of another 3M fluorochemical plant at Cottage Grove in Minnesota (MPCA, 2006).

Fire training areas have also been revealed to constitute a source of PFOS emissions due to the presence of PFOS in fire-fighting foams. High levels of PFOS have been detected in neighbouring wetlands of such an area in Sweden (Swedish EPA, 2004) as well as in groundwater in the US close to a fire-training area (Moody et al., 2003).

An investigation on the uses of PFOS and PFOS-related compounds in Norway in 2005 shows that approximately 90% of the total use is in fire extinguishers (Submission to SC, 2006). Estimated releases of PFOS related to fire extinguishers are at least 57 tonnes since 1980 to 2003 (2002; 13-15 tonnes). Remaining quantities of fire extinguisher foam in Norway are estimated to be a minimum of 1.4 million litres, which corresponds to an amount of approximately 22 tonnes PFOS. Releases from the municipal sector in Norway, 2002, were estimated to be 5-7 tonnes (Submission to SC, 2006).

The use of PFOS in semiconductors is estimated to result in a release of 43 kg per year in the EU, according to the Semiconductur Industry Association (SIA) (SIA, Submission to SC, 2006). This corresponds to 12 % of the total PFOS use in this application. PFOS released in the USA from semiconductors is estimated to be in the same range (SIA, 2006).

The releases of sulfonated perfluorochemicals, including PFOS or PFOS-related substances, from different product usages have been estimated (3M Speciality Materials, 2002). For example, garments treated with home-applied products, are expected to lose 73 % of the treatment during cleaning over a 2-year life span. A loss of 34 % to air is expected from spray can products during use, while up to 12.5 % of the original content may be remaining in the cans at the time of disposal.

One route for PFOS and PFOS-related substances to the environment may be through sewage treatment plants (STPs) and landfills, where elevated concentrations have been observed compared to background concentrations. Once released from STPs, PFOS will partially adsorb to sediment and organic matter. A substantial amount of PFOS may also end up in agricultural soil, due to the

application of sewage sludge. The primary compartments for PFOS are therefore believed to be water, sediment and soil (RIKZ, 2002).

Dispersion of PFOS in the environment is thought to occur through transport in surface water, or oceanic currents (Yamashita *et al*., 2005, Caliebe *et al*., 2004), transport in air (volatile PFOS-related substances), adsorption to particles (in water, sediment or air) and through living organisms (3M, 2003a).

One major obstacle when trying to estimate the releases of PFOS to the environment is that PFOS can be formed through degradation of PFOS-related substances. The rate and the extent of that formation are presently unknown. In a study on Swedish STPs, higher concentrations of PFOS were found in the effluents compared to incoming sewage water, which could indicate that PFOS was formed from PFOS-related substances (Posner and Järnberg, 2004).

2.2 Environmental fate

2.2.1 Persistence

PFOS is extremely persistent. It does not hydrolyse, photolyse or biodegrade in any environmental condition tested (OECD, 2002).

A study on the hydrolysis of PFOS in water has been performed following US-EPA OPPTS protocol 835.2210. The study was conducted at pH varying from 1.5 – 11.0 and at a temperature of 50°C, to facilitate hydrolysis, but did not indicate any degradation of PFOS. The half-life of PFOS was set to be greater than 41 years.

A study on the photolysis of PFOS in water following US-EPA OPPTS protocol 835.5270 has been conducted. No evidence of direct or indirect photolysis was observed under any of the conditions tested. The indirect photolytic half-life of PFOS at 25°C was calculated to be more than 3.7 years.

Biodegradation of PFOS has been evaluated in a variety of tests. Aerobic biodegradation of PFOS has been tested in activated sewage sludge, sediment cultures and soil cultures in several studies. Anaerobic biodegradation has been tested in sewage sludge. None of the studies demonstrated any signs of biodegradation.

Modelling with a simulator program of microbial degradation, the CATABOL system, and expert judgment predicted that of 171 studied perfluorinated substances over 99% would biodegrade to extremely persistent perfluorinated acids. Of them, 109 substances were predicted to end up as perfluorinated sulfonic acids, including PFOS, and 61 as perfluorinated carboxylic acids (Dimitrov et al., 2004).

The only known condition whereby PFOS is degraded is through high temperature incineration under correct operating conditions (3M, 2003a). Potential degradation at low temperature incineration is unknown.

2.2.2 Bioaccumulation

It should be noted that PFOS does not follow the “classical” pattern of partitioning into fatty tissues followed by accumulation, which is typical of many persistent organic pollutants. This is because PFOS is both hydrophobic and lipophobic. Instead, PFOS binds preferentially to proteins in the plasma, such as albumin and β-lipoproteins (Kerstner-Wood et al., 2003), and in the liver, such as liver fatty acid binding protein (L-FABP; Luebker et al., 2002). Because of the unusual physical-chemical characteristics of PFOS, the mechanism of bioaccumulation probably differs from other POPs.

In a study following OECD protocol 305, the bioaccumulation of PFOS in bluegill sunfish (*Lepomis macrochirus*) has been tested. The whole-fish kinetic bioconcentration factor (BCFK) was determined to be 2796 (3M, 2002).

In another study on rainbow trout (*Oncorhynchus mykiss*), a bioconcentration factor (BCF) in liver and plasma was estimated to be 2900 and 3100, respectively (Martin, *et al*., 2003).

When strictly looking at the BCF values, it is clear that these values are below the numeric BCF criteria in Stockholm Convention Annex D (the reported BCF values are below 5000) but, in this particular case, as noted above, the BCF numeric criteria may not adequately represent the bioaccumulation potential of the substance. Monitoring data from top predators at various locations show highly elevated levels of PFOS and demonstrate substantial bioaccumulation and biomagnification (BMF) properties of PFOS. It is notable that the concentrations of PFOS found in livers of Arctic polar bears exceed the concentrations of all other known individual organohalogens (Martin et al., 2004a). Based on the concentration of PFOS in predators (e.g., the polar bear) in relation to the concentration in their principal food (e.g., seals), hypothetical BMF values can be calculated. Such data are reported in Table 4. It should be noted that there are uncertainties in these comparisons. Even if either liver or blood concentrations are compared in two species, species differences in specific protein binding in that particular compartment may affect the concentration in the organ without having affected the whole-body concentration of the substance.

Table 4. Measured concentrations of PFOS in biota from various locations. Calculated BMF is shown where applicable.

Species and Location	Concentrations of PFOS	Reference
• Polar Bear, Canadian Arctic	- Concentrations of PFOS in liver (1700 – > 4000 ng/g) exceeding all other individual organohalogens. - BMF > 160 based on concentrations in Arctic seals.	Martin et al., 2004a.
• Arctic fox, Canadian Arctic	- Very high concentrations of PFOS in liver (6.1 - 1400 ng/g)	Martin et al., 2004a.
• Mink, US	- Very high concentrations of PFOS in liver (40 - 4870 ng/g). - BMF = 22 based on data from fish in the same area. - nother mink study also show very high concentrations of PFOS in liver (1280 - 59 500 ng/g, mean 18 000 ng/g,) - BMF ~145 to ~4000 based on data from their prey such as crayfish (whole body), carp (muscle) and turtles (liver	Giesy and Kannan, 2001 Kannan et al., 2005

• Bald Eagle, US	- Very high concentrations of PFOS in plasma (1 – 2570 ng/g).	Giesy and Kannan 2001.
• Dolphin, US	- Very high concentrations of PFOS in liver (10 – 1520 ng/g).	3M, 2003a.
• Seal in the Bothnian Sea, Finland	- Very high concentrations of PFOS in liver (130 – 1100 ng/g). - BMF > 60 based on data from salmon in the same area.	Kannan et al., 2002

In a study by Kannan et al. (2005), the whole body BCF for round gobies (*Neogobius melanostomus)* was calculated to be approximately 2400, which is comparable with laboratory data. PFOS concentrations in fish (whole body of round gobies) compared to concentrations in liver of salmon results in BMFs of approximately 10-20. In bald eagles, the mean PFOS concentration in the livers, 400 ng/g ww, gives a BMF of four to five when compared to fish at higher trophic levels in the study. For mink, BMFs from 145 to 4000 can be calculated when based on the mean liver concentration, 18 000 ng/g ww, compared to their prey items such as crayfish (whole body), carp (muscles) and turtles (liver).

In general, data show that animals at higher trophic levels have higher concentrations of PFOS than animals at lower trophic levels, indicating that biomagnification is taking place. For instance, a trophic magnification factor (TMF) of 5,9 was calculated for PFOS based on a pelagic food web including: one invertebrate species, Mysis; two forage fish species, rainbow smelt and alewife; and a top predator fish species, lake trout. A diet-weighted bioaccumulation factor of approximately 3 was determined for the trout (Martin et al., (2004b).

Morikawa *et al.* (2005) showed a high bioaccumulation in turtles. Results from a study performed by Tomy *et al*. (2004a) indicated that PFOS biomagnified in an eastern Arctic marine food web (liver concentrations of PFOS were used for seabirds and marine mammals). Houde *et al.* (2006) showed PFOS biomagnification in the Atlantic Ocean bottlenose dolphin food web.

A study by Bossi *et al*. (2005a) further supports that biomagnification is taking place. In this study, a preliminary screening of PFOS and related compounds has been performed in liver samples of fish, birds and marine mammals from Greenland and the Faroe Islands. PFOS was the predominant fluorochemical in the biota analyzed, followed by perfluorooctane sulfonamide (PFOSA). The results from Greenland showed a biomagnification of PFOS along the marine food chain (shorthorn sculpin < ringed seal < polar bear).

It is assumed that the main and most relevant route of exposure to PFOS for birds is through the diet as biomagnification in bird tissues can occur this way. BMFs above one are reported for several bird species collected in the Gulf of Gdansk (Gulkowska *et. al.* 2005). Kannan *et al*. (2005) reported a BMF of 10 to 20 in bald eagles (relative to prey items). Tomy *et al*. (2004a) calculated a trophic level BMF for black-legged kittiwake:cod of 5.1 and a BMF for glaucous gull:cod of 9.0. Newsted *et al.* (2005) indicated that PFOS has relatively shorter half-lives in blood and liver tissue in birds compared to mammals. For example, the estimated elimination half-life for PFOS from serum is 13.6 days in male mallards whereas in male rats, it is greater than 90 days. A recent study has suggested that PFOS is excreted relatively rapidly from birds (Kannan *et al*., 2005). However, if birds are chronically exposed to PFOS in their diet, biomagnification can still occur. Environmental monitoring of birds in northern parts of their range in fact indicates accumulation of PFOS.

The fact that PFOS binds to proteins leads to the relevant question -- *at what concentrations of PFOS will the binding sites on these proteins be saturated?* Serum albumin is most likely the binding pool of PFOS (Jones *et al*., 2003) and several studies have been carried out with regard to bioconcentration in plasma. In Ankley *et al*. (2005), the bioconcentration in fish was studied at concentrations of PFOS in water up to 1 mg /L; the concentration of PFOS in water and plasma followed an almost linear relationship in the doses tested up to 0.3 mg/l without any signs of saturation (1 mg/l was not tested due to mortality at that dose). This is far above environmentally relevant concentrations.

In a study by 3M (2003a), the bioconcentration factor (BCF) in whole fish was determined to be approximately 2800 at a PFOS concentration of 86 µg/l, based on calculations of uptake and depuration of PFOS. Steady-state levels were attained after 49 days of exposure. Depuration occurred slowly and 50% clearance for whole fish tissues was estimated to be 152 days. Due to mortality, a BCF could not be calculated for the other concentration used, 870 µg/l. Thus, it is not likely that saturation of serum protein binding sites will limit the bioconcentration of PFOS in fish. In Cynomolgus monkeys, cumulative doses of PFOS (0,03, 0,15, or 0,75 mg/kg/day, orally, for 182 days) showed a linear increase in plasma at the low- and mid-dose groups while a nonlinear response was showed in the high-dose group (Covance Laboratories, Inc. 2002a). We are not aware of similar data in other mammals, but considering the high level of bioaccumulation observed in mammals, and that mammalian serum contains high concentrations of protein, binding sites are not likely to limit the bioaccumulation of PFOS in environmentally exposed mammals.

2.2.3 Long-range environmental transport

The potassium salt of PFOS has a measured vapour pressure of 3.31×10^{-4} Pa (OECD, 2002). Due to this vapour pressure and a low air-water partition coefficient ($< 2 \times 10^{-6}$), PFOS itself is not expected to volatilise significantly. It is therefore assumed to be transported in the atmosphere predominantly bound to particles, because of its surface-active properties, rather than in a gaseous state.

Some of the PFOS-related substances have a considerably higher vapour pressure than PFOS itself, and are as a result more likely to be volatile. The vapour pressures of precursors, such as N-EtFOSEA and N-MeFOSEA, may exceed 0.5 Pa (1000 times greater than that of PFOS) (Giesy and Kannan 2002). Other PFOS precursors considered volatile include N-EtFOSE alcohol, N-MeFOSE alcohol, N-MeFOSA and N-EtFOSA (3M, 2000). These precursors to PFOS could evaporate into the atmosphere and be more widely transported through air than is possible for PFOS itself. Once in the atmosphere, they can remain in gas phase, condense on particles present in the atmosphere and be carried or settle out with them, or be washed out with rain (3M, 2000). Martin *et al*. (2002) measured the air in Toronto and Long Point, Ontario, for some precursors of PFOS. They found an average N-MeFOSE alcohol concentration of 101 pg/m^3 in Toronto and 35 pg/m^3 at Long Point. The average concentrations of N-EtFOSE alcohol were 205 pg/m^3 in Toronto and 76 pg/m^3 in Long Point.

For precursors released to water, the vapour pressure may be significant enough to allow the substance to enter into the atmosphere. For N-EtFOSE alcohol, the tendency to leave the water phase is indicated by its relatively high Henry's law constant (1.9×10^3 Pa·m^3·mol^{-1}) (Hekster *et al*. 2002). It has been reported that when these PFOS precursors are present as residuals in products, they could evaporate into the atmosphere when the products containing them are sprayed and dried (3M, 2000).

PFOS has been detected in rainwater from an urban center in Canada with a concentration of 0.59 ng/L. Whether or not PFOS originates from precursors either being transported and subsequently wet deposited and degraded to PFOS, or atmospherically degraded and then wet deposited, is unclear. Measurements of potential precursors for PFOS were not performed in this study (Loewen *et al*, 2005)

The atmospheric half-life of PFOS is expected to be greater than two days. This statement, while not specifically tested, is based on the fact that PFOS has exhibited extreme resistance to degradation in all tests performed. However, an atmospheric half-life of 114 days has been calculated for PFOS using an AOP computer modeling program v1.91 (Environment Agency,, 2004). The indirect photolytic half-life of PFOS at 25°C has been estimated to be more than 3.7 years (OECD, 2002).

How perfluoralkyl acid substances have come to be globally disseminated in the environment has been the key question, since, for example, the vapour pressure and Henry's law constant of PFOS indicates it is too involatile and therefore unlikely to enter directly into the atmosphere (Stock *et al.* 2004). Therefore it has been hypothesized that PFOS must be globally distributed via more volatile, neutral airborne contaminants that undergo long-range transport and then degrade to yield the free acids.

In support, Stock *et al.* (2004) have recently reported that polyfluorinated sulfonamides are widely distributed throughout the North American troposphere. Mean concentrations ranged from 22-403 pg/m^3 with the dominant polyfluorinated contaminant dependent on the sampling location.

High mean concentrations of N-methyl perfluorooctane sulfonamidoethanol (NMeFOSE) of 359 pg/m^3, were identified in the air of Griffin, Georgia. The authors speculate that, as Griffin is located in the midst of the main carpet manufacturing and treatment zone of the US, it probably is entering the environment from carpet treatment products, many of which consist of fluorinated molecules linked to polymeric materials. For example, it is possible that free chemical may be left in the carpet fibres, with publicly available information on 3M produced products indicating the concentration of free polyfluorinated sulfonamides is typically 1-2% or less. Alternatively, it is postulated that chemically bound NMeFOSE may also be released from carpets due to chemical, physical, and/or biological degradation processes.

Support for this hypothesis comes from Shoeib *et al.* (2004), who measured both NMeFOSE and the related N-ethyl perfluorooctane sulfonamidoethanol (NEtFOSE) in both indoor and outdoor air. Mean indoor air concentrations for these were 2590 and 770 pg/m^3, respectively, and the ratios between indoor and outdoor air were 110 and 85, respectively. Again carpets were identified as a possible source of NMeFOSE, and high usage of paper in the building as a possible source of NEtFOSE. Paper products were also suggested by Stock *et al.* (2004) as a possible source for the high levels of NEtFOSE in the air of Reno, Nevada.

Recently Dinglasan-Panlilio and Maybury (2006) have demonstrated that residual fluorinated substances detected in materials, including 0.39% of a perfluoroalkyl sulfonamido alcohol present in a commercially available carpet protector product, are the likely sources for these volatile precursors. Further N-methyl perfluorobutane sulfonamidoethanol (NMeFBSE) has been demonstrated in the laboratory to degrade to perfluorobutane sulfonate (PFBS), albeit in low yield (D'eon et al, 2006).

PFOS has been measured in a wide range of biota in the Northern Hemisphere such as the Canadian Arctic, Sweden, the US and the Netherlands. In a study by Martin *et al.* (2004a), the levels of PFOS were measured in liver samples from biota in the Canadian Arctic and were found in the vast majority of the species examined. The presence of PFOS in Arctic biota, far from anthropogenic sources, demonstrates the potential of PFOS for long-range transport. The mechanisms of this transport are not known, but it could be due to the transport of volatile PFOS-related substances that eventually degrade to PFOS.

While precursors will undergo degradation once released to the environment, transformation rates may vary widely. Precursors that reach a remote region through the atmosphere or other media may be subject to both abiotic and biotic degradation routes to PFOS (Giesy and Kannan 2002a; Hekster *et al*. 2002). The mechanisms of this degradation are not well understood. When rats metabolize N-MeFOSE-based compounds, several metabolites have been confirmed in tissue samples, including PFOS and N-MeFOSE alcohol (3M Environmental Laboratory 2001a, 2001b). PFOS appears to be the final product of rat and probably other vertebrate metabolism of POSF-based substances.

A recent study performed with rainbow trout (*Onchorhynchus mykiss)* liver microsomes has demonstrated that *N*-ethyl perfluorooctanesulfonamide (N-EtPFOSA) is a precursor of PFOS in fish (Tomy et al., 2004b). These findings combined with the recent measurements of concentrations up to 92.8 ± 41.9 ng/g wet weight of *N*-EtPFOSA in aquatic organisms from Arctic regions (Tomy et al., 2004a) strengthen the hypothesis that perfluorinated sulfonamides are one of the volatile precursors of PFOS transported over long distances to the Arctic. However, the hypothesis that these volatile precursors reach the Arctic latitudes by atmospheric transport has not yet been confirmed by atmospheric measurements (Bossi et al., 2005b)

2.3 Exposure

2.3.1 Measured environmental levels

A screening study was assigned by the Swedish Environmental Protection Agency (Swedish EPA) and performed by ITM, Institute of Applied Environmental Research, on the levels of PFOS in the Swedish environment (Swedish EPA, 2004). The results showed highly elevated levels of PFOS in a wetland in the vicinity of a fire drill area with a declining gradient out in the adjacent bay (2.2 – 0.2µg/L). Elevated levels were also detected outside sewage treatment plants (STPs) and landfills. Effluents from STPs contained levels of PFOS up to 0.020 µg/L and leachate levels from landfills were between 0.038 – 0.152 µg/L.

The occurrence of PFOS and other perfluoroalkyl sulfonate substances in open ocean waters such as the Atlantic and the Pacific Ocean have been investigated. The detection of PFOS in oceanic waters suggests another potential long-range transport mechanism to remote locations such as the Arctic. The results showed that PFOS is present in central to western Pacific Ocean regions in concentrations ranging from 15 – 56 pg/L, comparable to the concentrations in the mid-Atlantic ocean. These values appear to be the background values for remote marine waters far from local sources (Taniyasu *et al*., 2004). PFOS was also detected in oceanic waters in several coastal seawaters from Asian countries (Japan, China, and Korea) at concentrations ranging from 1.1 - 57 700 pg.L^{-1} (Jin *et al.*, 2004; Yamashita *et al*., 2005). PFOS was also observed in the North Sea (estuary of the river Elbe, German Bight, southern and eastern North Sea) (Caliebe *et al*., 2004).

In a study in cities across China, PFOS was detected in all water samples (surface and sea water, groundwater, municipal and industrial effluents and tap water), showing that PFOS pollution existed generally in water compartments in China. Concentrations were generally at levels of approximately 1 ngéL (Jin *et al.*, 2004).

Studies in the US have identified the presence of PFOS in surface water and sediment downstream of a production facility, as well as in wastewater treatment plant effluent, sewage sludge and landfill leachate at a number of urban centres in the US (3M Multi City study, reviewed in OECD (2002) and 3M (2003a). Four of the cities (Decatur (AL), Mobile, Columbus (GA), Pensacola) were cities that have manufacturing or industrial use of fluorochemicals; two of the cities (Cleveland (TN), Port St. Lucie) were control cities that do not have significant fluorochemical activities. The ranges of PFOS levels in these cities are provided in Table 5.

Table 5. Environmental Levels of PFOS in Six US Urban Centres in the US (from OECD, 2002)

Medium	Range of PFOS levels (µg/L or µg/kg)
Municipal wastewater treatment plant effluent	0.041 - 5.29
Municipal wastewater treatment plant sludge	0.2 - 3.120 (dry weight)
Drinking water	ND - 0.063
Sediment	ND - 53.1 (dry weight)
Surface water	ND - 0.138
'Quiet' water	ND - 2.93

Note: ND: not detected

The control cities' samples generally inhabited the lower end of the above ranges, except for the municipal wastewater treatment plant effluent and sludge findings for one of the control cities (Cleveland), which were intermediate in their ranges, and the 'quiet' water samples at control city (Port St. Lucie), which were the highest. In Canada, suspended sediment samples were collected annually at Niagara-on-the-Lake in the Niagara River over a 22 year period (1980-2002). PFOS concentrations ranged from 5 to 1100 $pg.g^{-1}$ (Furdui *et al.,* 2005). Preliminary findings suggest that PFOS concentrations increased during the study period from < 400 $pg.g^{-1}$ in the early 1980s to > 1000 $pg.g^{-1}$ in 2002.

Samples of effluent from fifteen representative industry sectors have been analysed for PFOS (Hohenblum *et al*, 2003). The industry sectors were printing (1 site), electronics (3), leather, metals, paper (6), photographic and textiles (2). The PFOS levels ranged from 0-2.5 µg/L (2.5 µg/L for leather, 0.120 µg/l for metal, 0.140-1.2 µg/l at four paper sites, 1.2 µg/l for photographic, not found in textiles or electronics).

Groundwater from below an air force base in Michigan, US, has been sampled (Moody et al, 2003). Fire fighting foams containing PFOS had been used there in training exercises from the 1950s to 1993 when the base was decommissioned. The groundwater was found to contain PFOS, at levels from 4 - 110 µg/l.

Sixteen Great Lakes water samples (eight locations) were analysed for perfluorooctane surfactants. PFOS was present in all samples with a concentration range of 21-70 ng/L. Three PFOS precursors were also found in the water samples. N-EtFOSAA (4.2-11 ng/L) and PFOSA (0.6 -1.3 ng/L) were present in nearly all samples while PFOSulfinate was identified at six out of eight locations (2.2-17 ng/L) (Boulanger et al, 2004). PFOS was detected in surface water as a result of a spill of fire-fighting foam from the Toronto International Airport into nearby Etobicoke Creek. Concentrations

of PFOS ranging from <0.017 to 2210 $\mu g.L^{-1}$ were detected in creek water samples over a 153-day sampling period. PFOS was not detected at the upstream sample site (Moody *et al*. 2003).

PFOS and related fluorochemicals have been detected in animals in a number of studies in a variety of locations around the globe. Generally, the highest concentrations are found in top predators in food chains containing fish. The highest North American or circumpolar concentration of PFOS in mammal tissue reported in the published literature is 59 500 $\mu g.kg^{-1}$ ww in mink liver from USA (Kannan *et al*., 2005a).

Martin *et al.* (2004a) measured the levels of PFOS in liver samples from biota in the Canadian Arctic. PFOS was found in the vast majority of the samples and higher levels were found in animals at the top of the food chain. The highest levels were found in polar bear, with a mean level of 3100 ng/g from seven animals (maximum value > 4000 ng/g). The concentrations of PFOS in polar bear are 5-10 times higher than the concentration of all other perfluoroalkyl substances and were higher than any other previously reported concentrations of persistent organochlorine chemicals (e.g., PCBs, chlordane or hexachlorocyclohexane) in polar bear fat (Martin *et al.,* 2004a). PFOSA, a precursor to PFOS, was also found in most of the samples. The concentration of PFOSA was higher than that of PFOS in fish, but not in mammals. This could indicate that PFOSA has been metabolised to PFOS in mammals and the high concentrations may be the result of both direct exposure to PFOS and metabolism from PFOSA.

PFOS is found in birds worldwide. In North America, PFOS has been found in eagles in the Great Lakes, mallards in the Niagara River, loons in northern Quebec, gulls in the Arctic and in Canadian migratory species in the United States (e.g., common loon in North Carolina). In Canadian or Canada-US migratory species, concentrations have been measured in liver ranging from not detectable to 1780 ng/g for loon in northern Quebec and bald eagle in Michigan, in blood plasma ranging from <1- 2220 ng/g blood plasma in bald eagles, and in eggs and egg yolk ranging from 21-220 ng/g in double-crested cormorant in Manitoba. In several monitoring studies, piscivorous water birds were found to have some of the highest liver and serum PFOS concentrations compared to other species (Newsted *et al.,* 2005). In a study of birds in the Niagara River Region, piscivorous birds (common merganser, bufflehead) contained significantly greater PFOS concentrations than non-piscivorous birds (Sinclair *et al*., 2006). Preliminary data on temporal trends show an increase in bird PFOS concentrations, in two Canadian Arctic species (thick-billed murres and northern fulmars) from 1993 to 2004 (Butt *et al*., 2005). It is noted that concentrations of PFOS in plasma have been reported in eagle, gulls and cormorants around the Great Lakes and in the Norwegian Arctic ranging from <1 ng/g to 2220 ng/g .

Kannan and Giesy (2002b) have summarised results of analyses on archived tissue samples. The tissues analysed came from marine mammals, birds, fish, reptiles and amphibians from around the world, including the Arctic and Antarctic Oceans. Samples collected in the 1990s were used. Around 1700 samples were analysed, with concentrations in liver, egg yolk, muscle or blood plasma determined. The detection limit varied from 1 ng/g to 35 ng/g wet weight. A summary of the results is shown in Table 6.

Table 6. Maximum concentrations of PFOS in various species as well as frequency of detection. Based on Kannan and Giesy (2002a)

Species	Maximum concentration ng/g wwt	Frequency of detection
Marine mammals	1520	77%
Mink and otter	4900	100%
Birds	2570	60%
Fish	1000	38%

PFOS was detectable in most of the samples, including those from remote marine locations, at concentrations >1 ng/g. The authors compared the results from remote areas with those from more industrial locations and noted that PFOS is widely distributed in remote regions, including the Polar Regions, but that the levels found in more urban and industrial areas (e.g. the Baltic, Great Lakes) are several times higher. The tissues of fish-eating birds in Canada, Italy, Japan and Korea all contained detectable levels of PFOS, suggesting that they are exposed through the fish they consume. A summary of several studies is given in Table 7.

Table 7. Monitored levels of PFOS in animals (data from selected studies, based on OECD, 2002)

Description	Reference	Reported Highest Concentrations (Max, Mean)	Location
Global monitoring survey of marine mammals (Florida, California, Alaska, northern Baltic Sea, Mediterranean Sea, Arctic, Sable Island (Canada)	A	Bottlenose dolphin (liver, n = 26): Max: 1520 ng/g wet wt. Mean: 420 ng/g wet wt.	Florida
		Ringed seal (liver, n = 81): Max: 1100 ng/g wet wt. Mean: 240 ng/g wet wt.	Northern Baltic Sea
Survey of mammals, birds and fish in the Canadian Arctic	B	Polar bear (liver, n = 7): Max: > 4000 ng/g wet wt. Mean: 3100 ng/g wet wt.	Canadian Arctic

Description	Reference	Reported Highest Concentrations (Max, Mean)	Location
		Arctic fox (liver, n = 10): Max: 1400 ng/g wet wt. Mean: 250 ng/g wet wt.	
Survey of fish (US, Europe, North Pacific Ocean, Antarctic)	C	Fish (muscle, n = 172): Max: 923 ng/g wet wt. Mean. 40 ng/g wet wt.	Belgian estuary
		Carp (muscle, n = 10): Max: 296 ng/g wet wt. Mean: 120 ng/g wet wt.	US Great Lakes
Survey of fish-eating birds (US, Baltic Sea, Mediterranean Sea, Japanese coast, Korean coast)	D	Bald eagle (plasma, n = 42): Max: 2570 ng/mL Mean: 520 ng/mL	Midwest US
Survey of mink and river otter in the US	E	Mink (liver, n = 77): Max: 4870 ng/g wet wt. Mean: 1220 ng/g wet wt.	US
		River otter (liver, n = 5): Max: 994 ng/g wet wt. Mean: 330 ng/g wet wt.	US
Survey of oysters in the US (Chesapeake Bay & Gulf of Mexico)	F	Oyster (Whole body, n =77) Max: 100 ng/g wet wt. Mean: 60 ng/g wet wt.	US
Fish samples upstream and downstream of 3M facility in Decatur, Alabama, US	G	Fish (whole body): Mean (upstream): 59.1 µg/kg wet wt. Mean (downstream): 1,332 µg/kg wet wt.	Decatur, US

Sources: A: 3M (2003a), B: Martin *et al.* (2004a); C: Giesy and Kannan (2001c) in 3M (2003a); D: Giesy and Kannan (2001b) in 3M (2003); E: Giesy and Kannan (2001d) in 3M (2003a); F: Giesy and Kannan (2001e) in 3M (2003); G: Giesy and Newsted (2001) in OECD (2002); H: Holmström *et al.* (2003).

Concentrations of PFOS in guillemot (*Uria aalge*) eggs from Stora Karlsö in the Baltic Sea have been measured retrospectively from 1968 to 2003 (Holmström et al, 2005). The results shown in Figure 2 display a trend of increasing concentrations since 1968 (17 – 623 ng/g).

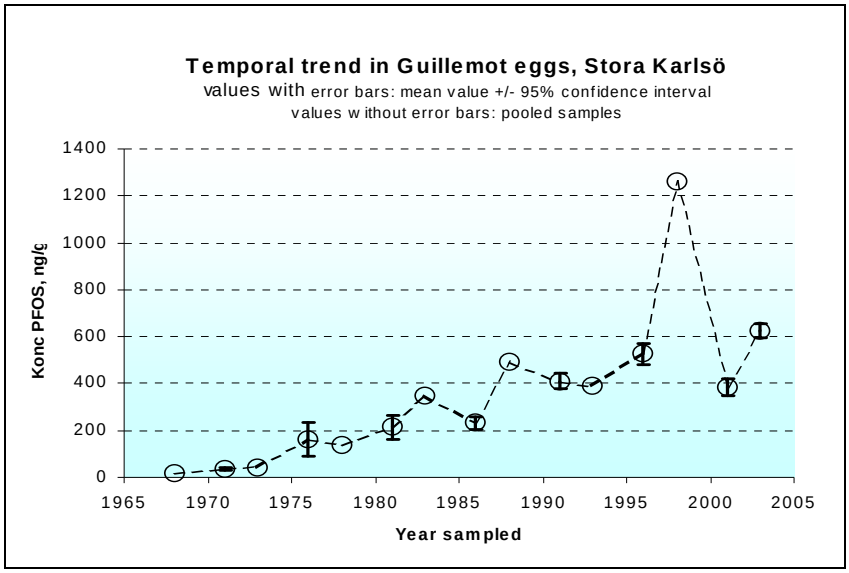

Figure 2. Measured concentrations of PFOS in Guillemot (*Uria aalge*) eggs sampled at Stora Karlsö in the Baltic Sea between the years 1968 – 2003. The graph is taken from the report "Screening av perfluorerade ämnen" by the Swedish EPA, Environmental Assessment Department (2004).

2.3.2 Bioavailability

Studies on fish have shown that PFOS has bioconcentration properties. In studies on bluegill sunfish (*Lepomis macrochirus*) and rainbow trout (*Oncorhynchus mykiss*), bioconcentration factors (BCFs) have been estimated to be 2796 (whole fish) as well as 2900 (liver) and 3100 (plasma), respectively. The major route of uptake is believed to be through the gills (Martin *et al.*, 2003).

Since PFOS is released from sewage treatment plants to the environment i.e. through water, one major route for PFOS into local food chains could be through fish. PFOS has shown a high oral uptake (95%) within 24 hours in the gastro-intestinal (GI) tract in studies on rats (OECD, 2002). Taken together, this could constitute the basis of the highly elevated levels that have been observed in top predators in food chains containing fish.

This could also be corroborated by two separate human monitoring studies on the Swedish population where the levels of PFOS in whole blood was higher (27.2 ng/g, 3.0 – 67, n = 10) in females with a high consumption of fish (Berglund, 2004) compared to samples from females in the general population (17.8 (ng/g, 4.6 – 33, n = 26) (Kärrman *et al.,* 2004).

In humans, the highest concentrations of PFOS have been detected in workers at 3M's manufacturing plant for perfluorochemicals in Decatur, US, where the levels in serum in the last year of measurement (2000) ranged between 0.06 – 10.06 ug/g (n = 263, OECD, 2002).

In a study of the general population, blood samples from families including three generations living in 12 European countries were tested for a large number of chemicals including PFOS and PFOSA. PFOS was present in 37 of 38 samples with concentrations from 0.36 to 35.3 ng/g blood, while PFOSA was present in 36 of 38 samples with concentrations from 0.15 to 2.04 ng/g blood (WWF, 2005).

Pooled serum samples from 3802 Australian residents, collected 2002-2003 and divided in relation to age, gender and region, were analysed for perfluoroalkylsulfonates, perfluoroalkylcarboxylates and PFOSA (Kärrman et al., 2006). PFOS and PFOSA were quantified in all pooled serum samples with a total range of 12.7-29.5 ng/ml (mean 17.2 ng/ml) and 0.36-2.4 ng/ml (mean 0.81 ng/ml), respectively. For PFOS, a significant correlation between age and concentration was shown. No substantial difference was found in levels of perfluorinated compounds between the urban and rural regions. According to gender some differences were shown for some of the age groups.

2.4 Hazard assessment for endpoints of concern

2.4.1 Mammalian Toxicity

Evidence of the mammalian toxicity of PFOS is available from acute, sub-chronic and chronic exposures to rats, sub-chronic exposures to monkeys, and a two-generation study on rats. Results are available from reproductive and teratogenicity studies on rats and rabbits. Details of these studies are not included here, they can be found in the assessment made by OECD (2002). The most relevant data for this risk profile are:

- A 90-day study on rhesus monkeys exposed to PFOS potassium salt via gavage at the doses 0, 0.5, 1.5 and 4.5 mg/kg bw/day. At 4.5 mg/kg bw/day all monkeys (4) died or were sacrificed in moribound condition. No deaths were observed at 0.5 or 1.5 mg/kg bw/day, but there were signs of gastrointestinal toxicity. A NOAEL could not be established since the lowest dose was a LOAEL (Goldenthal et al., 1978a).
- A 90-day oral repeated dose toxicity study in rats that were fed diets containing 0, 30, 100, 300, 1000 and 3000 mg PFOS potassium salt per kg diet. All rats died when fed diets containing 300 mg/kg PFOS and above (equivalent to 18 mg/kg bw/day and above). At 100 mg/kg (6 mg/kg bw/day), 50% (5/10) of the animals died. All rats receiving diets containing 30 mg/kg PFOS (2.0 mg/kg/day) survived until the end of the study, but small changes in body and organ weights were reported. Since the lowest dose tested was a LOAEL, a NOAEL could not be established (Goldenthal et al., 1978b).
- A two-generation reproductive toxicity study on rats that were fed PFOS potassium salt via gavage at the doses 0.1, 0.4, 1.6, and 3.2 mg/kg bw/day. At the doses 1.6 and 3.2 mg/kg bw/day a significant reduction in the viability of the F1 generation was observed. In the 1.6 mg/kg bw/day group, 34% (86/254) of the F1 pups died within four days after birth. In the 3.2 mg/kg bw/day group, 45% (71/156), of the F1 pups died within one day after delivery. None of these pups survived beyond day 4. Maternal toxicity at 1.6 and 3.2 mg/kg bw/day was manifested as reduced

food consumption, body weight gain, and terminal bodyweight. Localised alopecia was also observed at 3.2 mg/kg bw/day. The LOAEL in this study was 0.4 mg/kg bw/day based on significant reductions in pup weight gain in the F1 generation animals. The NOAEL was 0.1 mg/kg bw/day (Christian et al., 1999). A new study by Luebker *et al.* (2005) supports these results.

- Cynomolgus monkeys administered PFOS for 26 weeks were observed to have thymic atrophy (females), and reduced high density lipoprotein, cholesterol, triiodothyronine, total bilirubin levels (males) (Covance Laboratories, Inc. 2002a). The LOEL dose was 0.03 $mg.kg^{-1}$ bw/day at which average mean female and male concentrations in sera and liver were 19.8 $\mu g.mL^{-1}$ and 14.5 $\mu g.g^{-1}$, respectively.
- A 2-year dietary rat study in which histopathological effects in the liver were seen in males and females at intakes as low as 0.06–0.23 mg PFOS/kg bw per day and 0.07–0.21 mg PFOS/kg bw per day, respectively (Covance Laboratories, Inc. 2002b). Average values were determined for males and females to establish LOELs of 40.8 ug/g in liver and 13.9 mg/L in serum.

A study by Grasty *et al.* (2003) concluded that exposure of pregnant rats to PFOS late in gestation, at 25 mg/kg b.w. PFOS by oral gavage on gestation day (GD) 17-20 or 50 mg/kg PFOS on GD 19-20, is sufficient to induce 100% pup mortality and that the causative factor may be inhibition of lung maturation. However, in a subsequent study by Grasty *et al.* (2005), the mechanism behind pup mortality could not be established.

2.4.2 Ecotoxicity

Environmental toxicity data for PFOS is predominantly found for aquatic organisms such as fish, invertebrates and algae, and for birds.

PFOS has shown moderate acute toxicity to fish. The lowest observed LC_{50} (96h) was estimated to be 4.7 mg/l in a study where fathead minnow (*Pimephales promelas*) were exposed to the lithium salt of PFOS. The lowest NOEC, 0.3 mg/l, has been observed in *Pimephales promelas* at prolonged exposure (42d) and was based on mortality (OECD, 2002). The lowest LC_{50} (96h) for aquatic invertebrates has been observed in the mysid shrimp (*Mysidopsis bahia)* and was estimated to be 3.6 mg/l. The lowest NOEC value has been observed in *Mysidopsis bahia* at 0.25 mg/l (OECD, 2002).

A study by Macdonald *et al*. (2004) reported a 10-day NOEC of 0.0491 mg/L for the growth and survival of the aquatic midge (Chironomous *tentans*). The authors concluded that PFOS is 2-3 orders of magnitude more toxic to chironomids than to other aquatic organisms possibly through some kind of interaction with haemoglobin, which is present at all levels of dissolved oxygen (DO) in chironomids as opposed to daphnids, where haemoglobin is produced only in response to declining DO levels.

The most sensitive algae appear to be the green algae *Pseudokirchnerilla subcapitata* with a IC_{50} (96h, cell density) of 48.2 mg/L. The lowest NOEC value for algae was determined in the same study for *Pseudokirchnerilla subcapitata*, 5.3 mg/L (Boudreau *et al.,* 2003).

Mallard and bobwhite quail were exposed to PFOS in feed for up to 21 weeks and a variety of endpoints examined including changes in adult body and organ weights, feed consumption rate, fertility, hatchability, and offspring survival. At a dose of 10 mg/kg diet PFOS, effects in male mallards (*Anas platyrhyncos)* included reduced testes size and decreased spermatogenesis (3M, 2003b). At this dose, the concentrations of PFOS in serum and liver were 87.3 ug/mL and 60.9 ug/g, respectively (3M, 2004). For quail (*Colinus virginianus*), at 10 mg/kg in diet, minor effects were observed in adults, including an increase in liver weight (females), an increase in the incidence of small testes size (males), and reduction in survivability in quail chicks as a percentage

of eggs set. Concentrations in serum and liver of adult quail females was 84 $\mu g.mL^{-1}$ serum (week 5, pre-reproductive phase), and 8.7 $\mu g.mL^{-1}$ serum (week 21) and 4.9 $\mu g.kg^{-1}$ wet weight liver; in adult quail males, concentrations were 141 $\mu g.mL^{-1}$ serum and 88.5 $\mu g.g^{-1}$ wet weight liver (3M, 2003c).

3 SYNTHESIS OF THE INFORMATION

Perfluorooctane sulfonate (PFOS) is a fully fluorinated anion, which is commonly used as a salt in some applications or incorporated into larger polymers. Due to its surface-active properties, it has historically been used in a wide variety of applications, typically including fire fighting foams and surface resistance/repellency to oil, water, grease or soil. PFOS can be formed by degradation from a large group of related substances, referred to as PFOS-related substances (see definition on page 4).

Due to their intrinsic properties, PFOS and its related substances have been used in a wide variety of applications. While historically, PFOS and PFOS-related substances have been used in eight different sectors as shown in Section 2.1.2. above, the present use in industrialized countries seems to be limited to five sectors, see 2.1.2. It is not known whether this also reflects the global use.

PFOS and PFOS-related substances can be released to the environment at their manufacture, during their use in industrial and consumer applications and from disposal of the chemicals or of products or articles containing them after their use.

The rate and the extent of the formation of PFOS from its related chemicals are largely unknown. Lack of data makes it very difficult to estimate the net contribution of the transformation of each of the PFOS-related substances to the environmental loadings of PFOS. However, based on its extreme stability, it is expected that PFOS is likely to be the final degradation product of all PFOS-related substances.

PFOS is extremely persistent. It has not shown any degradation in tests of hydrolysis, photolysis or biodegradation in any environmental condition tested. The only known condition whereby PFOS is degraded is through high temperature incineration.

With regard to bioaccumulation potential, PFOS meets the Annex D criteria given the highly elevated concentrations that have been found in top predators such as the polar bear, seal, bald eagle and mink. Based on the concentrations found in their prey, high BMFs have been estimated for these predators. BCF values in fish, although (rather) high do not in themselves meet the specific numeric criteria. However, due to the properties of PFOS, which binds preferentially to proteins in non-lipid tissues, application of numeric criteria for BCF or BAF, which are derived based on consideration of lipid-partitioning substances, may be inappropriate for PFOS. Most notable and alarming are the high concentrations of PFOS that have been found in Arctic animals, far from anthropogenic sources. PFOS has been detected in higher trophic level biota and predators such as fish, piscivorous birds, mink, and Arctic biota. Also, predator species, such as eagles, have been shown to accumulate higher PFOS concentrations than birds from lower trophic levels. Even with reductions in manufacturing of PFOS by some manufacturers, wildlife, such as birds, can continue to be exposed to persistent and bioaccumulative substances such as PFOS simply by virtue of its persistence and long-term accumulation.

According to available data, PFOS meets the criteria for the potential for long-range transport. This is evident through monitoring data showing highly elevated levels of PFOS in various parts of the northern hemisphere. It is especially evident in the Arctic biota, far from anthropogenic sources. PFOS also fulfils the specific criteria for atmospheric half-life.

PFOS fulfils the criteria for adverse effects. It has demonstrated toxicity towards mammals in sub-chronic repeated dose studies at low concentrations, as well as rat reproductive toxicity with mortality of pups occurring shortly after birth. PFOS is toxic to aquatic organisms with mysid shrimp and *Chironomus tentans* being the most sensitive organisms.

Table 8. POP characteristics of PFOS (studies performed with the potassium salt of PFOS, unless otherwise noted).

Criterion	Meets the criterion (Yes/No)	Remark
Persistence	Yes	Extremely persistent. No degradation recorded in chemical or biological tests
Bioaccumulation	Yes	Found in highly elevated concentrations in top predators. Calculated hypothetical BMFs = 22 - 160. BCF in fish = 2796 - 3100.
Potential for Long-Range Environmental Transport	Yes	Atmospheric half life > 2 days (estimated value based on photolytic half life > 3.7 years)
Toxicity	Yes	Sub-chronic exposure: Mortality in monkeys at 4.5 mg/kg bw/day. Reproductive toxicity: mortality in rat pups at 1.6 mg/kg bw/day. Acute toxicity to Mysid shrimp (*Mysidopsis bahia)*: LC_{50} (96h) = 3.6 mg/L Acute toxicity to fish, Fathead minnow (*Pimephales promelas*): LC_{50} = 4.7 mg/L[1]

[1]The study compound was the lithium salt of PFOS

A risk quotient analysis, where known or potential exposures are integrated with known or potential adverse environmental effects, have been performed on PFOS for the wildlife in Canada (Environment Canada, 2006). The results indicate that the higher trophic level mammals may be at risk at current environmental concentrations of PFOS.

In the risk quotient analyses for polar bear, the highest concentration was found in South Hudson Bay with a maximum concentration of 3.77 $\mu g.g^{-1}$ ww liver (range 2.00-3.77 $\mu g.g^{-1}$, mean 2.73 $\mu g.g^{-1}$ ww liver, Smithwick *et al*. 2005). In comparing this value of 3.77 $\mu g.g^{-1}$ ww liver of PFOS in polar bear with a critical toxicity value of 40.8 $\mu g.g^{-1}$ ww liver for histopathological effects in liver

of rats (a 2-year study, Covance Laboratories, Inc. 2002), the difference is only about a factor 10. Using an application factor of 100[2], as was used in the Canadian Ecological Screening Assessment Report, a risk quotient of 9.2 was calculated, where values above one indicate risk. Risk quotients were also calculated on toxicological endpoints from other studies in rats and monkeys but with the same maximum exposure concentration from the south Hudson Bay polar bear, showing risk quotients from 2.1 to 19.

Concentrations in Canadian Arctic polar bear are among the highest in polar bears worldwide but the exposure concentrations are not considered an anomaly given similar concentrations in polar bears in other North America and European Arctic locations and high concentrations in other wildlife globally as shown above.

Risk quotients were also calculated for a number of bird species that are native to Canada, including many piscivorous birds and migratory species. The range of risk quotients is either above or approaching one that indicates potential for harm at concentrations observed in native species, including migratory species (Environment Canada, 2006).

4 CONCLUDING STATEMENT

PFOS is a synthetic substance of anthropogenic origin with no known natural occurrence. It can be concluded therefore that the presence of PFOS and its precursors in the environment are the result of anthropogenic activities and that PFOS found in remote areas far from possible sources has been brought there through long-range environmental transport. While PFOS related substances may be degraded to PFOS, PFOS itself is extremely persistent in all media and can bioaccumulate and biomagnify in mammals and piscivorous birds.

The voluntary phase out of PFOS production by the major producer in the USA has led to a reduction in the current use of PFOS-related substances. However, it can be assumed that it is still produced in some countries and it continues to be used in many countries. Given the inherent properties of PFOS,[3] together with demonstrated or potential environmental concentrations that may exceed the effect levels for certain higher trophic level biota such as piscivorous birds and mammals; and given the widespread occurrence of PFOS in biota, including in remote areas; and given that PFOS precursors may contribute to the overall presence of PFOS in the environment, it is concluded that PFOS is likely, as a result of its long-range environmental transport, to lead to significant adverse human health and environmental effects, such that global action is warranted.

[2] An application factor of 100 applied for extrapolation from laboratory to field conditions and for intraspecies and interspecies variations in sensitivity, and extrapolation from the observed effects level to a no-effect level.

[3] A decision on the inclusion of PFOS precursors has been postponed until the Committee has evaluated the information requested under Annex F.

The information contained in this statement is based on the Veolia group's understanding and know-how of the scientific, regulatory and technical fields discussed herein as of the time of publication. No contractual undertaking or offer is made on the basis hereof and no representation or warranty is given as to the accuracy, completeness or suitability for the purpose of the relevant information. Descriptions contained herein apply exclusively to those examples and/or to the general situations specifically referenced, and in no event should they be considered to apply to specific scenarios without prior review and validation. Statements that may be interpreted as predictive of future outcomes or performance should not be considered guarantees of such, but rather reasoned assessments of the possible evolution of the technologies described.

No contractual undertaking or offer is made on the basis of this statement, any contractual commitment or relationship being subject to the conclusion of separately documented written agreement(s) between Veolia and its co-contractant(s).

Contributors

Ivan Labaye is Senior Director, Technical and Performance for Veolia's Environmental Solutions and Services Business. He has 24 years of experience with Veolia across five different countries and three continents. Ivan holds a master's degree in chemical engineering from the Conservatoire National des Arts et Métiers in Paris, France. He has conducted extensive research as well as laboratory and pilot scale work on the topics of PFAS incineration and water membrane technology.

Flore Martin is a Senior Technical Manager for Veolia's Environmental Solutions and Services Business. She holds a master of science degree in engineering from Ecole Polytechnique in France with a major in energy and environment.

Tom Baker is the Senior Vice President of Environment, Health, Safety and Government Affairs for Veolia's Environmental Solutions and Services Business. He has over 37 years experience in managing regulatory, compliance and safety programs for Veolia's waste treatment and services business. He holds a bachelor of science degree in chemistry from the University of Delaware.

Yoon Chae is the Senior Vice President of Operations responsible for the Thermal and Landfill business for Veolia's Environmental Solutions and Services Business. He has over 40 years of experience in chemical, power plant, and waste treatment operations, including 35 years with Veolia spanning the hazardous waste, energy and technical organizations. Yoon holds a bachelor's of science degree in chemical engineering from the University of Florida.

Reviewers

Philip Taylor, PhD is the President of P Taylor and Associates. He served as Assistant Vice President for Research at the University of Cincinnati, a Distinguished Research Scientist at the University of Dayton, and a National Research Council Postdoctoral Fellow at the National Bureau of Standards. With over 30 years of experience in incineration of hazardous materials, he has contributed to over 250 publications and conference proceedings and served as an environmental consultant for the U.S. EPA, the National Science Foundation, the US Department of Energy, and the U.S. Air Force. He holds a PhD in Fuel Science from Penn State University. He received the EPA STAR Award for the development of the Incinerability Index for Hazardous Organic Wastes.

Executive Summary

PFAS incineration tests were performed in two campaigns in July and October 2024 at the Veolia Port Arthur, Texas facility to demonstrate that the facility can effectively destroy PFAS-contaminated waste with minimal release of PFAS into the environment.

The campaigns were performed at the Veolia RCRA incinerator in Port Arthur, Texas in collaboration with the stack testing company, AECOM. Eurofins laboratory was used for analysis of all solid and liquid samples and for stack gas samples obtained using EPA methods OTM-45 and OTM-50.

Four different streams were incinerated: A3F, PFAS-contaminated soil, spent activated carbon and CF4. The results of the testing were:

- Stack testing during PFAS incineration showed that PFAS were either non detect or emitted at very low levels (< 2 10^-5 lb/hr) in normal conditions. For PFAS with high feed concentration, thermal treatment can remove or destroy up to 99.9999% of PFAS.
- CF4 incineration indicated a DRE of less than 50%, consistent with predictions that temperatures above 2,550 °F are necessary to destroy this compound.
- Products of incomplete combustion (PIC) listed in OTM-50 were either non-detect at stack, or close to Method Detection Limit (MDL). Tetrafluoromethane (three detections) was the only PIC measured at or above the Level of Quantification (LoQ) in these samples.
- For a majority of solid residues, no PFAS were detected. Only 7 solid samples out of 69 showed PFAS levels close to the MDL
- Liquid residues contained PFAS at ppt level due to background PFAS present in the process water, unrelated to PFAS incineration. This level remains very low and did not increase during PFAS incineration.
- HF measurement at the stack was within regulatory limits.

The results demonstrated high destruction and removal efficiency for PFAS compounds during the incineration process, with values up to 99.9999%. These findings suggest that hazardous waste incineration, when properly operated under high-temperature conditions, can effectively break down PFAS compounds. Notably, very few PICs were detected in any of the output streams, suggesting a complete mineralization of the PFAS compounds rather than partial decomposition. The consistent achievement of high DRE values across multiple test runs, coupled with the absence of PICs, provides strong confidence in the reliability of the thermal treatment process for PFAS destruction.

Analysis of solid residues and liquid residues showed relatively low to no detectable concentrations of PFAS compounds, further supporting the effectiveness of the thermal treatment process. The minimal presence of PFAS compounds in these residual streams indicates successful destruction rather than mere phase transfer of the contaminants.

These results present compelling evidence that high-temperature incineration is an effective solution for PFAS disposal, addressing a critical data gap in PFAS destruction methods as mentioned in the EPA 2024 guidance on the Destruction and Disposal of PFAS and Materials Containing PFAS. The comprehensive study demonstrated efficient PFAS destruction under normal operating conditions. These results conclusively demonstrate that high-temperature incineration at Port Arthur is a viable and environmentally responsible method for PFAS disposal.

The study demonstrates Veolia's commitment to innovation and leadership in addressing emerging environmental challenges. With minimal environmental releases, effective handling of various waste streams, and compliance with regulatory standards, this achievement reinforces Veolia's position as an industry leader committed to providing cutting-edge environmental solutions while ensuring the highest standards of environmental protection and customer service.

Note : There are more than 10,000 different PFAS in nature. Due to analytical limitations, the PFAS campaign conducted at Port Arthur focused on a limited list of 79 targeted PFAS listed in OTM-45, OTM-50 and EPA 1633.

4. Introduction

4.1 Background

In July and October 2024, a groundbreaking full-scale test of PFAS thermal treatment was conducted at Veolia RCRA-permitted hazardous waste combustor facility in Port Arthur, Texas. As one of North America's leading hazardous waste management service providers, Veolia initiated this testing to confront the growing issue of per- and poly-fluorinated alkyl substances (PFAS) in environmental media. The volume of PFAS-containing waste streams continues to surge across industries, presenting an urgent need for effective disposal solutions. As regulatory scrutiny intensifies and remediation efforts expand, stakeholders are increasingly seeking viable treatment options for these persistent compounds.

High-temperature incineration has emerged as a potentially promising disposal pathway, particularly given its demonstrated success in destroying other challenging chemical compounds. While the exceptional stability of PFAS molecules poses unique challenges due to the strength of the multiple carbon-fluorine (C-F) chemical bonds in these compounds, properly engineered thermal treatment systems could offer a practical approach to permanently eliminating these substances from the waste stream. This is especially relevant for concentrated PFAS wastes, such as aqueous film-forming foam (AFFF) stockpiles, where other treatment technologies may prove less effective or economically feasible.

In early 2024, the EPA released its *Guidance on the Destruction and Disposal of PFAS and Materials Containing PFAS,* and in that report acknowledged a lack of data on PFAS fate via incineration. The agency highlighted the need to evaluate destruction efficiency of targeted PFAS, along with the potential creation of products of incomplete combustion (PIC). In January 2024, the EPA released OTM-50, a new method to sample PFAS in air emissions and detect volatile short-chain PFAS that are thermally stable and could potentially form as PICs.

To bridge the knowledge gap regarding PFAS incineration, Veolia developed and implemented a comprehensive full-scale testing program to evaluate the efficiency of PFAS destruction via high temperature incineration. The test program was conducted in collaboration with AECOM to conduct PFAS stack testing, and Eurofins to perform laboratory analysis of the collected samples. Veolia also involved the EPA in the planning process and shared the protocol of its testing program as well as the results of the study.

In a significant demonstration of its technological leadership and innovative capabilities, Veolia implemented the cutting-edge OTM-50 sampling methodology for PFAS stack emissions testing at full-scale. This achievement marks a notable advancement in PFAS analysis, as OTM-50 represents the most recent and sophisticated approach to quantifying short-chain PFAS, or volatile fluorinated compounds (VFC) in air emissions. By mastering this newly developed sampling technique, Veolia has positioned itself at the forefront of environmental testing technology, showcasing its ability to adapt and implement emerging methodologies.

The test was performed at Veolia RCRA incinerator Port Arthur, TX, one of the three RCRA incineration facilities that Veolia owns and operates in the U.S.A. The two others are Gum Spring, AR, and Sauget, IL. Worldwide, Veolia owns or operates 51 hazardous waste incineration plants in 18 different countries. Prior to the US campaign, Veolia has already performed PFAS testing campaigns in other parts of the world: the company's European operations, in particular, has showcased state-of-the-art technology for PFAS treatment since 2022.

Note : There are more than 10,000 different PFAS in nature. Due to analytical limitations, the PFAS campaign conducted at Port Arthur focused on a limited list of 79 targeted PFAS listed in OTM-45,

OTM-50 and EPA 1633.

Therefore, all the findings and conclusions below are limited to this list of PFAS. When it is said that no PFAS was detected in a waste or at stack, or that a sample is PFAS-free, this means that none of the targeted PFAS were detected. It is possible that other PFAS were present in the waste/sample but could not be detected with today's analytical technique.

4.2 Test objectives

The data quality objective of the Veolia test program was to demonstrate the ability of the Port Arthur RCRA incinerator to destroy PFAS in the waste feed without releasing PICs in air emissions, or PFAS in the solid and liquid residues during normal process operating conditions. To demonstrate this, Veolia incinerated four different waste streams contaminated with PFAS in various concentrations.

The primary objective was to determine if PICs in the form of Volatile Fluorinated Compounds (VFC) are formed during PFAS incineration via OTM-50. OTM-50 is a new sampling method for PFAS released by the EPA in 2024 to detect PICs, that is to say short-chain PFAS or VFCs. PICs may form from PFAS incineration when their destruction is incomplete. OTM-50 sampling was performed at the stack during PFAS incineration. The absence of PICs measured at the stack indicates, within the limit of current analytical detection limits, that the degradation of PFAS is complete. This data supports complete mineralization of PFAS to HF.

The second objective was to establish the destruction and removal efficiency (DRE) for a list of targeted PFAS. DRE is defined by 40 Code of Federal Regulations [CFR] §264.343 as follows:

$$DRE = (1 - Waste\ out/Waste\ in) * 100$$

Where:

- Waste in = mass feed rate of PFAS in the waste stream feeding the incinerator
- Waste out = mass emission rate of the same PFAS present in exhaust emissions prior to release to the atmosphere

DRE is only calculated for medium to long-chain PFAS (C>4) listed in OTM-45 and EPA 1633, i.e. PFAS that can be measured both in the PFAS waste and at the stack.

A related objective was to study the total DRE from OTM-45 sampling. Total DRE is defined as follows:

$$Total\ DRE_{OTM\ 45} = (1 - Sum\ of\ PFAS\ out_{OTM\ 45}/Sum\ of\ PFAS\ in_{1633}) * 100$$

Where:

- $Sum\ of\ PFAS\ out_{OTM\ 45}$ is the sum of PFAS detected at the stack via OTM-45
- $Sum\ of\ PFAS\ in$ is the sum of PFAS detected in the waste via EPA Method 1633 or EPA Method 537

In case of PFAS undetected at the stack or in the waste, the MDL is used in the calculations. In case of PFAS measured below the LoQ, the LoQ is used in the calculations.

The last objective was to calculate the Total Destruction Efficiency based on OTM-50, OTM-45 and PFAS detected in liquid and solid residues.

$$DE = (1 - (PFAS\ in\ liq + PFAS\ in\ solids + PFAS\ in\ air)/PFAS\ in) * 100$$

Where:

- PFAS in = total mass feed rate of PFAS fed into the incinerator
- PFAS in air = total mass emission rate of PFAS present in exhaust emissions and detected via in OTM 45 or OTM 50.
- PFAS in liquids = total mass emission rate PFAS present in liquid residues
- PFAS in solids = mass emission rate PFAS present in solid residues

4.3. Incinerator and Process Description

Veolia Environmental Services Technical Solutions, L.L.C., (Veolia) operates a hazardous waste incinerator at their Port Arthur, Texas location. This incinerator processes hazardous materials in accordance with the Resource Conservation and Recovery Act (RCRA) Permit HW-50212, Air Permit 42450 from the Texas Commission on Environmental Quality (TCEQ), and a Toxic Substances Control Act (TSCA) permit from the United States Environmental Protection Agency (US EPA).

The following sections provide a description of the Veolia Port Arthur incineration system. Two process flow diagrams (PFD) are included in Figures 1 and 2. The PFD are a representation of the combustion and air pollution control systems and include all major process flow streams.

Description of Combustion System

The incinerator at the Port Arthur facility consists of waste receiving and waste feeding equipment, rotary kiln, an ash/slag removal system, a secondary combustion chamber (SCC), a quench tower, two acid gas absorbers, four cooling towers, a four-stage ionizing wet scrubber, a wet electrostatic precipitator, an induced draft fan, an exhaust stack, and a scrubber water treatment/recycle system.

Description of Rotary Kiln

The rotary kiln measures 60 feet in length and the slope of the kiln from inlet to ash discharge is approximately one degree. The nominal rotation speed is one rpm with an average solid residence time of approximately one hour. The shell of the kiln is 16 feet in outside diameter and is lined with refractory material which protects the carbon steel shell from the high temperatures of incineration. The inside diameter of the kiln with the insulation in place is approximately 14 feet. The kiln is normally operated under negative pressure maintained between zero- and one-inch water column vacuum to prevent fugitive emissions from the kiln ends. The kiln temperature is measured with three thermocouples inserted through the roof of the ash dropout chamber, approximately 4 feet past the end of the kiln.

Secondary Combustion Chamber Design

Hot flue gases from the transition section enter the cylindrical secondary combustion chamber (SCC) approximately 14 feet above the base of the tower. The SCC is 78 feet tall and equipped with eight burners evenly arranged around the perimeter of the SCC tower. The combustion gases are raised to the current, minimum temperature of 2,012 °F. The burners, which fire tangentially, are rated at 15 million Btu/hr each. The burners are dual fuel burners and have the capability to fire waste liquid and/or fossil fuel. The burners are equipped with external steam and air atomizers and natural gas fired pilot lights. A compressed gas cylinder feed system is designed to feed waste gases to the secondary combustion chamber. The SCC temperature is measured with three thermocouples inserted through the top of the hot cross-over duct between the SCC and quench, approximately 7.5 feet downstream of the SCC.

Quench Tower

Cooling of the combustion gases occurs in the quench tower. Three rows of water spray nozzles are arranged around the circumference of the tower and spray water directly into the hot combustion gas.

As the gas flows downward, it is cooled to an adiabatic saturation temperature of about 185°F. Water is supplied from the scrubber water recycle loops and from clean process water. A caustic solution is added to the quench water for initial neutralization of acid gases. The ash particulate collected by the water sprays falls to the bottom of the quench tower.

Air Pollution Control System

Removal of particulate matter and acid gases occur in the Air Pollution Control System (APCS). The APCS consists of the following equipment:

- Two parallel Acid Gas Absorbers;
- An Ionizing Wet Scrubber; and
- A Wet Electrostatic Precipitator.

Process Parameter Continuous Monitoring Systems

The incinerator uses process instruments, which include thermocouples, flowmeters, pH meters, and pressure transmitters to document compliance with applicable operating parameters. The process instruments continuously monitor and record operating parameters of the incinerator.

Veolia operates two identical EcoChem MC3 multi-component gas analyzers (one for compliance and one for redundancy). Each individual multi-component instrument analyzes the stack gas for O2, CO, CO2, SO2 and HCl.

Incineration Residues

The liquid residues from incineration are injected into an on-site Class IV underground injection well after treatment. The three solid residues (ashes from the kiln, slag from the quench and SCC, and filter cake from the water treatment) are sent to an off-site Subtitle C landfill.

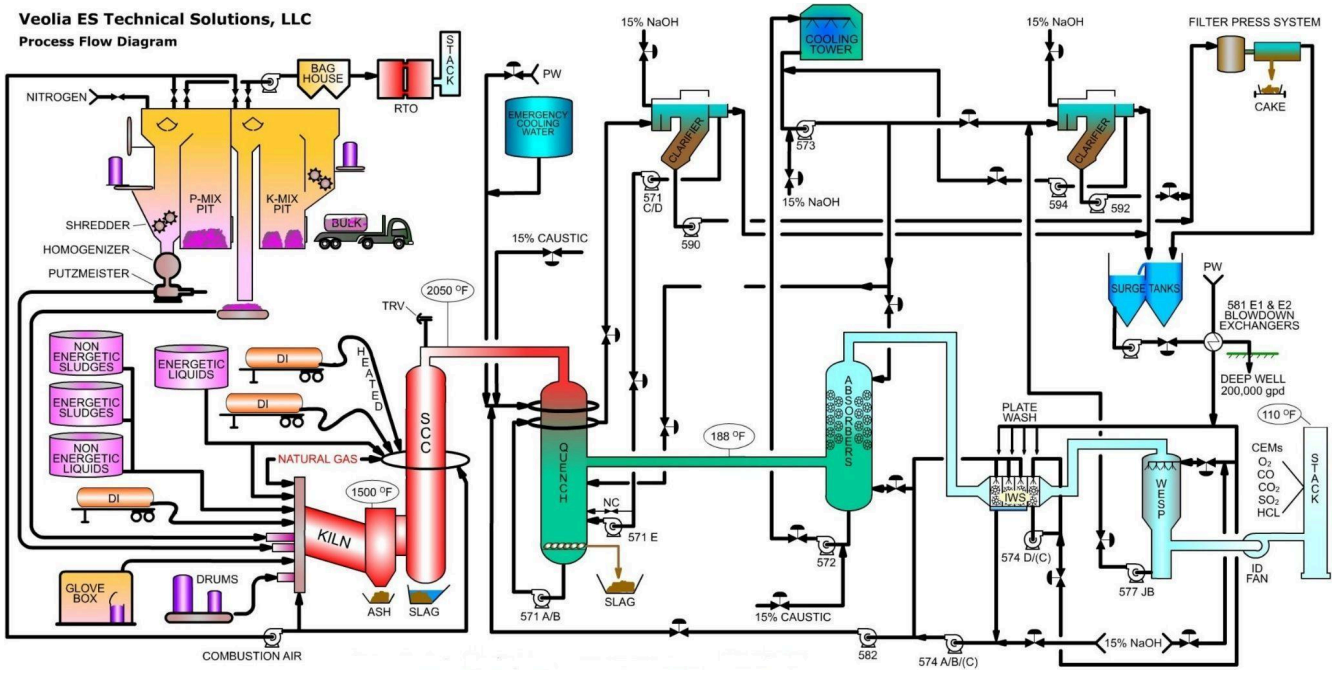

Figure 1 - Process Diagram at Port Arthur

5. Protocol and Sampling

The PFAS testing program at Port Arthur was performed in 2 campaigns :

Campaign	Date	Analysis	PFAS waste
Campaign 1	July 29 to August 5, 2024	Analysis of air emissions, liquid (blowdown) and solids (ashes, slag and filter cake)	AFFF (3 runs) AFFF-contaminated soil (3 runs)
Campaign 2	October 6th to October 24th, 2024	Analysis of air emissions, liquid (blowdown) and solids (ashes, slag and filter cake)	AFFF (2 runs) AFFF with lime injection (1 run) Contaminated soil (3 runs) Spent activated carbon (2 runs) Carbon tetrafluoride CF4 (1 run)

Campaign 1 & 2 were performed in collaboration with AECOM, a reputable stack testing company, who was tasked with performing OTM-45 & OTM-50[1] and HF sampling at stack. Eurofins USA performed the laboratory analysis on all matrix samples at their laboratory facilities in Knoxville, TN and Lancaster, PA.

Campaign 2 was performed in collaboration with the EPA. Veolia shared with EPA the protocol in advance and the results of the test. The testing program followed *EPA Guidance to Conduct PFAS Emissions Field Testing at Commercial Thermal Destruction Sources (Appendix A of the 2024 EPA guidance on PFAS waste disposal).*

Before each new matrix, a baseline run was performed : liquid and solid residues are sampled, OTM-45, 50 and HF sampling is performed at the stack while no PFAS is incinerated in the kiln.

5.1. Sampling Procedure

All residues (liquid, solid and air emissions) were sampled for PFAS during PFAS incineration either during the run or at the end. The average duration of a run was between 3-4 hours. The list of sample points is provided below :

- 1 liquid sample at the end of the water treatment line at the end of each PFAS run and 24 hours afterwards when no PFAS has been incinerated in between.
- 3 solid samples: ashes in the kiln, slag from the SCC and quench, and the filtercake in the water treatment line. Solids are sampled once they have cooled (<24 hours after the run).
- 3 air emission samples at the stack: OTM-45, OTM-50 and HF samples were collected..

Parameter	Stream	Analytical Method	Sampling method
HF	Stack Gas	IC - EPA Method 26A	EPA Method 26A

[1] OTM-45 and OTM-50 are 2 sampling methods for PFAS developed by the EPA. OTM-45 targets 49 semi-volatile PFAS and OTM-50 targets 30 volatile non-polar PFAS.

PFAS	Stack Gas	LC – MS EPA Method 537 (modified)	OTM-45
VFC	Stack Gas	GC/MS - ASTM D5466-21	OTM-50
O_2, CO_2	Stack Gas	Instrument Analyzers	EPA Method 3A
Moisture	Stack Gas	Gravimetric	EPA Method 4
Process water	Tap	LC – MS EPA Method 537 (modified)	S004
Liquid residues	Blowdowns	LC – MS EPA Method 537 (modified)	S004
Solid residues	Ashes, Slag, Filtercake	LC – MS EPA Method 537 (modified)	S007
PFAS	Waste Feeds	LC – MS EPA Method 537 (modified) or EPA Method 1633	

Table 1 - Summary of analytical and sampling methods

5.1.1. Waste Feed Sampling Procedures

Samples of the liquid and solid waste feed streams were collected in glass bottles or plastic containers by Veolia staff and handed to AECOM at the end of the program. Pre-cleaned bottles were purchased and used to collect the samples.

Liquid waste feed samples were collected using the tap sampling procedure specified in U.S. EPA Method S004, *"Sampling and Analysis Methods for Hazardous Waste Combustion."* The sample tap was flushed each time (allowed to flow briefly) before the sample was collected to ensure that any stagnant accumulation of solids, or other contaminants that may be present in the tap, did not affect the sample integrity or its representation of the stream being sampled.

Solid waste feed samples were collected using the scoop sampling procedure specified in U.S. EPA Method S007, *"Sampling and Analysis Methods for Hazardous Waste Combustion."* Samples of the bulk solid wastes (i.e., "regular wastes") fed to the kiln were collected by Veolia personnel for each of the three test runs. In the case where multiple samples of "regular wastes" were collected, the average analysis result for each test run was utilized.

5.1.2. Stack Gas Sampling Procedures

The stack gas emissions were sampled for determination of the parameters indicated in **Table 2**. The sampling methods used are described below.

For all of the stack gas emission parameters measured using sampling trains (i.e., Method OTM-45, OTM-50 and Method 26A) a field blank sample was collected by assembling the sampling train, taking it to the stack sampling location, and then performing a leak check. The field blank was then recovered and analyzed in the same manner as actual samples. The primary purpose of the field blank samples is to evaluate any bias to sample results due to contamination of the sampling system and/or sampling media.

5.1.3. EPA Methods 2 and 4 (Flowrate and Moisture)

Concurrent with the performance of isokinetic sampling trains, measurements were made to determine gas velocity by EPA Method 2, and moisture by EPA Method 4.

5.1.4. EPA Method OTM-45 for PFAS

Samples of exhaust emissions of PFAS compounds were collected according to OTM-45 for determination of PFAS.

A schematic diagram of the sampling train is shown in **Figure 2-1**. According to this method, sample gas was removed isokinetically from the stack and passed through the following components:

- Glass (quartz) nozzle;
- Heated, glass (quartz)-lined probe;
- Heated glass-fiber filter with a glass filter support;
- Coil condenser;
- Sorbent trap containing XAD-2® resin;
- One short-stem Knockout impingers empty;
- Modified Greenburg-Smith impinger containing 100 mL of water;
- Greenburg-Smith impinger containing 100 mL of water;
- Modified Greenburg-Smith impinger containing 100 mL of water;
- Second sorbent trap containing XAD-2® resin; and
- Modified Greenburg-Smith impinger containing silica gel.

After sample collection, the sampling train was recovered to provide the following fractions:

- Solvent (5% ammonium hydroxide) rinse of the nozzle, probe and front half of the filter holder;
- Filter;
- 5% ammonium hydroxide rinse of back half of the filter holder, transfer line, and condenser;
- XAD-2® sorbent trap; and
- Condensate catch from Impingers 1 through 4;
- 5% ammonium hydroxide rinse of Impingers 1 through 4 and connecting glassware; and
- 2nd XAD-2® sorbent trap.

All samples, except the particulate filter were maintained cold and on ice prior to transportation. The particulate filter is stored at 68±5 °F and shipped unrefrigerated. These samples were shipped to the Eurofins Test America laboratory in Knoxville, TN, for analysis as follows:

- PFAS analysis using liquid chromatography coupled with tandem mass spectrometry (LC-MS/MS) multiple reaction monitoring (MRM).

Sampling data sheets are presented in Appendix I (campaign 1) and II (campaign 2).

OTM-45 fractions were sent to Eurofins for analysis. Eurofins analysed separately the 4 fractions shown in Figure 2-1:

- Fraction 1 : #1 Filter and #2 Front Half Rinse
- Fraction 2 : #3 XAD1, #4 Back Half Rinse, #6 Impinger Rinse
- Fraction 3 : #5 Condensate and Impingers Water

- Fraction 4 : #7 Breakthrough XAD2

5.1.5. EPA Method OTM-50 for PICs in the form of Volatile Fluorinated Compounds (VFC)

Samples of exhaust emissions of PICs in the form of VFCs were collected according to OTM-50 for determination of volatile fluorinated compounds

A schematic diagram of the sampling train is shown in **Figure 2-2.** In this method, a gas sample is extracted from the gas stream and collected in an evacuated canister. Sample conditioning was necessary for sources with moisture content exceeding 3% volume/volume (v/v) or for sample gas temperatures above 250 °F. For Veolia sampling, sample conditioning is included due to the high moisture content in the gas stream. The stack sample passes through the following components:

- Heated, glass (quartz)-lined probe;
- Heated glass-fiber filter with a glass filter support;
- Perfluoroalkoxy (PFA) heated transfer line;
- One short-stem Knockout impingers empty;
- Mini impinger with open stem containing 15 mL of water;
- Mini impinger with tapered stem containing 15 mL of water;
- Mini impinger with tapered stem containing 15 mL of water;
- Mini impinger with open stem, empty; and
- Stainless steel canister.

After sample collection, the sampling train was recovered to provide the following fractions:

- Stainless steel canister.

These samples were transferred to the Eurofins Test America laboratory in Knoxville, TN, for analysis as follows:

- VFC analysis using gas chromatography coupled with mass spectrometry (GC/MS).

Sampling data sheets are presented in Appendix I (campaign 1) and II (campaign 2).

5.1.6. EPA Method 26A (HF)

Samples for the determination of HF in stack emissions were collected using a single sampling train meeting the requirements of EPA Method 26A. A schematic diagram of the sampling train is shown in **Figure 2-3**. This sample train consists of the following components:

- Glass (quartz) nozzle;
- Heated, glass (quartz)-lined probe;
- Heated Teflon mat filter with a Teflon filter support;
- Greenburg-Smith impinger containing 100 mL of 0.1 N H2SO4;
- Greenburg-Smith impinger containing 100 mL of 0.1 N H2SO4;
- Modified Greenburg-Smith impinger containing 100 mL of 0.1 N NaOH;
- Modified Greenburg-Smith impinger containing 100 mL of 0.1 N NaOH;
- Optional empty knockout impinger, modified Greenburg-Smith; and
- Modified Greenburg-Smith impinger containing silica gel.

These procedures require the isokinetic extraction of particulate matter on a filter maintained at a controlled temperature. In accordance with the requirements of EPA Method 26A, the filter and probe were kept at a temperature between 248°F and 273°F, and a Teflon-backed filter was used. A Teflon union was used to connect the quartz nozzle to the quartz probe liner.

Fluoride analysis was performed on the impinger contents using ion chromatography according to Method 26A.

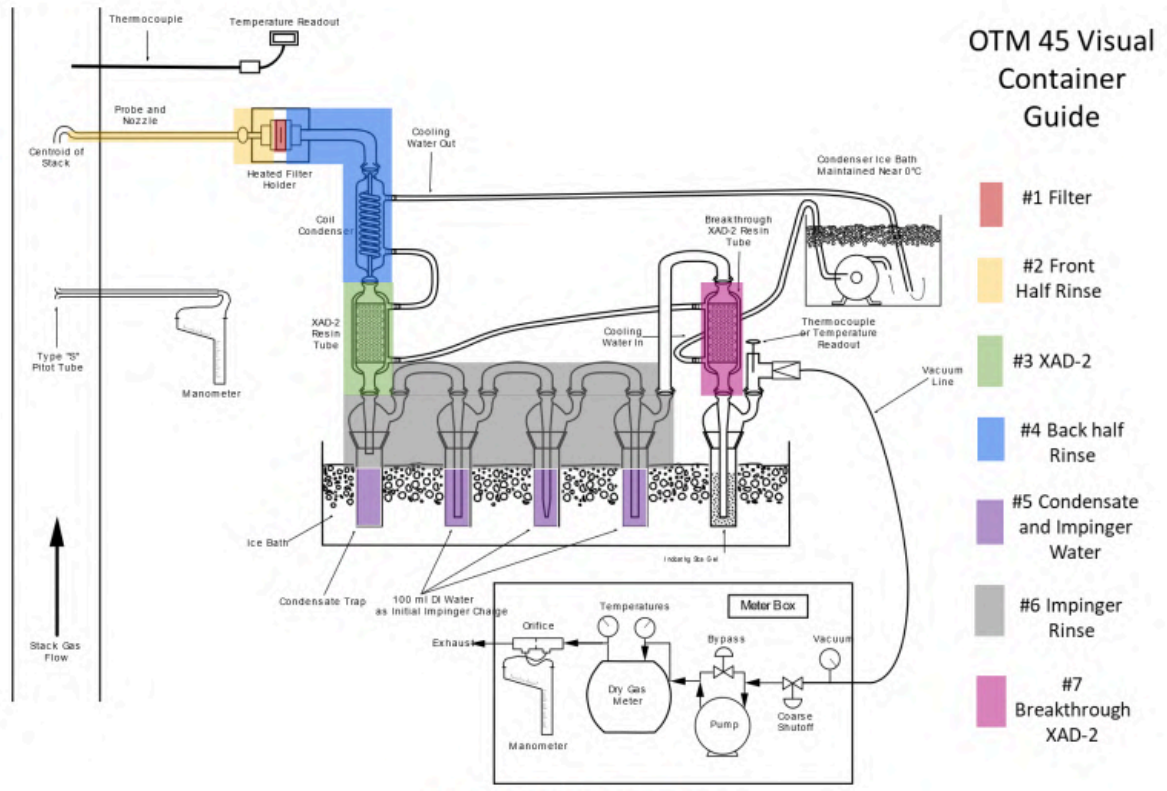

Figure 2-1 - OTM-45 sampling train

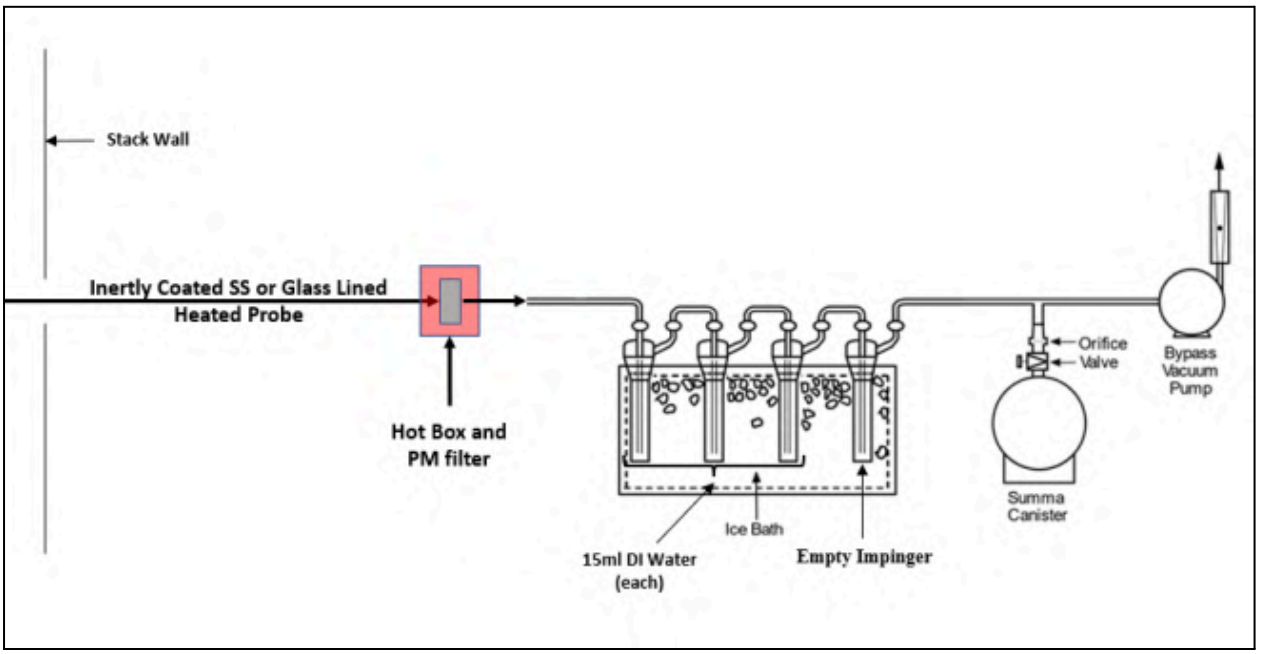

Figure 2-2 - OTM-50 sampling train

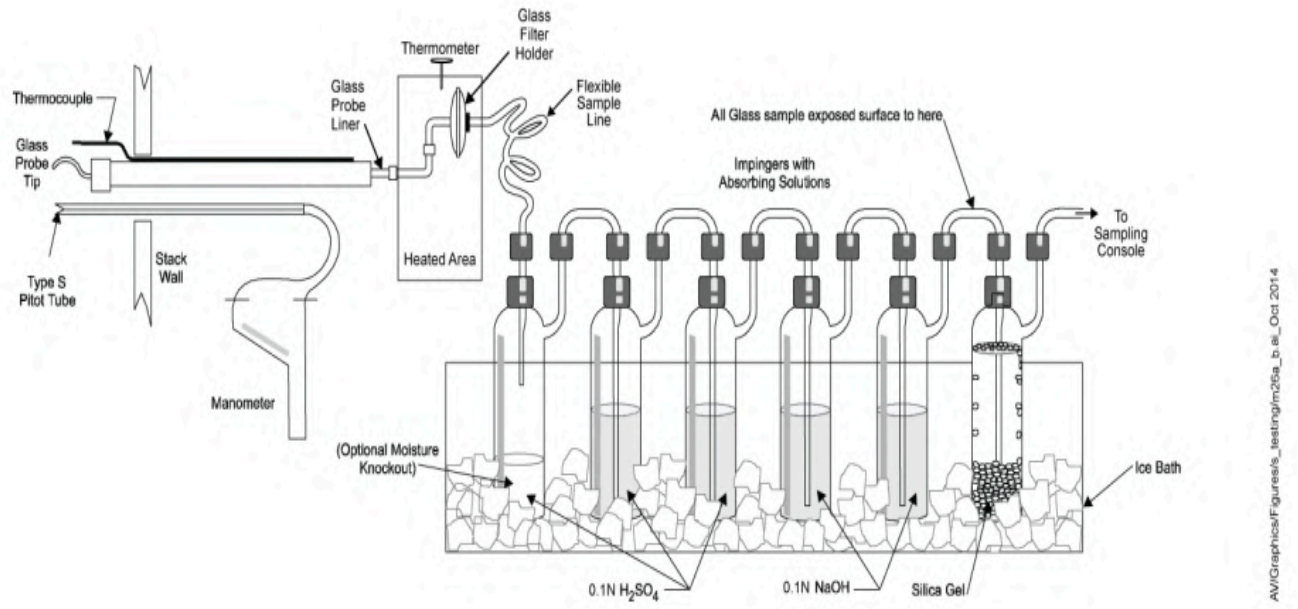

Figure 2-3 – Sampling Train Schematic – EPA Method 2

5.2. Operating conditions

The incinerator was operated under normal conditions in terms of temperature and residence time. In addition to the PFAS waste, regular waste was injected into the kiln, with the exception of waste with F content > 2%. Regular waste includes a wide variety of liquid and solid hazardous waste including waste with high H content like aqueous waste. A high ratio H/F is known to be useful to enhance HF formation and avoid incomplete PFAS destruction.

Tables 2-1 and 2-2 present additional information regarding the conditions evaluated in the final campaign phase. **Table 2-3** summarizes the combustion conditions in the SCC during the test.

Date		Run	Avg Feedrate (lb/hr)	Stack Gas Flow (DSCFM)	Blowdown Flow (GPM)	SCC (Deg F)	Solid residual Generation (lb/hr)
7/31	Morning	**Baseline**	NA			2049 *

6. Quality Assurance/Quality Control

The primary objectives of the QA/QC effort were to control, assess, and document data quality. To accomplish these objectives, the QA/QC approach consisted of the following key elements:

- Definition of data quality objective that reflects the overall technical objectives of the measurement program (see section 4.2);
- Design of a sampling, analytical, QA/QC and data analysis system to meet those objectives;
- Evaluation of the performance of the measurement system; and
- Initiation of corrective action when measurement system performance does not meet the specifications

These QA procedures include sampling and analytical procedures, along with specified calibration requirements, QC checks, data reduction and validation procedures, and sample tracking. A review of analysis results for QA/QC samples and assessment of overall data quality is presented in this section.

The sections below present discussions of the QA/QC activities associated with sampling and analysis, as well as with data quality assessment.

6.1. Analysis of Waste Feeds for PFAS

Samples of waste feed materials were analyzed for PFAS using SW-846 Method 537 (Modified). These same samples were analyzed for PFAS using Liquid Chromatography/Tass Spectrometry. These samples were prepared for analysis using appropriate extraction or dilution techniques. Quality assurance and quality control activities associated with these analyses included:

- Sample handling and preservation;
- Preparation and analysis of samples within specified holding times;
- Preparation and analysis of laboratory blanks;

- Preparation and analysis of laboratory control samples;
- Preparation and analysis of samples collected in duplicate; and
- Preparation and analysis of matrix spike and matrix spike duplicate samples.

Review of these field-related QA/QC activities indicates that these data are supportable and usable. See the detailed data quality assessment in Appendix III (campaign 1) and IV (campaign 2). Any issues with the sample analysis were identified in the laboratory reports. Media checks were sufficient to qualify the data, and a sufficient number of reagents blanks were collected and analysed to further qualify the data.

6.2. Stack Gas

6.2.1. Isokinetic Sample Collection

The following isokinetic sampling trains were used for the collection of air emission compliance samples:

- Hydrogen fluoride using a sampling train meeting the requirements of EPA Method 26A; and
- PFAS in accordance with OTM-45.

Quality assurance and quality control activities associated with the collection of these samples included:

- Collection of the specified volumes of stack gas over the specified duration;
- Collection of stack gas within 90-110 percent of isokinetic;
- Maintaining the probe, filter, and heated transfer line at the specified temperatures, as applicable;
- Maintaining the impinger exit and the condenser exit at the specified temperature, as applicable;
- Performing sampling train leak checks before sample collection, at port changes, and after sample collection;
- Performing pitot tube leak checks before and after sample collection; and
- Recording all data on pre-printed data sheets.

6.2.2. Non-Isokinetic Sample Collection

The following non-isokinetic sampling trains were used for the collection of air emission compliance samples:

- VFC using EPA Method OTM-50.

Quality assurance and quality control activities associated with the collection of these samples included:

- Collection of the specified volumes of stack gas over the specified duration;
- Maintaining the probe, filter, and heated transfer line at the specified temperatures, as applicable;
- Maintaining the impinger exit and the condenser exit at the specified temperature, as applicable;
- Performing sampling train leak checks before sample collection, at port changes, and after sample collection;
- Performing pitot tube leak checks before and after sample collection; and
- Recording all data on pre-printed data sheets.

6.2.3. Monitoring of Stack Gas for Oxygen and Carbon Dioxide

The stack gas was monitored for oxygen (O_2) and carbon dioxide (CO_2) according to EPA Methods 3A (O_2 and CO_2).

Quality assurance and quality control activities associated with continuous emission monitoring include:

- Use of calibration gas standards of known and acceptable quality;
- Use of calibration gas standards in the specified ranges;
- Performance of calibration error tests;
- Performance of system bias checks;
- Performance of zero and span drift checks; and
- Performance of a NOx analyzer converter efficiency check.

Review of these QA/QC activities indicates that these data are supportable and usable. See the data quality assessment in Appendix III (campaign 1) and IV (campaign 2). Copies of certifications of calibration gas standards; the raw data for continuous emission monitors is presented in Appendix V (campaign1) and VI (campaign 2).

7. Results and discussion

7.1. Campaign 1 : Incineration of A3F and PFAS-contaminated soil

Campaign 1 Summary :

Campaign 1 demonstrated that Port Arthur incinerator can efficiently treat PFAS waste and reach DRE at stack above 99.9999% for the most concentrated PFAS, including PFOS, PFHxS, PFHpS and PFPeS.

OTM-50 results demonstrated that no PICs were detected in any runs of the campaign, showing that PFAS mineralization was complete, within the limit of current analytical detection limits.

Solid residues were PFAS-free, or contained PFAS at levels close to the MDL.

Liquid residues contained PFAS at low levels (ppt), reflecting the background presence of PFAS in the pond water supplying the process water to the incinerator.

7.1.1. Waste analysis

Three different A3F were incinerated in three different runs, with PFAS feed rate in the kiln ranging from 8 g/hr to 188 g/hr. A3F profiles are in **Appendix VI.**

3 runs of contaminated soil were incinerated with a PFAS injection rate of 29 g/hr in the kiln. The solid mix was spiked with A3F to create the contaminated soil. The soil profile is in **Appendix VIII.**

7.1.2. Solid and liquid residues

No PFAS were detected in significant quantities in the solid residues. 2 PFAS (PFOSAm and 6:2 FTS) were detected at the MDL in the ashes and filtercake in 2 samples out of 18. Detailed results are provided in **Appendix IX-A and X-A.**

All blowdowns had the same PFAS concentration and signature. A dozen PFAS were detected at ppt level (Figure 3), that is to say at the order of magnitude of the EPA drinking water standard[2]. Results were similar for samples collected during baseline (at the beginning of the campaign, before PFAS incineration) and in the samples collected after PFAS incineration.

Detecting PFAS at ppt level in the blowdown was unexpected. It was later explained by the background presence of PFAS in the pond water supplying the process water. This pond is supplied by rain water and is likely contaminated by PFAS from various industrial sources as Port Arthur is an industrial area. PFAS contamination in water bodies is not uncommon across the USA.

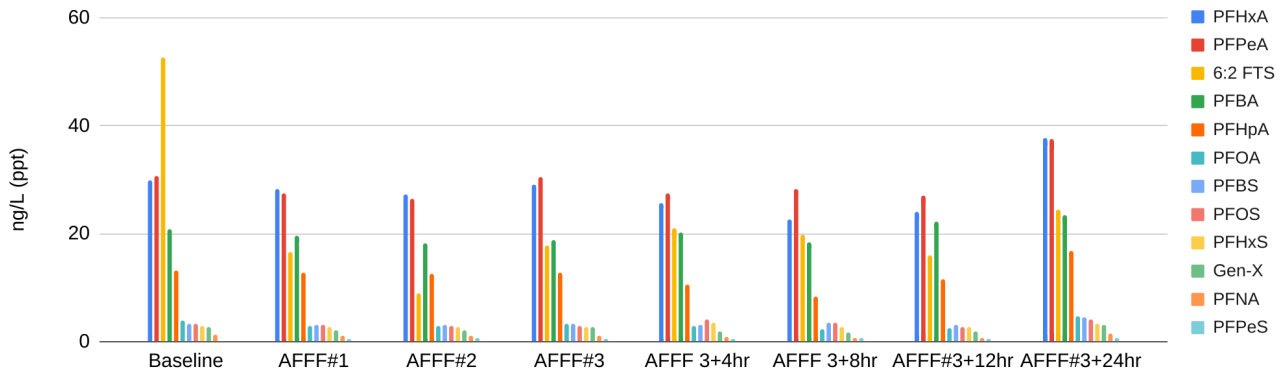

Figure 3 - PFAS detected in blowdowns during A3F incineration

This PFAS presence in liquid residues is due to PFAS background presence in the pond water used in the incinerator : the same signature of PFAS was observed in the process water and in the blowdown sampled during the baseline (without PFAS incineration), with PFAS being twice as concentrated in the blowdowns than in the pond water because of evaporation (Table 3-1). The only difference between the PFAS signature in the process water and blowdown is the presence of 6:2 FTS in the blowdown, detected in every run even during the baseline. During campaign 1, 6:2 FTS was not detected at the stack, so it seems unlikely that 6:2 FTS is a PIC generated during the incineration process. However, 6:2 FTS was detected at the stack in campaign 2. Port Arthur is currently studying the possibility that some equipment inside the incinerator releases PFAS during normal operations. Otherwise 6:2 FTS could be a residual PIC from previous PFAS incineration.

The process water comes from a nearby pond, supplied by rainfall. As many water sources in the USA, this pond is contaminated with PFAS at low level (< 100 ppt). Veolia was not aware that the pond water was contaminated with PFAS before performing the PFAS campaign and sampling process water. Veolia is currently studying PFAS removal technology to treat the pond water prior to injecting process water in the incinerator.

The process water sample was not collected during campaign 1 but 6 weeks after, when the first results of blowdowns were analysed. Therefore, PFAS contamination in process water during campaign 1 may have been slightly different. However, the second sample of process collected in

[2] EPA Maximum Contaminant Level : PFOA & PFOS : 4 ng/L each PFHxS, PFNA, HFPO-DA : ng/L

campaign 2 shows a similar PFAS signature and concentration compared to the one obtained for campaign 1, suggesting that PFAS contamination in the process water does not vary, at least over short time periods.

PFAS	Process water (ng/L)	Blowdown baseline (ng/L)
6:2 FTS	ND	52.6
PFBA	11.20	20.8
PFPeA	16.10	30.8
PFHxA	14.90	29.9
PFHpA	8.41	13.1
PFOA	2.88	3.88
PFNA	1.26	1.33
HFPO-DA	2.02	2.77
PFBS	1.81	3.33
PFHxS	1.49	2.84
PFOS	2.48	3.4

Table 3-1 : PFAS concentration in process water and blowdown baseline (ng/L). *The column "blowdown baseline" is an average of the 2 baselines collected during campaign 1. All PFAS listed in EPA 1633 were tested but only the ones detected are shown in this table.*

Table 3-2 shows the difference in PFAS concentration entering the incinerator via the process water, vs PFAS exiting the incinerator via the liquid residue (blowdowns). In all runs except Soil run#3, there are more PFAS entering via the process water than exiting in the liquid residues. That confirms that PFAS in the process water pass through the stack gases and are emitted at the stack.

	AFFF run 1	AFFF run 2	AFFF run 3	Soil run 1	Soil run 3
PFAS in process water entering the incinerator - PFAS in (lb/hr)	1.10E-05	1.07E-05	1.09E-05	9.67E-05	1.32E-04
PFAS in liquid residue exiting the incinerator - PFAS out (lb/hr)	8.22E-06	7.29E-06	8.44E-06	8.91E-05	2.02E-04
% PFAS out / PFAS in	74.73%	68.13%	77.43%	92.14%	153.03%

Table 3-2 : Comparison of PFAS flowrate in liquid entering and exiting the incinerator. *Soil run 2 is not shown because process water flowrate was not measured.*

Port Arthur is equipped with a wet flue gas treatment. The stack gases are in contact with process water after the incineration process, and it is possible that some PFAS transfer from water to stack gases after thermal treatment.

Detailed results for PFAS concentrations in liquid residues are provided in **Appendix IX-B (AFFF) and X-B (contaminated soil).**

7.1.3. Air Emissions

7.1.3.1. PFAS Mass Emission Rate at Stack (OTM-45)

Table 4-1 and 4-2 present PFAS mass emission rate at the stack during campaign 1 for baselines, AFFF incineration and contaminated-soil incineration.

> Analysis of OTM-45 during baseline :

Analysis of PFAS flowrate at the stack during baseline tests shows that most of the OTM-45 listed PFAS are not detected at the stack.

In the baseline performed before AFFF was fed, 10 PFAS are detected at low level, close to the MDL during the baseline. These PFAS were PCFAs only, and 3 of them are present in the process water (PFPeA, PFHxA, PFOA) which could explain their detection at the stack. Among the 7 other PFAS (PFDA, PFDoA, perfluorohexadecanoic acid, perfluorooctadecanoic acid, PFTeA, PFTriA and PFUnA), perfluorohexadecanoic acid and perfluorooctadecanoic acid could not be measured in the process water due to analytical limitations and may be in the water.

There is no apparent reason to explain the presence of PFDA, PFDoA, PFTriA, PFUnA, PFTeA at the stack while no PFAS were incinerated during the baseline.

Results for the baseline before contaminated soil was fed were similar to the AFFF baseline except for the additional presence of PFHxS at the stack. PFHxS was not detected in the process water. Its measurement at the stack during the soil baseline was very close to the MDL.

> Analysis of OTM-45 mass emission rate during AFFF and contaminated soil incineration

During AFFF incineration, only 13 PFAS out of the 49 listed in OTM 45 were detected above MDL in at least one run. They are in bold in Table 4-1. They are exclusively PFCAs:

- PFBA, PFHpA, PFHxA, PFOA, PFPeA, PFNA, which are present in the process water. Their presence at the stack during AFFF incineration most likely comes from the process water.
- PFDA, PFDoA, PFTeA, PFTriA, PFUnA, perfluoroctadecanoic acid, perfluorohexadecanoic acid, which were detected during the AFFF baseline at the stack.

Comparison of OTM-45 between the baseline and AFFF or soil incineration shows that the same PFAS are detected at the stack, reflecting mainly the presence of PFAS in the process water.

Comparing total PFAS emission at the stack between baselines and PFAS incineration, OTM-45 results indicated higher total PFAS emissions for the PFAS waste incineration tests compared to baseline tests. However, given that PFAS were present in the water fed to the quench and wet scrubber downstream of the incineration process, these data are not considered conclusive.

	Baseline	Run 1		Run 2		Run 3

Total PFAS (lb/hr)	**6.58E-06**	**1.98E-02**	**6.98E-06**	**1.65E-02**	**9.65E-06**	**1.71E-02**	**6.20E-06**

Table 4-2 - OTM-45 results for contaminated soil incineration in campaign 1. *PFAS highlighted in blue were detected in the process water. Values in bold were PFAS detected above MDL in at least one of the OTM-45 fractions. ND means PFAS was not detected at the stack. DLL means that some portions of the sample were above the MDL, while the others were ND.*

> Comparison between total PFAS mass emission rate during baseline vs PFAS incineration.

Table 4-3 compares total PFAS mass emission rate at the stack between baseline and PFAS incineration. The OTM-45 results indicated higher total PFAS emissions for the PFAS waste incineration tests compared to baseline tests in Campaign 1. However, given that PFAS were present in the water fed to the quench and wet scrubber downstream of the incineration process, these data are not considered conclusive.

Campaign 1	**Average Baseline**	**Average AFFF**	**Average Soil**	**Average AFFF & Soil**
Total PFAS mass emission rate at the stack : OTM-45 (lb/hr)	**3.97E-06**	**8.32E-06**	**7.61E-06**	**7.97E-06**
Ratio PFAS incineration/Baseline		**2.1**	**1.9**	**2.0**

Table 4-3 : Total PFAS mass emission rate at the stack during baselines and PFAS incineration. *Average baselines refers to the average total stack emission rate of PFAS observed during the 2 baselines in Campaign 1. Average AFFF (resp. Soil) refers to the average total stack emission rate of PFAS observed during the 3 runs of AFFF (resp. soil) in Campaign 1.*

Figure 4-1 and 4-2 shows the PFAS signature at the stack (4-1) and in the 3 different AFFF feed streams (4-2). While the 3 incinerated AFFF samples have different PFAS composition (especially AFFF3 vs AFFF1 and AFFF2), the PFAS signature at the stack does not significantly vary to reflect AFFF signature. The same 13 PFCAs were detected in the process water and in the baseline. By comparison, the AFFFs are rich in PFHxS, 6:2 FTS, PFOS. The same result was observed for the contaminated soil. This suggests that AFFF and contaminated soil incineration produce similar PFAS emissions at the stack.

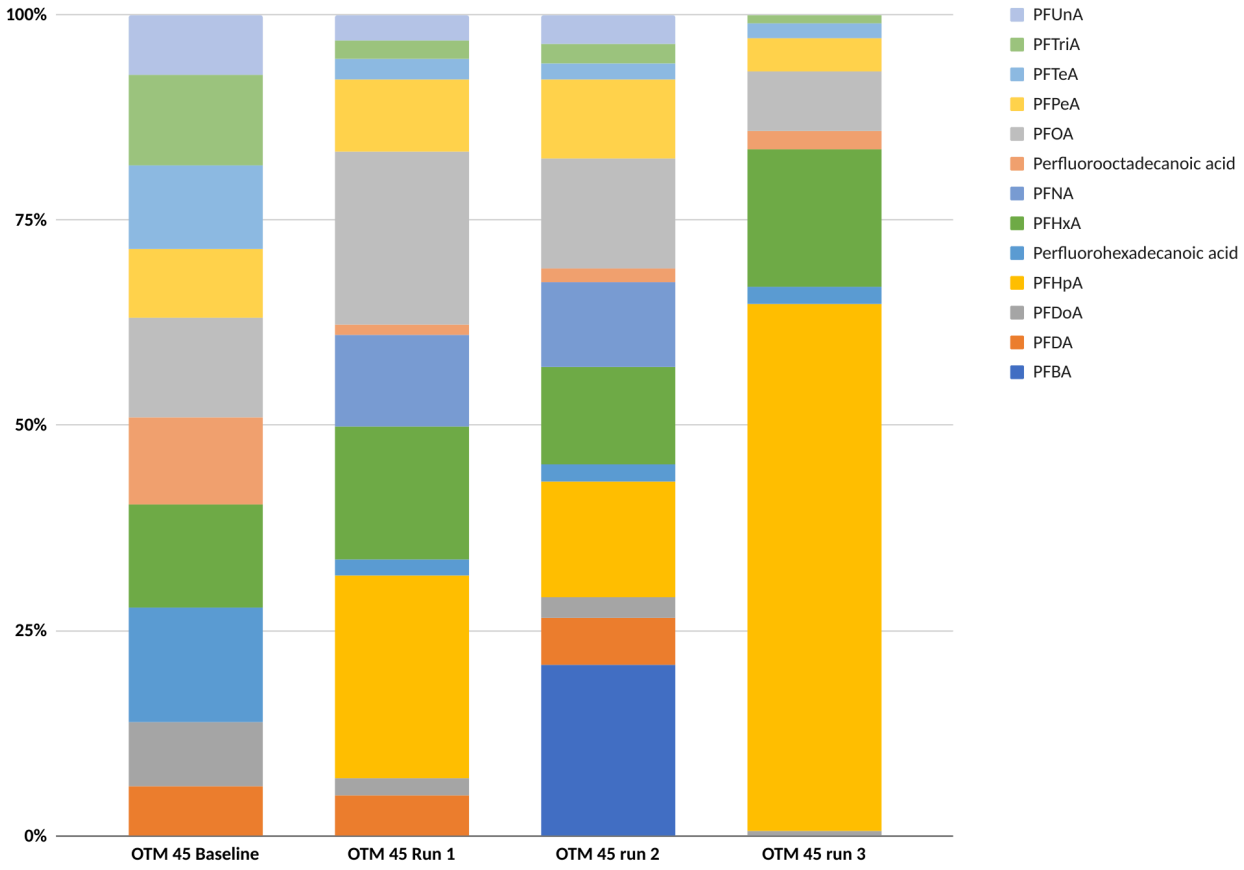

Figure 4-1 : PFAS signature at the stack (OTM-45) during AFFF incineration and baseline

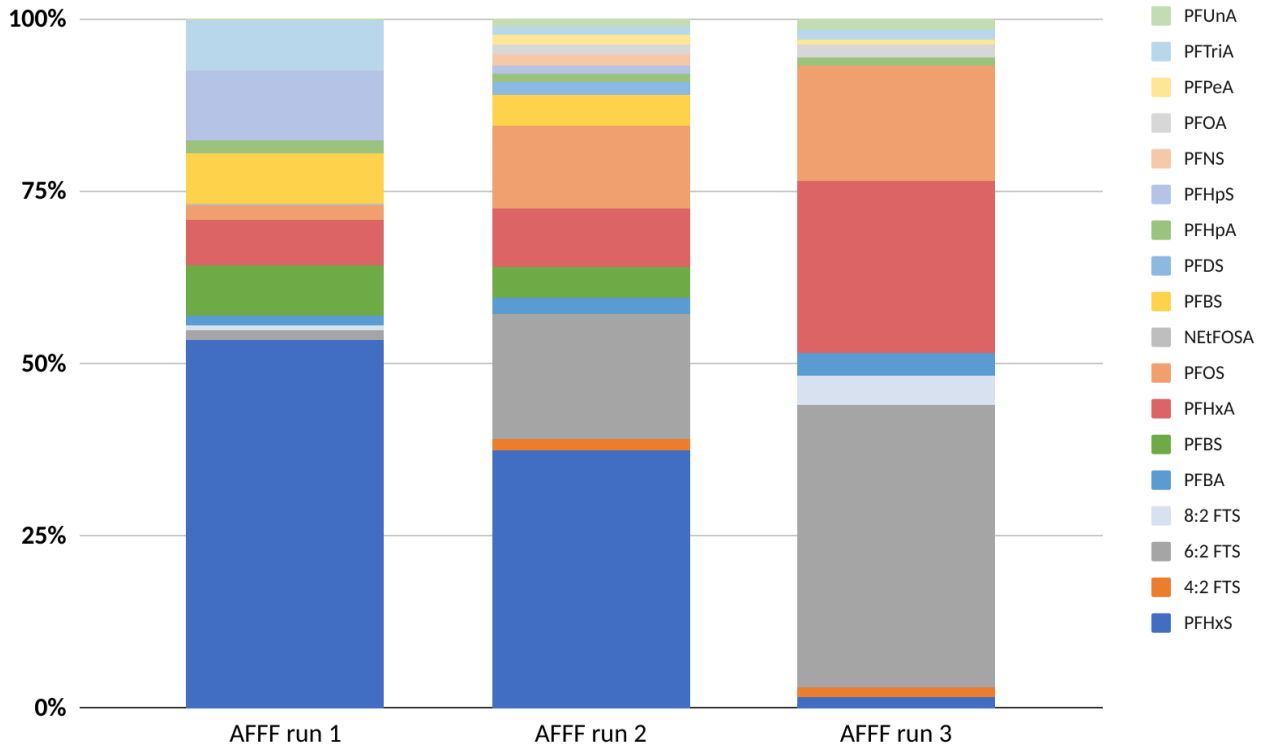

Figure 4-2 : PFAS signature in the AFFF

7.1.3.2.Destruction and Removal Efficiency

The DRE was computed for each run, as it is a parameter of interest to assess the performance of thermal treatment of PFAS according to the 2024 EPA interim guidance on destruction and disposal of PFAS material. When a PFAS is not detected at the stack, the MDL was used. When a PFAS is detected between the MDL and LoQ, the LoQ is used. This approach underestimates DRE.

DRE for the 6 runs of campaign 1 are provided in **Appendix XI (AFFF) and XII (contaminated soil).** Table 5 gives an overview of the DRE obtained in AFFF run#1 for the 20 most concentrated PFAS. PFAS in blue were not detected at the stack, while PFAS in yellow were detected below the LoQ.

Of the 20 most concentrated PFAS in the waste, 14 were either undetected at the stack or below the LoQ. The 6 PFAS detected above the MDL at the stack include 4 coming from process water (PFHxA, PFOA, PFPeA, PFHpA). In conclusion, only 2 PFAS were detected at the stack above LoQ while present in the waste and not coming from process water (PFDA, PFDoA).

Table 5 - DRE obtained for the 20 most concentrated PFAS in AFFF run #1. *PFAS in blue were not detected at the stack, while PFAS in yellow were detected below the LoQ.*

Figure 5 shows how the DRE increases with the PFAS feed rate in the kiln. This is, in part, an effect of the conservative approach to quantify PFAS not detected at the stack (considered as present at MDL). But the same correlation is observed for PFAS detected at the stack. There seems to be a residual level of PFAS detected at the stack, independent of the PFAS concentration in the waste. As an effect, DRE increases with the PFAS concentration in the waste. For the same feed rate, PFSAs seem to have a higher DRE than PFCAs. This may be explained by the background presence of PFCAs in the process water.

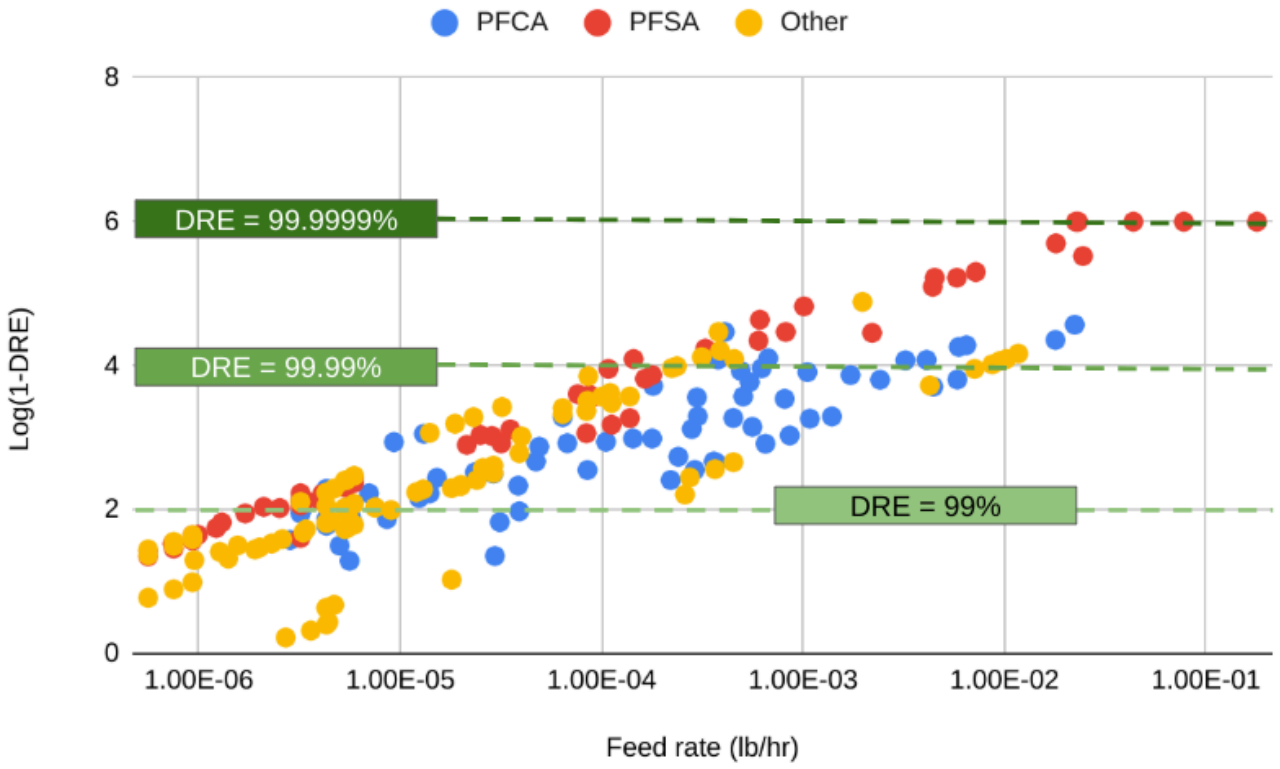

Figure 5 - Relation between DRE and feed rate. Log scale used for feed rate in the x-axis.

DRE > 99.9999% was obtained for the 4 of the 5 most concentrated PFAS : PFOS, PFHxS, PFPeS and PFHpS. For the 3 PFAS classified as Persistent Organic Pollutant (POP) according to Stockholm convention (PFOS,PFOA,PFHxS), the DRE was above 99.99% and even above 99.9999% for 2 of them (PFOS, PFHxS). PFOS and PFOA are also listed as hazardous substances under CERCLA.

Because of the stack gas contamination from process water, the DRE are artificially lower than they should be for the following PFAS: PFHxA, PFPeA, PFHpA, PFOA, HFPO-DA, PFHxS, PFOS, PFBA, and PFBS. **Table 6** shows the total DRE for OTM 45[3] obtained during campaign 1 for each run.

	A3F #1	A3F #2	A3F #3	Soil#1	Soil#2	Soil #3
PFAS feedrate (lb/hr)	0.3575	0.1236	0.0187	0.0265	0.0215	0.0161
Total DRE from OTM 45 train	99.9974%	99.9937%	99.9584%	99.9741%	99.9540%	99.9613%

Table 6 - Total DRE for the 6 runs of campaign 1

7.1.3.3. Products of Incomplete Destruction (OTM-50)

OTM-50 is a sampling method to trap and detect 30 PICs, that is to say, volatile short-chain PFAS potentially formed during AFFF or contaminated soil incineration. OTM-50 results were negative for all runs, showing that either no PICs were formed during the incineration process, or they were present at levels below the MDL. OTM-50 measurements for campaign 1 are presented in **Appendix XII.**

7.1.4. Total Destruction Efficiency

The Total Destruction Efficiency was computed for each run, as described in section 4.2. When a PFAS was not detected in the liquid, solid residue or at the stack, the MDL is used. When a PFAS was detected below the LoQ, the LoQ was used.

The total DE for the A3F and contaminated soil runs were very low or even negative (ranging from negative to 74%). This is due to the high MDL for OTM-50 (0.01 lb/hr to 0.1 lb/hr). The PFAS concentration in the waste was sometimes lower than the MDL for OTM-50. This demonstrates the need to improve detection levels for OTM-50 to align them with EPA Methods 537 and 1633.

The comparison between PFAS mass emission rate in the process water (PFAS entering the incinerator) vs PFAS mass emission rate in the blowdown (PFAS exiting the incinerator) shows that there is a transmission of PFAS from the process water to the stack gas. PFAS mass emission rate in the process water is higher than in the blowdown.

7.1.5 HF Measurements

HF measurements are available in **Appendix XIV** for campaign 1. HWC MACT standards for existing hazardous waste incinerators from §63.1219 applicable to the incinerator at Veolia's Port Arthur facility require HF at the stack to be below 32 ppmv, dry, at 7% O2. HF remained below the regulatory limit during campaign 1 testing.

7.1.6. Non Targeted Screening

Veolia has developed its own methodology to perform Non Targeted Screening (NTS) analysis on some of the pre-test samples. The objective of this innovative methodology is to detect PFAS that are not targeted in OTM-45 and OTM-50. It was developed by a Veolia R&D team based in France.

3

Veolia has looked for non-targeted PFAS in the AFFF used in run#1, and in the OTM-45 fractions of run #1 and the related baseline run.

Prior to non-targeted screening, sample preparation must be as non-selective as possible. The analysis was performed on AFFF after dilution and on OTM-45 fractions, which allows the extraction of a wide range of PFAS.

The non-targeted screening approach uses Liquid Chromatography coupled to High-Resolution Mass Spectrometry (LC/HRMS) as the analytical technique. It was performed on an Exploris 120 system (Thermo Scientific).

For the detection part, two acquisition methods are used to maximize the amount of recorded information and enable efficient data processing:

- Fullscan ESI+/ESI- R 60,000 for peak detection
- Fullscan ESI+/ESI- + DDA-MS2 (Data-dependent analysis) for identification.

All samples are analyzed in triplicates with both methods. Data processing is the most complex part of non-targeted screening analyses. A complete workflow in three main campaigns was developed using Compound Discoverer software (Thermo Scientific):

- Pre-processing for peak detection
- Signal prioritization to isolate data corresponding to potential PFAS compounds
    - Number of Fluorine in proposed molecular formulas
    - KMD (Kendrick Mass Defect) to identify homologue series
    - PFAS-specific fragments
- Annotation or identification of prioritized signals
    - Use of spectral libraries
    - In-silico fragmentation
    - Comparison with literature data

NTS results on the AFFF used in run #1

To test the reliability of the NTS method developed by Veolia, results from NTS (performed by Veolia) were compared with targeted analysis (performed by Eurofins) for the AFFF. If the NTS method is valid, it should detect all the targeted compounds detected by Eurofins.

It appears that most of the compounds detected in targeted analysis are also detected in NTS. 6 out of 32 detected in the targeted analysis were not detected in the NTS. One PFAS listed in the targeted analysis was not detected by Eurofins but by the NTS.

Table 7 - comparing PFAS detected in the targeted analysis (Eurofins) vs NTS (Veolia)

In total, 321 compounds suspected to be PFAS were detected in the AFFF, many more than the 32 detected in the targeted analysis. Among the 20 compounds with the highest intensities in the NTS, only 5 are in the targeted analysis. However, for the LC/HRMS used for NTS, the intensity can be different for compounds at the same concentration, as it is not fully proportional to concentration.

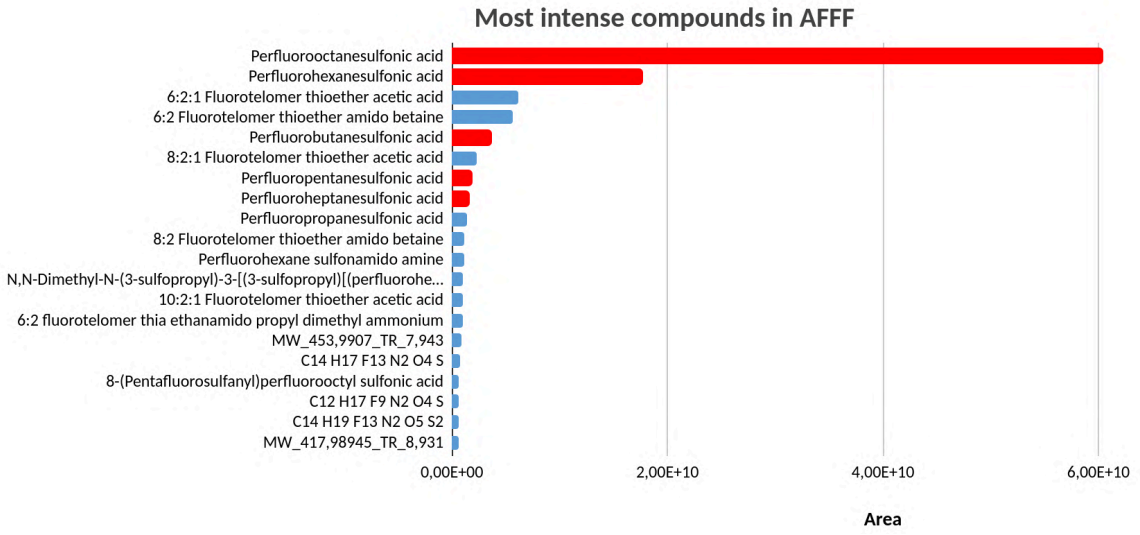

Figure 6 - Results of NTS for AFFF. The compounds with the highest intensity according to NTS. In red, compounds were also detected in the targeted analysis.

NTS results on OTM-45 fractions (air emissions)

PFAS detected in OTM-45 fractions from AFFF incineration were compared to PFAS detected in OTM-45 fractions from the baseline run. Only 8 PFAS compounds were detected in the OTM-45 fractions from AFFF incineration exclusive of being detected in the baseline. All these compounds had very low responses, indicating low concentration. None of the most intense compounds detected in the AFFF were detected in the OTM-45 fractions.

Table 8 - Results of NTS for OTM 45 fractions from AFFF incineration and from the baseline. *MW means "molecular weight" : in that case, a PFAS is identified but its formula is unknown.*

Conclusions

NTS shows that more PFAS were present in the AFFF than the 32 PFAS detected in the targeted analysis. Results show that these non-targeted PFAS were not detected in OTM-45 fractions, which suggests they were destroyed during the incineration process, as observed for targeted PFAS. It must be noted, however, as the OTM-45 sampling and sample preparation used for the NTS are selective to semi-volatile PFAS (boiling point > 212°F), it is possible that some PFAS are emitted in the air but not trapped in OTM-45.

7.2. Campaign 2 : Incineration of A3F, contaminated soil, CF4 and spent carbon

Campaign 2 summary :

Campaign 2 confirms campaign 1 results.

In a majority of runs (11 out of 15), no PICs were detected via OTM-50. CF4 was detected in three runs : during the CF4 run, a baseline run and an AFFF incineration run. In these 2 latter runs, the CF4 level is close to the MDL. The source of the CF4 in the latter two tests is unclear. It is unlikely to form as a PIC due to the high H/F ratio in the SCC during these tests. The incineration test where CF4 was fed into the SCC indicated a DRE of less than 50%, consistent with predictions that temperatures above 2,550 F are necessary to destroy this compound. Another OTM-50 PFAS was detected during a baseline at a level close to MDL. It is unlikely to be a PIC due to its low thermal stability (polyfluoroether) and is more likely a contaminant from the analytical laboratory.

DRE > 99.999% is reached for PFOS in 3 runs. The waste streams incinerated in this campaign are less concentrated in PFAS than during campaign 1 which explains why the 99.9999% could not be reached.

Solid residues are PFAS-free, or contain PFAS at levels close to MDL.

Liquid residues contain PFAS at low level (ppt), reflecting the background presence of PFAS on the pond water supplying the process water of the incinerator.

Contrary to campaign 1, a contamination issue is suspected in the OTM-45 results: 4 runs contained background >C10 PFAS detected in OTM-45 fractions, whose source is still under investigation.

7.2.1. Waste Analysis

Four waste streams were injected separately: A3F, spent carbon, AFFF-contaminated soil and CF4. Waste profiles are available in **Appendix XV for AFFF, spent carbon and AFFF-contaminated soil.**

Run 2 and 3 of A3F were performed with the same A3F but under different conditions. In run 3, lime was injected at 2 gpm, simultaneously with A3F injection, to study its ability to enhance PFAS destruction.

7.2.2. Solid and Liquid Residues

In the solid residues, no PFAS was detected in significant quantities. All slag and filtercake samples were PFAS-free. PFAS were detected in four samples of ashes, with detection level close to MDL. Detailed results of these 4 samples are available in **Appendix XVII. Table 10** gives a summary of the results for PFAS in solid residues.

	Baseline	Run 1	Baseline 2	Run 2	Run 3[4]
A3F	**ashes : PFAS detected close to MDL** filtercake : ND slag : ND	ashes : ND slag : ND Filter cake : ND	**ashes : PFAS detected close to MDL** filtercake : ND slag : ND	**ashes : PFAS detected close to MDL** filtercake : ND slag : ND	ashes : ND slag : ND Filter cake : ND

Table 9 - PFAS analysis in solid residues of the campaign 2

For the liquid residues, 20 blowdown samples were collected. 16 had the same signature and PFAS concentration as observed in the campaign 1, while 4 of them had PFAS levels above 200 ppt (A3F

[4] In run#3 A3F, lime is injected simultaneously to A3F injection

baseline #1, A3F run#2, A3F run3+24hr, carbon run#2+24 hr). Three of these samples were collected at a time when no PFAS were being incinerated. It is unclear whether these results come from laboratory background or from PFAS in the blowdown water that is transferred from the stack gas. The profile of these 4 atypical samples is available in **Figure 7.**

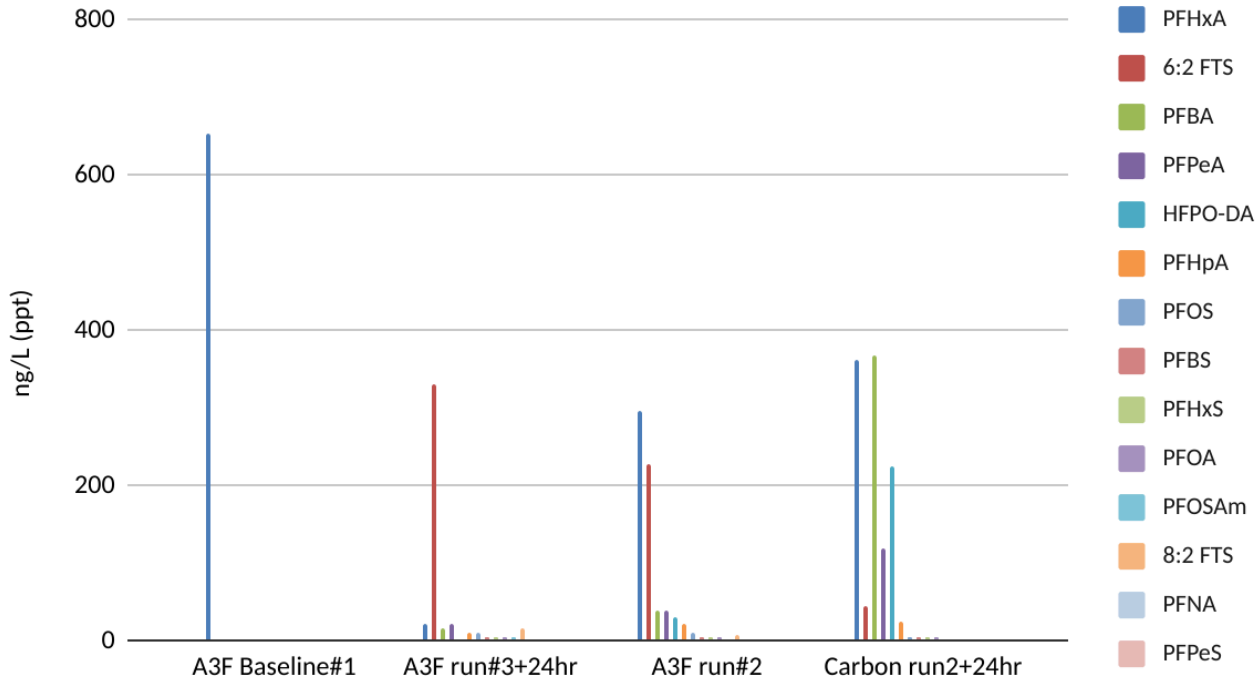

Figure 7 - Profile of the atypical samples of blowdowns obtained in campaign 2

In the 16 other blowdown samples, the same results as in campaign 1 were obtained. Because of background PFAS presence in the pond water, a dozen PFAS were detected at ppt level, both in the baseline sampled at the beginning of the campaign (before PFAS incineration), and in the samples collected during PFAS incineration. PFAS are twice to four times more concentrated in the blowdowns than in the pond water because of evaporation. Results for the typical blowdown samples are shown in **Figure 8.**

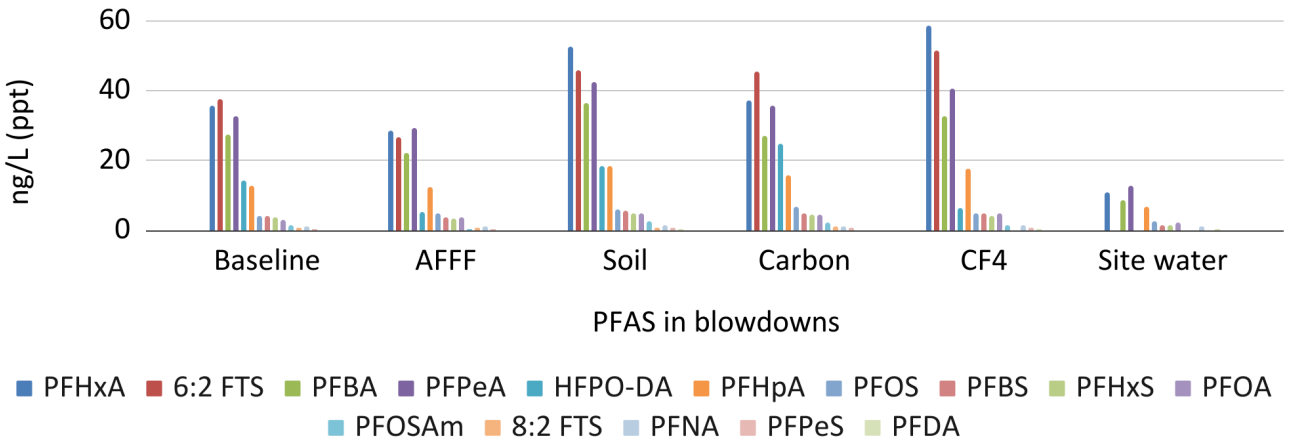

Figure 8 - PFAS signature in the blowdown (left) vs process water (on the right side of the graph)

Table 10 shows the results for process water collected in campaign 1 and 2. PFAS concentration in process water is similar in campaign 1 and 2, which means that the PFAS concentrations in the pond water are stable. The only differences are :

- the detection of PFDA in campaign 2 at very low level (<1 ppt), undetected in campaign 1
- the detection of HFPO-DA in campaign 1 at very low level (<3 ppt) undetected in campaign 2

PFAS	Concentration process water campaign 1 (ng/L)	Concentration process water campaign 2 (ng/L)	Concentration in blowdown baseline campaign 2 (ng/L)
PFHxA	14.90	11.1	35.73
PFBA	11.20	8.57	27.50
PFPeA	16.10	12.9	32.61
PFHpA	8.41	6.81	12.80
PFOS	2.48	2.57	4.10
PFBS	1.81	1.36	4.14
PFHxS	1.49	1.53	3.78
PFOA	2.88	2.11	2.89
PFNA	1.26	1.21	1.02
PFDA	ND (0.293)	0.344	ND (0.292)
HFPO-DA	2.02	ND (1.56)	14.14
6:2 FTS	ND (1.07)	ND (1.07)	37.59
PFOSAm	ND (0.293)	ND (0.293)	1.56
8:2 FTS	ND (0.586)	ND (0.586)	0.86
PFPeS	ND (0.293)	ND (0.293)	0.57

Table 10 - PFAS concentration in process water in campaign 1 and 2 and in the blowdown baseline in campaign 2. *All PFAS listed in EPA 1633 were tested but only the ones detected are shown. Concentration in the blowdown baseline in campaign 2 is an average of all the baselines collected, excluding the 1st baseline collected during AFFF incineration which is considered not representative.*

In campaign 2, the only differences between the PFAS signature in the process water and blowdown is the presence of:

- **6:2 FTS** in the blowdown - could be a PIC from previous PFAS incineration or from the PFAS campaign.
- **HFPO-DA -** was detected in every blowdown sample, and was also detected in the process water during campaign 1 but not campaign 2. It is likely that this was a false negative and HFPO-DA was also in the process water during the campaign 2 at very low level, maybe non detectable. Evaporation during the process makes it detectable in the blowdown.
- **8:2 FTS, PFOSAm and PFPeS** were found in low quantities (1 ppt or less, very close to MDL) in some blowdowns but not the process water. It is possible that they were also present in the process water below MDL, or that there was a false positive in the blowdowns samples.

Detailed results for PFAS concentration in liquid residues for Campaign 2 are available in **Appendix XVI.**

7.2.3. Air Emissions

7.2.3.1. PFAS Mass Emission Rate at Stack (OTM-45)

The following OTM-45 samples were collected during the campaign 2, with 2 patterns emerging :

- **Pattern 1 :** PFAS concentration & signature at stack is similar to campaign 1. PFAS < C10 were found at stack at < 2 10^-5 lb/hr in total. PFAS signature at the stack reflects the PFAS signature in process water.
- **Pattern 2** : High concentration at stack for C>10 PFAS: PFDA, PFUnA, PFDoA, PFTriA, PFTeA. Total PFAS emissions < 9.5 10^-5 lb/hr)

Runs	Comment on OTM-45 results

CF4 run#1	Pattern 1
Soil baseline #2	Pattern 1
Soil run#2	Pattern 1
Soil run #3	**Pattern 2**

Table 11 -Repartition of each run to pattern 1 and 2

Table 12 shows the PFAS stack emissions (OTM-45) for the different baselines performed prior to each incineration test. Two baselines were performed for AFFF because there were 2 conditions (with and without lime). Two baselines were performed for contaminated soil because run#2 and run#3 were performed 5 days after run#1 because of equipment damage.

The 6 baseline runs were similar in terms of PFAS signature and PFAS stack emissions. Compared to the baseline tests in campaign 1, there are the same dominant PFAS, with the additional presence of FOSA, NEtFOSE, NMeFOSA, 6:2 FTS and 6:2 FTUCA at very low levels close to MDL.

Total PFAS (lb/hr)	**5.18E-06**	**3.14E-06**

Table 13-4 : PFAS emissions at the stack (OTM-45) for CF4 incineration. *PFAS highlighted in blue were detected in the process water. Values in bold when PFAS was detected above MDL in at least one OTM-45 fractions. DLL means that some portions of the sample were above the MDL, while others were below the detection limit (ND).*

Pattern 1: AFFF run 2 &3, soil #2, carbon #2 → PFAS emission < 2.10^-5 lb/hr and PFAS signature at the stack during PFAS incineration similar to baseline

As in the campaign 1, even if the PFAS containing wastes fed in the kiln had different signatures, the PFAS signature at stack is the same for all runs. The same 6 PFAS are found at stack substantially above MDL in all runs: PFBA, PFHpA, PFHxA, PFNA, PFOA, PFPeA. These PFAS are also found in the PFAS-contaminated process water entering the incinerator, and in contact with the stack gases after thermal treatment.

As in the campaign 1, the flowrate at the stack of these 6 PFAS is higher during PFAS incineration than during the baseline.

Figure 9-1 shows the PFAS stack emissions for pattern 1.

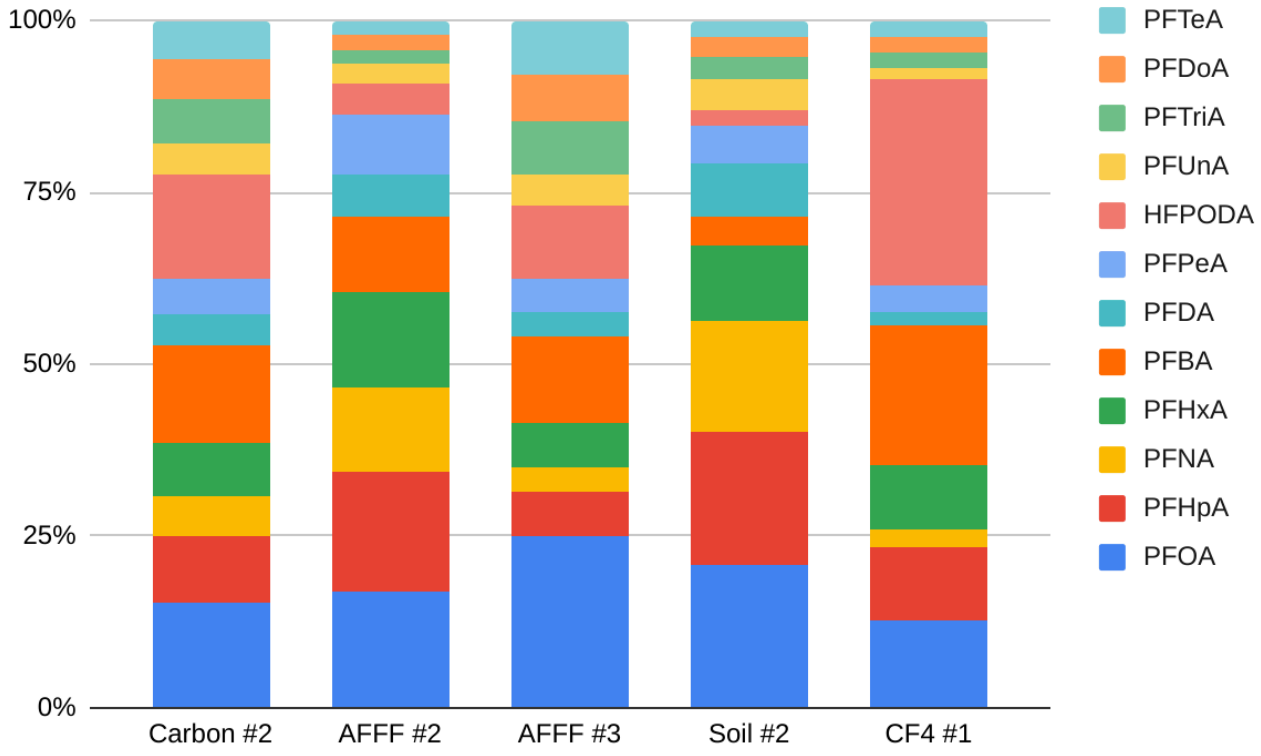

Figure 9-1 - PFAS stack emission observed in pattern 1 (OTM-45). *For readability, only the 12 dominant PFAS are represented.*

Comments on lime injection during the A3F runs:

The same AFFF was incinerated in run 2 and 3, but in run 3, lime was injected during AFFF incineration. Lime injection decreases PFAS stack emission for PFAS with less than 7 carbons like PFBA, PFHxA, PFPeA. Stack emission for these PFAS in AFFF run 3 (lime injection) is lower than in run 2 (without lime) and lower than the baseline. The lime effect on PFAS with C>7 is less certain. PFOA emissions decrease with lime but PFOS, PFTeA, PFTriA, PFDoA emissions increase. Lime was not tested for PFAS content, but according to manufacturer description there is no PFAS in it. Overall, lime injection decreases total PFAS emissions at the stack to a small degree, PFAS emissions at the stack are 1.10^-5 lb/hr without lime injection (AFFF run 2) and 6.15.10^-6 lb/hr with

lime injection (AFFF run 3). The impact of lime was only tested in one run; more tests should be performed to confirm the results.

Comments on the carbon run :

PFAS mass emission rate at stack during the carbon incineration run was lower than the baseline.A possible explanation could be an effect of unique surfaces provided by the activated carbon that may enhance PFAS degradation during incineration.

Pattern 2: AFFF run#1, carbon #1, soil #1 & #3

Figure 9-2 shows the PFAS stack emissions for 4 runs that showed a different PFAS signature (pattern 2) and concentration than the one established during campaign 1. There were: AFFF#1, Soil#1, Carbon#1, and Soil#3. In these runs, high emissions of long chain PFAS like perfluorohexadecanoic acid (C16), PFDoA (C12), PFTeA (C14), PFTriA (C13), PFUnA (C11) and perfluorohexane (C6) were detected at the stack. These 4 runs have the same PFAS signature at stack while the other runs involving AFFF, carbon, soil and CF4 and all baseline runs had PFAS signatures consistent with pattern 1.

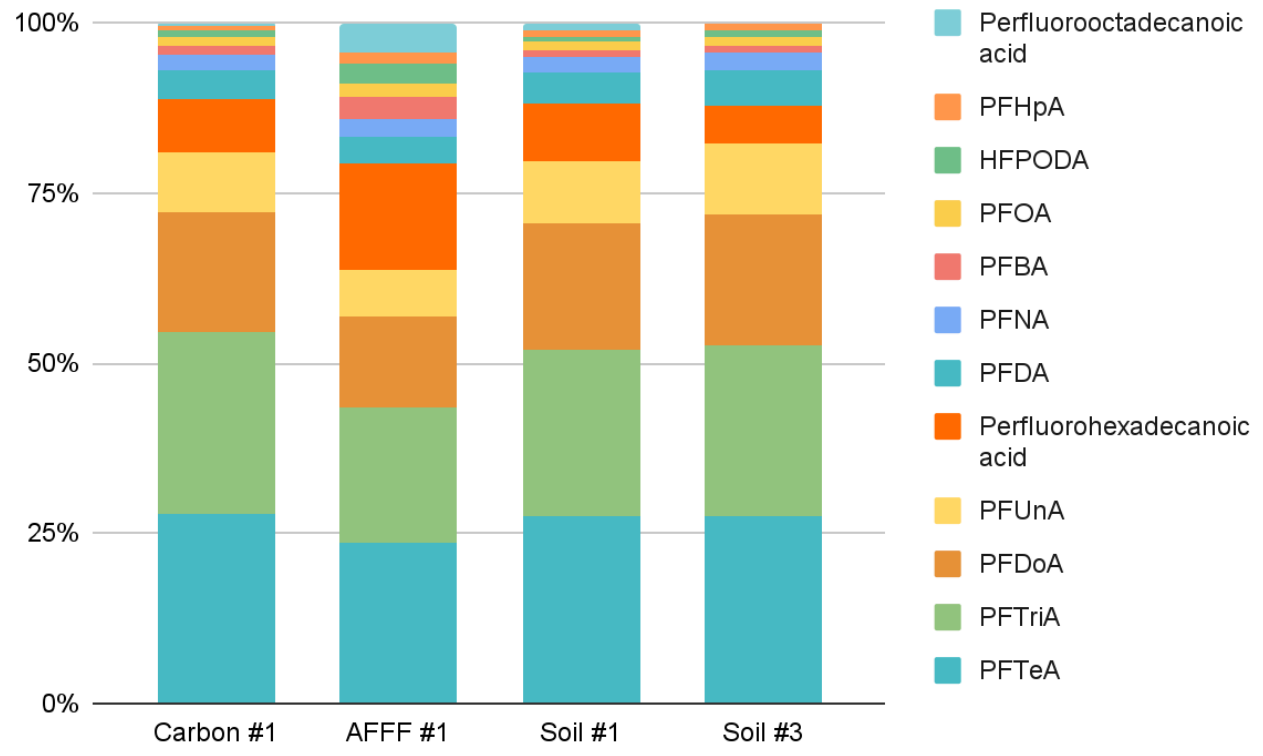

Figure 9-2 - PFAS stack emission observed in pattern 2 (OTM-45). *For readability, only the 12 dominant PFAS are represented.*

For carbon run#1 and run#2, the same carbon mix was incinerated, but very different OTM-45 results were obtained (run#2 gave pattern 1 while run#1 showed pattern 2). This is the same for soil#2 and soil#3. The same soil mix was used but with a different pattern at the stack. These inconsistencies confirm that pattern #2 is likely contaminated by background PFAS. The source of this background PFAS presence is unknown. It is unlikely that emissions from PFAS with C>10 (pattern 2) are PICs from PFAS incineration, because campaign 1 has shown that the incinerator can efficiently destroy PFAS with C<9 like PFOS, PFHxS, PFPeS.

> Comparing PFAS incineration vs baseline in Campaign 2

Table 14 compares the total PFAS mass emission rate at the stack (OTM-45 results) during baseline vs PFAS incineration in Campaign 2.

As in campaign 1, the OTM-45 results indicated higher total PFAS emissions for the PFAS waste incineration tests (excluding the CF4 tests) compared to baseline tests in campaign 2. However, given that PFAS was present in the water fed to the quench and wet scrubber downstream of the incineration process, these data are not considered conclusive.

Campaign 2	Average Baseline	Average AFFF	Average soil	Average carbon	CF4
Total PFAS mass emission rate at the stack : OTM-45 (lb/hr)	7.63E-06	1.05E-05	6.77E-05	3.82E-05	3.14E-06
Ratio PFAS incineration/Baseline		**1.4**	**8.9**	**5.0**	**0.4**

Table 14 : **Total PFAS mass emission rate at the stack during baselines and PFAS incineration.** *Average baselines refers to the average total stack emission rate of PFAS observed during the 6 baselines in Campaign 2. Average AFFF, average soil, and average carbon refers to the average total stack emission rate of PFAS observed during the runs of AFFF, contaminated soil and spent activated carbon in Campaign 2.*

7.2.3.2. Destruction and Removal Efficiency

Tables 15 and 16 present the DRE and total DRE measured in campaign 2. Overall, total DRE >98% were measured in all runs, despite the background presence of long-chain PFAS (pattern 2) from unknown sources. PFAS concentrations in the waste streams in campaign 2 are lower than in campaign 1, leading to lower DRE.

PFAS	AFFF run#1	AFFF # 2	AFFF # 3	Soil # 1	Soil # 2	Soil # 3	Carbon # 1	Carbon # 2
PFAS feed rate (lb/hr)	0.0105	0.0223	0.0231	0.0065	0.0123	0.0186	0.0065	0.0072
Total DRE (%)	99.8552%	99.9547%	99.9734%	98.5462%	99.8374%	99.5242%	98.8923%	99.9399%

Table 15 - Total DRE obtained during campaign 2

	AFFF run #1			AFFF run #2			AFFF run #3			Soil run #1

Table 16-2 - DRE for campaign 2. Part 2. PFAS highlighted in blue were detected in the process water. *indicates that values were below the MDL or the LoQ. ND indicates PFAS was not detected at the stack. DLL indicates that the PFAS was detected above MDL in one of the OTM-45 fractions while the others were ND.

Tables 16-1 and 16-2 shows that a large number of PFAS were undetected at the stack, despite being detected in the PFAS waste. Eight PFAS including 8:2 FTS, 7:3 FTCA, 5:3 FTCA, 4:2 FTS, HFPO-DA, NEtFOSE, NETFOSAA and PFDS were systematically not detected at the stack. DRE for PFOS was >99.999% in 3 runs. DRE >99.9999% could not be reached because of the limited PFOS concentration in campaign 2.

PFAS with DRE inferior to 99% were :

- PFDA - detected in the process water, stack gas likely contaminated with PFDA from process water
- PFDoA - contamination issue suspected in AFFF run #1, soil run #3 and carbon run #1. Very low concentration in waste for soil run #2 leads to low DRE.
- PFHpA - detected in the process water, stack gas likely contaminated with PFHpA from process water
- PFNA - detected in the process water, stack gas likely contaminated with PFNA from process water
- FOSA - very low concentration in waste for soil run 3 and carbon 1,2 leads to low DRE.
- PFOA - DRE close to 99%, PFOA detected at the stack likely from process water rather than waste incineration
- PFTeA - contamination issue suspected in carbon run 1 and soil run 3. Low concentration in soil run#2 leads to low DRE.
- PFTriA - contamination issue suspected in AFFF run#1, soil run 3 and carbon run #1. Very low concentration in waste for AFFF run 2 and 3 and carbon 2 and soil 2 leads to low DRE.
- PFUnA - contamination issue suspected in AFFF run#1 and carbon run#1. Very low concentration in waste for carbon 2 and soil 2 leads to low DRE.
- NMeFOSA - very low concentration in waste in soil run 2 leads to low DRE

7.2.3.3 Products of Incomplete Destruction (OTM-50)

PICs measured from OTM-50 sampling were detected in 3 runs out of 13. Detailed OTM-50 tables are available in **Appendix XVIII.**

	Baseline	Run 1	Run2	Run 3
A3F	Blank #1: C5 detected at 9.9X10^-5 lb/hr (MDL: 8.4X10^-5 lb/hr)	ND	ND	CF4 detected at 5.1X10^-3 lb/hr (MDL : 4.4X10^-4 ;b/hr)
	Blank #2: CF4 detected at 2.4X10^-3 lb/hr (MDL : 4.4X10^-4 lb/hr)			

Carbon	ND	ND	ND	N/A
CF4	ND	CF4 detected at 17.6 lb/hr	N/A	N/A
Contaminated soil	ND	ND	ND	ND

Table 17 - OTM-50 results in campaign 2. ND means no OTM-50 PFAS was detected at stack during the run. N/A indicates no additional run was performed

The baseline for AFF #1 could be a false positive as no PFAS was supposed to be incinerated at that time.

CF4 was detected in the baseline performed before AFFF run #3 and during AFFF run #3. The high H/F ratio reached in the incinerator prevents CF4 formation during PFAS incineration. The detection of CF4 during these 2 runs could be a false positive, as the level is close to the MDL.

CF4 was also detected at stack during CF4 incineration. The DRE for CF4 is 43%. According to literature, CF4 destruction requires a temperature > 2500 F, while the incinerator temperature is 2040 F in the SCC. The fact that 43% of the CF4 was destroyed suggests that in some parts of the incinerator, temperatures above 2500 F are reached.

OTM-50 results show that in most runs, no PICs were detected at stack during the campaign 2.

The C5 compound detected in AFFF baseline run#1 is a polyfluorinated ether. It is a very unlikely PIC due to its low thermal stability and is more likely a contaminant from the analytical laboratory.

7.2.4 HF measurement.

HF measures are available in **Appendix XIX** for campaign 2. HWC MACT standards for existing hazardous waste incinerators from §63.1219 applicable to the incinerator at Veolia's Port Arthur facility require HF at the stack to be below 32 ppmv, dry, at 7% O2. HF remained well below the regulatory limit during PFAS incineration.

7.2.5 Total Destruction Efficiency

The Total Destruction Efficiency was computed for each run, as described in 4.3. When PFAS was not detected in the liquid, solid residue or at stack, the MDL is used. When a PFAS is detected below the LoQ, the LoQ is used.

The total DE for all runs were very low or even negative. This is due to the high MDL for OTM-50 (0.01 lb/hr to 0.1 lb/hr). The PFAS concentration in the waste was sometimes lower than the MDL for OTM-50. This demonstrates the need to improve detection levels for OTM-50 to align them with EPA Method 537 and EPA Method 1633.

7.3 Conclusions and Recommendations for Further Study

The results demonstrated high destruction and removal efficiency for PFAS compounds during the incineration process, with values up to 99.9999%. These findings suggest that hazardous waste incineration, when properly operated under high-temperature conditions, can effectively break down PFAS compounds. Notably, a single VFC, CF4, was detected in one sample near the LOQ,

suggesting a complete mineralization of the PFAS compounds rather than partial decomposition. The consistent achievement of high DRE values across multiple test runs, coupled with the absence of PICs, provides strong confidence in the reliability of the thermal treatment process for PFAS destruction.

Analysis of solid residues and liquid residues showed relatively low to no concentrations of PFAS compounds, further supporting the effectiveness of the thermal treatment process. The minimal presence of PFAS compounds in these residual streams indicates successful destruction rather than mere phase transfer of the contaminants.

Initial findings from this Veolia PFAS incineration campaign have brought to light several important challenges that warrant further investigation. One significant hurdle remains finding waste streams with sufficiently high PFAS concentrations to demonstrate DRE higher than 99.9999%.

The current detection limits of samples obtained from OTM-50 are significantly higher than samples analyzed from OTM-45, making it difficult to quantify thermally stable, short-chain PFAS in the gaseous emissions. This limitation severely impacts the ability to calculate total PFAS destruction efficiency compared to DRE calculations of the PFAS being fed to the incinerator.

A significant challenge encountered during the study was the detection of background PFAS in some OTM-45 fractions. The source of this PFAS presence remains unclear and this observation highlights the complexity of PFAS sampling near industrial sources and the need for more comprehensive monitoring strategies.

While the targeted analysis of 79 PFAS compounds listed in OTM-45 and OTM-50 provides valuable insights, the potential presence of unknown PFAS necessitates the implementation of non-targeted analytical approaches. Such comprehensive screening would help identify previously uncharacterized PFAS compounds and transformation products that may form during the incineration process. This broader analytical scope would provide a more complete understanding of the treatment effectiveness and potential environmental implications.

An interesting avenue for future research would be investigating the potential catalytic effect of lime on PFAS destruction. As lime is commonly used in air pollution control systems for acid gas removal, understanding its role in PFAS decomposition mechanisms could provide valuable insights into process optimization. Preliminary results suggest that the presence of lime in the system might enhance PFAS destruction through surface-mediated or catalytic effects, potentially allowing for more efficient treatment at lower temperatures or shorter residence times. This knowledge could lead to improved treatment efficiencies and inform future design modifications of incineration systems.

City Government

City of Edmonds update: Resolution of wastewater treatment plant operational issues ongoing

May 7, 2026

Will you chip in to support **our nonprofit newsroom** with a donation today? **Yes, I want to support My Edmonds News!**

The Edmonds Wastewater Treatment Plant

As questions continue to swirl over the operational issues affecting the Edmonds Wastewater Treatment Plant, the City of Edmonds issued a statement Thursday regarding recent efforts to address the issues that have blocked the plant's carbon recovery system from performing as originally promised.

Edmonds embarked on the carbon recovery project in 2018, aiming to replace the plant's aging incinerator with a more environmentally sustainable gasification system designed to produce biochar, a potentially marketable byproduct. The technology, developed by EcoRemedy, promised a greener option to disposing of the city's solid wastes.

Advertiser Content

Amaresco served as the general contractor for the EcoRemedy installation under a guaranteed-performance contract managed by the Washington State Department of Enterprise Services (DES). Under the contract term, Ameresco guaranteed that the work would be completed, finished on time and that the system would function as intended. Construction began in 2021.

However, the project has been marred by significant delays and technical failures since construction began.

According to City documents, the project cost escalated from $26 million to $31 million between 2020 and 2023. Commissioning efforts in 2023 and 2024 were hindered by numerous issues, including clogged conveyance systems and dryers, equipment breakage, smoke plumes exiting the facility, and consistent failure to achieve steady operations.

While these issues persisted, the city has been forced to haul wastewater solids to a landfill in eastern Oregon. As of late 2025, the total cost for this has been more than $5 million. However, under the Edmonds Regional Wastewater Treatment Plant agreement, the City of Edmonds pays approximately 51% of these costs, while its partners (City of Mountlake Terrace, Olympic View Water and Sewer District and Shoreline/Ronald Sewer District) split the remaining 49%.

In the most recent effort to address the plant's operational issues, on April 14 the Edmonds City Council approved a $415,000 contract with Jacobs Engineering, an engineering consultant, to assist the City with operating the technology. While Ecoremedy and Ameresco remain responsible for the actual commissioning and construction of the system, Jacobs will serve as an independent consultant to ensure the City can operate the facility once substantial completion is reached.

Funding for the contract comes from the City's wastewater utility fund.

Here is the full statement from City of Edmonds on the current status of the efforts to address the wastewater issues:

"The City Council originally approved Ameresco's Energy Services Proposal for Phase 6 of the wastewater treatment plant upgrades based on two key understandings: first, that the aging incinerator needed to be replaced, and second, that the new gasification system would provide long-term economic and environmental benefits for the City and its ratepayers.

Although the project has experienced significant delays, the City has remained committed to the project and to holding Ameresco accountable for delivering the solids handling facility that was promised.

At the same time, the City has been clear that construction progress has not met expectations. Following an early 2025 attempt to operate the gasifier, a number of operational issues became apparent. Earlier this year, the State, acting as the City's contract administrator, involved Ameresco's bonding company to help ensure contractors returned to the site to continue work toward making the system operational.

As progress on the plant was approaching a critical trial run, and with Ameresco's primary subcontractor preparing to move to another job site, the Council made the difficult decision to bring in independent experts with the experience needed to give the project the best possible opportunity for long-term success. The Jacobs Engineering contract gives the City the best chance of achieving the project's original goals.

At the end of April 2026, Ameresco and its subcontractor conducted a multi-day trial run of the gasifier. Jacobs Engineering is still evaluating the results. While some elements of the test appeared encouraging, other issues remain a concern and require further review.

Throughout this process, the City's focus has remained consistent: to ensure Edmonds either receives the facility it was promised or is compensated to the fullest extent allowed under the law.

The City's ability to comment further is limited given the status of the project and possible disputes that will require resolution. The City commits to being transparent to the extent possible without jeopardizing the City's legal rights."

Aries Clean Technologies looks for fresh start with funding infusion

The company's Linden, New Jersey, plant was idled last year due to mechanical challenges. But with new capital from its lead investor, Aries is plotting a restart and second facility in Maine.

Published May 21, 2026

Jacob Wallace
Senior Reporter

Aries Clean Technologies began construction of its first biosolids gasification plant in Linden, New Jersey, in 2019 and began operations in 2024. The plant suffered from intermittent shutdowns, forcing Aries to pursue a redesign.
Permission granted by Aries Clean Technologies

Aries Clean Technologies is looking for a fresh start thanks to a new infusion of capital.

Last month, lead investor Spring Lane Capital announced it would purchase two bond series issued by Aries. The announcement gave Aries sufficient runway to resume payments on two newer bond series and move ahead with a restart of the company's first facility.

Aries, which built its first biosolids gasification facility in Linden, New Jersey and plans to build a second in Maine, has gone through a transition since last year. It idled its only plant in November after failing to keep it operating consistently since it first began operations in 2024.

And last month, former CEO Jon Cozens transitioned to a role as strategic advisor, with senior vice president of operations Kari Mueller stepping in to take the top position. She now plans to lead the company as it moves toward construction on its new plant in Sanford, Maine.

"These facilities take a while to build, and you have to be very, very attention-to-detail focused," Mueller said. "This whole job is to

execute."

Lessons from New Jersey

Aries began construction on its Linden plant in 2019. The project was designed to process 130,000 tons of biosolids annually from the region. It was designed to run with two biosolids dryers and a gasification system, producing biochar as an output.

The system began operating five years later, but the company repeatedly ran into issues with equipment that needed to come offline, according to executives. The trouble centered mostly on the facility's dryers — if one unit needed to come offline for maintenance, the entire facility had to shut down, said Jason Dana, Aries' vice president of technology.

He said the Linden plant worked well as a demonstration of Aries' process. But moving forward, the company plans to install a third dryer at Linden and all future facilities, plus intermediate storage after the biosolids drying process to ensure redundancy and minimize downtime.

"When it came to commercial operation and profitability, it just wasn't where it needed to be," Dana said. "The dryer is the primary area that we're looking to improve upon."

The company also faced local pushback in 2022 when it attempted to build a second facility in Newark. It eventually abandoned those plans, which was celebrated by local advocates who were fearful of added air emissions from the facility and trucks bringing in feedstock.

Aries executives said the decision to move on from that site was motivated mostly by size constraints. Once the company realized it needed at least three dryers to run its plants efficiently, the site it had been looking at in Newark no longer seemed big enough. Aries explored another site in Taunton, Massachusetts, but later abandoned it for similar reasons.

Second facility in Maine

Aries landed on Sanford as the best location for the second facility for multiple reasons, according to company executives. It was big enough to accommodate the new expanded facility design, but it also served a state looking for solutions for its biosolids.

Maine has some of the most restrictive biosolids disposal rules in the nation. The state banned land application of the material in 2022 after concerns grew about contamination from per- and polyfluoroalkyl substances on farmland where biosolids were used as fertilizer. That led to significant increases in disposal costs as

more biosolids were routed to landfills both in the state and in other states and Canada.

Mark Lyons, Aries' senior director of business development, said Sanford currently sends its biosolids up to 150 miles away. While the company has faced tough questions from nearby residents, community leaders have been broadly supportive of Aries' project, Lyons said. He also noted the proposed site has several advantages for Aries, including underlying water, sewer and power infrastructure and good truck access.

"The city is aware of the biosolids disposal problem. They're very encouraged by our PFAS destruction capabilities, and they're ... looking for a new technology that can safely manage biosolids, reduce volume, create value-added products, and destroy PFAS," Lyons said.

Aries hopes to bring the site online by the end of 2028, though it still has permitting hurdles to get through. Mueller said the company began the process two years ago, before the issues at Linden became apparent. But it's always been the company's goal to expand, and it now sees a clear path to move forward.

"We expect Linden to come online shortly after Sanford. We're still working on that schedule with our engineering to understand it,"

Mueller said. “Did we set out to do it this way? No. Has it worked out to be this way? Yes.”

ABSTRACT: Per- and polyfluoroalkyl substances (PFASs) are fluorinated organic chemicals that are concerning due to their environmental persistence and adverse human and ecological effects. Remediation of environmental PFAS contamination and their presence in consumer products have led to the production of solid and liquid waste streams containing high concentrations of PFASs, which require efficient and cost-effective treatment solutions. PFASs are challenging to defluorinate by conventional and advanced destructive treatment processes, and physical separation processes produce waste streams (e.g., membrane concentrate, spent activated carbon) requiring further post-treatment. Incineration and other thermal treatment processes are widely available, but their use in managing PFAS-containing wastes remains poorly understood. Under specific operating conditions, thermal treatment is expected to mineralize PFASs, but the degradation mechanisms and pathways are unknown. In this review, we critically evaluate the thermal decomposition mechanisms, pathways, and byproducts of PFASs that are crucial to the design and operation of thermal treatment processes. We highlight the analytical capabilities and challenges and identify research gaps which limit the current understanding of safely applying thermal treatment to destroy PFASs as a viable end-of-life treatment process.

KEYWORDS: *Thermal treatment, pyrolysis, combustion, incineration, PFAS*

1. INTRODUCTION

Per- and polyfluoroalkyl substances (PFASs) are synthetic organic chemicals containing a completely or partially fluorinated alkyl chain. Fluorine is strongly electronegative, causing a short bond length between the C and F. While these structures are desirable for the numerous applications of PFASs, C−F bonds are highly stable and thus poorly susceptible to degradation by hydrolysis, oxidation, photolysis, and biological processes.[1]

The unique chemical structures of PFASs make them naturally hydrophobic, oleophobic, and thermodynamically stable. PFASs have been utilized for over 70 years to produce consumer products with water, stain, and chemical repellence, and/or resistance to thermal degradation. PFASs have been used in food packaging, cookware, textiles and carpets, cosmetics, ski wax, building and automotive materials (e.g., wiring, piping, sealants, adhesives, paints, roofing), and mist-suppression in chrome-plating factories.[2−6] They have also been used in aqueous film-forming foams (AFFFs), which represent a significant source of environmental contamination stemming from military and nonmilitary fire training and hydrocarbon fire suppression.[7−13] Approximately 2000 PFASs have been identified in the global market for intentional use, and at least 6000 CAS-indexed PFASs exist with more than 5000 having defined structures.[14] As a result, PFASs are ubiquitous in the environment,[15,16] and they are detectable in wildlife and humans.[17−19] The likelihood of exposure in combination with the potential for adverse ecological and health effects[20−25] has caused tremendous concern.

In the United States (U.S.), the regulatory landscape for PFASs at the state and federal levels is rapidly changing. In 2016, the U.S. Environmental Protection Agency (US EPA) announced a drinking water health advisory limit of 70 ng/L for the sum of perfluorooctanoic acid (PFOA) and perfluorooctanesulfonate (PFOS),[26,27] and some U.S. states have adopted more stringent guidance.[28] As of 2021, no additional federal regulations have been set, but drinking water primary

standards under the the Safe Drinking Water Act and waste disposal rules under the Resource Conservation and Recovery Act are expected.[29] While replacements for PFOS and PFOA have been developed with increased renal clearance rates and/or biodegradability, for example, shorter-chain perfluorocarboxylic acids (PFCAs), perfluoroether carboxylic acids, and perfluorosulfonic acids (PFSAs),[30,31] recent toxicological studies have shown they are potentially harmful.[32] For example, in 2021, the US EPA established a chronic oral reference dose for one of the most common PFOA replacements, hexafluoropropylene oxide (i.e., GenX, 3 ng/kg-day), which is ∼10 times lower than for PFOA and PFOS and 100 times lower than for perfluorobutanesulfonate (PFBS).[33]

Various physical and chemical treatment processes have been explored to remove PFASs from environmental media.[34] Physical treatment processes such as adsorption,[35−37] ion exchange,[37−39] and membrane filtration[16,40] are effective for contaminated water or aqueous waste streams (e.g., soil washing[41]), but they produce solid or liquid wastes containing high concentrations of PFASs that still require defluorination to alleviate long-term environmental impacts. While conventional and advanced chemical treatment methods such as oxidation (e.g., ozone, UV/H_2O_2) are largely ineffective for destruction of PFASs, a number of advanced methods are being developed including electrochemical oxidation, sonolysis, bioremediation, advanced reduction, and nonthermal plasma.[42−48] In general, these latter technologies are unproven at scale and/or poorly defluorinate PFASs in time frames that are useful for full-scale application. There is therefore a need for a proven and scalable destruction method for waste streams which contain PFASs.

Thermal treatment processes (e.g., incineration) offer a common, scalable, and widely available approach for managing contaminated solids, liquids, or gases,[49] and many incineration facilities are already knowingly or unknowingly treating PFASs (e.g., consumer products, activated carbon regeneration). Thermal treatment of PFASs has been demonstrated at scale by several commercial interests and is thought to result in mineralization.[50] While thermal treatment processes are generally energy intensive and costly, the technology has already been deployed, and together, these advantages place them as a key solution for managing PFAS-containing wastes.

Many unknowns remain about the thermal behavior of PFASs, despite a growing body of research. In this review, we critically evaluate and summarize the volatility, decomposition mechanisms and pathways, and products of the thermal degradation of PFASs. We further discuss the implications of these mechanisms on thermal degradation of PFASs for industrial-scale thermal treatment systems and highlight analytical methods and needs.

2. SURFACE INTERACTIONS AND VOLATILITY

Thermal decomposition of PFASs sorbed to materials can be initiated via two pathways. First, as the temperature of a solid increases, some PFASs volatilize and undergo gas-phase reactions. Second, some less volatile PFASs undergo thermal degradation in/on the solids. Thus, the extent and type of thermal degradation byproducts are likely to differ based upon the parent PFAS compounds volatility. Aqueous PFASs that are deprotonated or adsorbed to solids via electrostatic or ion exchange interactions have very low propensity to enter the gas phase until the temperature rises above 100 °C, when water evaporates and interactions with the solid weaken. For example, during regeneration of a PFAS containing media, PFOA did not volatilize below 90 °C, then gradually decreased in surface concentration as the temperature increased from 90 to 400 °C.[51]

Vapor pressure describes the equilibrium between a pure liquid and the gas phase in a closed system. This is reflective of the volatility of a pure compound and is useful in understanding thermal treatment processes. In Figure 1a, we show the vapor pressure for different groups of PFASs as a function of chain length. Note that these are computational estimates by the Antoine equation, rather than experimentally derived values. Two other semiempirical models are shown in Figure S1 for comparison, and a comparison of modeled and experimentally measured vapor pressures of fluorotelomer alcohols (FTOHs) is listed in Table S1. Volatility of various structures followed the order of perfluorocarbons (PFCs) > fluorotelomer carboxylic acids (FTCAs) > FTOHs ≈ PFCAs > PFSAs > fluorotelomer sulfonates (FTSAs). Across these same functional groups, vapor pressure increased with decreasing chain length. These modeled trends are further supported by the experimentally derived data shown in Figure 1b and an additional study which reported boiling points of C4−C8 PFCAs and PFSAs increasing from 121 to 192 °C and 210 to 249 °C, respectively.[35] Lower sublimation

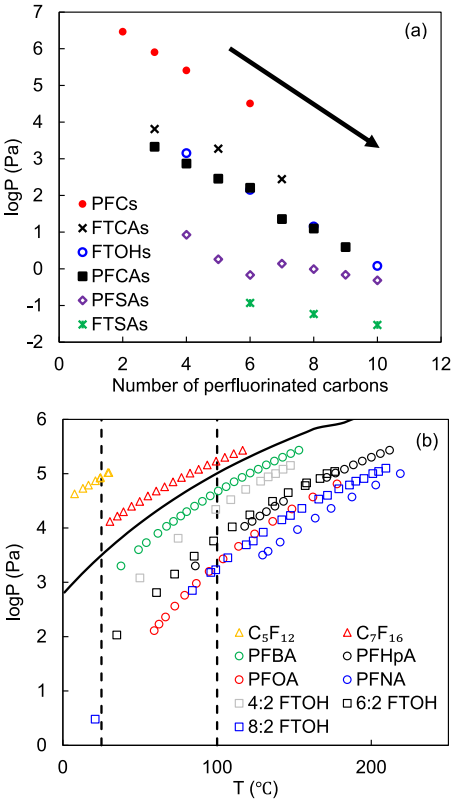

Figure 1. (a) Perfluorocarbon (PFC), fluorotelomer carboxylic acid (FTCA), fluorotelomer alcohol (FTOH), perfluorinated carboxylic acid (PFCA), perfluorinated sulfonic acid (PFSA), and fluorotelomer sulfonate (FTSA) vapor pressures (P) at 25 °C from the semiempirical Antoine method in EPISuite.[57] Arrow indicates a trend of decreasing vapor pressure for longer-chain PFAS. (b) Experimentally determined vapor pressure of specific PFASs over a range of temperatures adapted from Ding and Peijnenburg.[53] Compounds with the same number of fluorinated carbons are shown in the same color, and compounds with similar structures or functional groups have the same marker. The black line shows water vapor pressure. Additional abbreviations are perfluorobutanoic acid (PFBA), perfluoroheptanoic acid (PFHpA), perfluorooctanoic acid (PFOA), and perfluorononanoic acid (PFNA).

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370
KD2860

vapor pressures have been reported for an increasing number of fluorinated carbons,[52] again providing evidence that shorter-chain PFASs are more volatile.

Experimental vapor pressures versus temperature for a limited set of PFASs[53] are shown in Figure 1b. PFCs were more volatile than water, indicating that PFCs are likely to volatilize before water. At temperatures lower than the boiling point of water, some liquid phase water may remain, and this is particularly meaningful for perfluoroalkyl acids (PFAAs). However, very few experimentally determined Henry's Law constants are available in published literature which presents a substantial weakness in the understanding of PFASs' volatilities.[53,54] Further, some PFASs decompose at temperatures lower than the temperature required for vaporization.[55]

However, considerations of pure-phase PFASs, PFASs on surfaces, or even single-solute solutions are probably over-simplifications. The presence of cations in solution can form salts with PFASs that influence the ability to predict volatilization. Also, the composition and heterogeneity of surfaces on which PFASs exist will likely influence the propensity of a PFAS to volatilize from a surface. For example, research on soil demonstrated that volatilization was minimal for both PFCAs and PFSAs at 220 °C over 14 days,[56] despite PFCAs boiling points suggesting they would volatilize at temperatures below 200 °C. The mechanisms and roles of surface hydrophobicity on temperatures at which PFASs volatilize from surfaces remain poorly understood. However, as temperatures increase to far above predicted temperatures for volatilization, the dependence of PFAS volatilization on the PFAS structure decreases.

3. DECOMPOSITION INITIATION, PRODUCTS, MECHANISMS, AND KINETICS

Reported primary thermolytic mechanisms of PFASs include cleavage of intramolecular bonds through transition states (TS), direct homolytic cleavage, radical reactions, hydrolysis, and oxidation. Each mechanism and pathway produce some distinct, but also some overlapping, decomposition products. Temperatures at which PFASs volatilize from surfaces may be higher than temperatures at which thermal decomposition initiates, making it difficult to differentiate between these two different mechanisms.[58,59] While acknowledging the potentially synergistic role of surfaces (see Section 4.2 for more discussion), the temperatures required to initiate PFAS decomposition appear to be related to both the number of perfluorinated carbons and functional groups. Pyrolysis (absence of oxygen) and combustion (presence of oxygen) are influenced by functional groups because pyrolysis is unimolecular and initiates with the decomposition of the least stable group, and combustion is initiated by reactions between O_2 and the most reactive group. A summary of experimentally derived thermal decomposition products of PFASs are provided in Table S2. Various perfluorinated gases and solids such as coke and polymeric materials may be formed during pyrolysis (in dry inert conditions) and may persist even at temperatures above 1000 °C.[60−65] Generally, PFASs are pyrolyzed into other forms of organofluorine, including volatile organofluorine (VOF), especially at temperatures less than 500 °C. The lack of closed mass balances (>90% F accounted for) for nearly all experiments strongly implies that some fluorinated products may escape thermal and post-treatment processes, elude detection, and be released to the environment. Additionally, nearly all studies of thermal decomposition of PFASs are conducted under pyrolytic conditions, and therefore, our discussion primarily focuses on pyrolysis, with combustion discussed where data are available.

3.1. Temperatures Required to Initiate Decomposition. Temperatures required to initiate decomposition in terms of structure decrease as follows: perfluorocarbons (PFCs) > perfluoroacyl fluorides > PFSAs > PFCAs > perfluoroether carboxylic acids.[66] The order of the decomposition rates of PFCs (C_xF_y) between 1000 °C and 1250 °C was CF_4 < C_2F_6 < cyclo-C_5F_{10} < C_3F_8 < n-C_4F_{10} < n-C_5F_{12},[61] indicating that the temperature required to decompose PFCs decreases with an increasing number of carbons, although isothermal rates (i.e., rates measured at a fixed temperature) may not perfectly represent overall thermal stability. Perfluorohexane (n-C_6F_{14}) did not decompose at temperatures less than 400 °C[67] nor in 450 °C air even in the presence of a palladium catalyst.[68] Pure 2H-heptafluoropropane (HFP, C_3HF_7) did not decompose at temperatures less than 640 °C,[65] and perfluoropentane (n-C_5F_{12}) was not decomposed below 840 °C.[60]

Xiao et al.[66] studied thermal stability of PFASs sorbed to GAC and found that the temperatures needed to degrade PFCAs increased with an increasing number of perfluorinated carbons. The decomposition of PFSAs generally requires higher temperatures (450 °C) than PFCAs (200 °C), and perfluoroether carboxylic acids are more readily decomposed than PFCAs with the same number of fluorinated carbons, demonstrating that ether bonds weaken the molecule.[66] For acids, the counterion may also impact the thermal stability. For example, Lines and Sutcliffe[69] reported that the thermal stability of PFOA salts increased with the following counterions: ammonium < cesium < potassium < silver < lead < sodium < calcium = barium < lithium.

The temperatures required to decompose fluoropolymers are related to monomeric structure, extent of fluorination, and physiochemical conditions (e.g., reactor material, atmosphere).[70−72] Baker and Kasprzak found that $-CF_3$ branching leads to reduced Teflon thermal stability.[73] Overall, polymers of perfluoroethylene are more stable than perfluorophenylene.[74] Fully fluorinated polymers made up of tetrafluoroethylene and/or hexafluoropropylene are the most thermally stable.[71,74] Also, increasing molecular weight tends to reduce thermal stability,[29,30] and some copolymers containing trifluoronitrosomethane (CF_3NO) or (OCF_2) monomers are poorly stable, decomposing at temperatures as low as 200 °C.[71,72]

Reactor materials and reaction conditions (e.g., presence of O_2) also influence the thermal stability of PFASs. For example, heptafluorobutyric anhydride decomposed at as low as 150 °C in a reactor containing alumina but was stable up to 850 °C in a tantalum or silver reactor.[75] Several fluoropolymers such as fluorosilicone B and polyvinylidene fluoride decomposed more rapidly in the presence of O_2 than in a vacuum/inert atmosphere,[71,72] although others have demonstrated that vacuum/inert vs oxidizing atmosphere causes minimal differences in decomposition rates.[70] Even some copolymers (e.g., CF_3NO/C_2F_3H) have been shown to decompose slower in an oxidizing atmosphere than an inert one.[71,72]

Overall, the thermal decomposition initiating temperatures are determined by the least stable part of a molecule, which is typically a nonfluorinated functional group. PFCs, which contain no such functional groups, are thus the most stable, and their stability decreases with increasing perfluoroalkyl chain length. This indicates that at a specific temperature the loss of a longer-chain PFAS should not be interpreted as mineralization,

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370
KD2861

as it is possible or likely that it was decomposed to a shorter-chain, more thermally stable, PFC or PFAS.

3.2. Decomposition Products. *3.2.1. Perfluorocarboxylic Acids.* Products of the pyrolysis of PFCA salts include perfluoroacyl fluorides and anhydrides, corresponding acids, and even dimers of the perfluoroalkyl chains (Figure 2).[76,77]

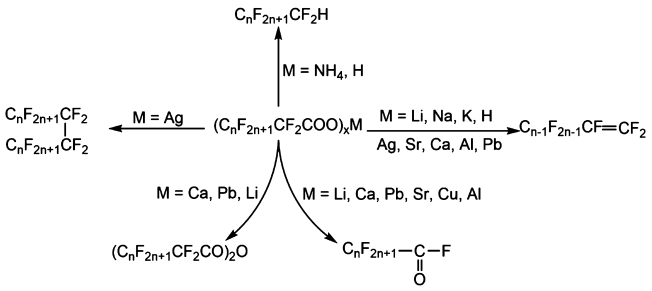

Figure 2. Pathways and products of PFCAs and their salts at temperatures of 200 to 305 °C during pyrolysis. Produced from results presented by LaZerte et al.[76]

Longer-chain PFCA pyrolysis products include shorter-chain PFCAs such as 1*H*-perfluoroalkanes, perfluoro-1-alkenes, and unidentified VOF, CO, CO_2, and HF (Table S2). Perfluoro-1-alkenes are a dominant product of metal salts of PFCAs (except trifluoroacetic acid [TFA] and its salt), and the yield varies with the species of counterion. TFA salts form trifluoroacetyl fluoride and trifluoroacetic anhydride as primary products.[76,78] Sodium or potassium salts of longer-chain PFCAs (C > 3) consistently had the greatest yields of the primary product, perfluoro-1-alkenes, and the yield increased with shortening carbon chain length.[76] Ammonium salts of PFCAs yield neither alkenes nor acetyl-containing compounds but instead almost quantitatively forms 1*H*-perfluoroalkanes.[76,79] Notably, the formation of dimers of the perfluoroalkyl chains was observed for the silver salts of PFCAs. Such detailed observations of varying counterions are not available for PFASs outside of PFCAs during pyrolysis, but given the significant differences between decomposition products and the likelihood of a diversity of counterions present in environmental samples, additional research is warranted, particularly for combustion of soils where PFCAs are likely to be present as salts.[80]

3.2.2. Perfluorosulfonic Acids. PFSAs appear to be thermally defluorinated to a greater extent than PFCAs (i.e., producing stoichiometrically more mineralized fluorine), although the number of investigations available to draw this conclusion is limited.[81−83] Quantification of organic intermediates are rarely presented in these studies, although mass fragments (CF_3^+, $C_2F_3^+$, $C_3F_3^+$, $C_2F_4^+$, $C_2F_5^+$, $C_3F_5^+$, $C_4F_7^+$, $C_5F_9^+$) of some products were observed by GC-MS after thermal decomposition in the presence of lime.[83] The presence of these mass fragments strongly suggests that VOF is a product of thermolysis of PFSAs.[58] Recently, some fluorinated olefins have been identified as thermal decomposition products of PFOS.[84]

3.2.3. Perfluorocarbons. Pyrolysis products of perfluoroalkanes and perfluoroalkenes are similar and include C_2F_6, C_2F_4, C_3F_8, C_3F_6, polymeric compounds, and solid-phase charred residues (Table S2). These products are thought to form as a result of homolysis of C−C bonds (each C retains one electron that formed the bond), forming radicals which in many cases yield stable PFASs such as polymers and cyclo-compounds.[60,64,65] Formation of the products has been shown to be temperature dependent. The thermal decomposition of C_2F_4 was studied from 300 to 800 °C, and the primary product was dimerization to cyclo-C_4F_8 at temperatures below 550 °C. *n*-C_3F_6 and *n*-C_4F_8 were generated between 550 and 700 °C, and C_2F_6, perfluoroisobutene (PFIB, $(CF_3)_2C{=}CF_2$), and other nonvolatiles were formed between 700 and 750 °C.[85,86] In another study, the thermal decomposition of cyclo-C_4F_8 formed *n*-C_3F_6 and C_2F_4 as principal products between 360 and 560 °C.[87] Matula[88] examined *n*-C_3F_6 from 550 to 675 °C and found that perfluoro-2-butene ($CF_3CF{=}CFCF_3$) and PFIB were the primary reaction products.

3.2.4. Fluoropolymers. The thermal decomposition products of fluoropolymers include monomers, dimers, trimers, perfluorocarbons, CO_2, and SiF_4 (when quartz is present).[74,89] C_2F_4 was the primary pyrolysis product of polytetrafluoroethylene (PTFE).[73] The subsequent decomposition of C_2F_4 is discussed in Section 3.2.3.[90] The copolymer-fluorinated ethylene propylene (FEP) more readily forms PFIB than PTFE likely because of the inclusion of a −CF-CF_3− monomer along with −CF_2− in FEP. PFIB is relatively stable and highly toxic.[73,91] Zuev et al.[89] investigated the thermal decomposition of acrylic polymers with fluorinated side chains at 450 to 750 °C and found that the key decomposition pathway of the polymer was scission of the primary polymer carbon bonds. The fluorinated alkyl ester side chains were highly stable and transformed into corresponding fluorinated cycloalkanes.

In the oxidizing atmospheres, carbonyl fluoride (COF_2) is a common gaseous product.[72,73] Defluorination occurs to a greater extent in air (∼60%) than in nitrogen (∼17%).[72,73] TFA and longer-chain perfluoro- and/or polychlorofluoro carboxylic acids (C3−C14) were formed during thermolysis of PTFE and Kel-F at temperatures lower than 500 °C in the presence of O_2 and H_2O.[92] Combustion of fluorinated polymers did not tend to produce PFOA when the temperature was above 1000 °C, similar to municipal and/or medical waste incineration.[50,93] This suggests that the risk of releasing well-known PFASs from incinerators when polymers are combusted may be limited, but there is still the potential to release low molecular weight VOF (Table S2).

Figure 3 is a visual representation of the thermochemical stability and defluorination of PFASs for which there are sufficient data. Although some of the regions are approximate because the experimental data are somewhat coarse, the figure demonstrates overall that mineralization tends to occur above 700 °C in oxidizing atmospheres and that at lower temperatures and in inert atmospheres VOF is formed. This has broad implications for incinerators, which are operated with supplemented air at temperatures greater than 700 °C, potentially limiting the release of VOF. Again, there are few studies of combustion of PFASs, and these studies are limited to select groups of compounds. There is a significant need to study additional PFAS decomposition during combustion to inform treatment approaches of potential gas-phase products. PFAS groups that are not included in this figure have no or too limited published data to make broad conclusions. For example, FTOHs are volatile and thus may escape in the gas phase prior to degradation, but there are limited data available regarding temperatures required to achieve thermal decomposition and/or products.[94] Study of significantly more PFASs (e.g., alcohols, ethers) that are expected to be present in environmental samples and waste streams is warranted to understand the byproducts in relation to the thermolysis temperature.

3.3. Mechanisms and Pathways. *3.3.1. HF Elimination via Transition States. 3.3.1.1. Perfluorocarboxylic Acids.*

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370
KD2862

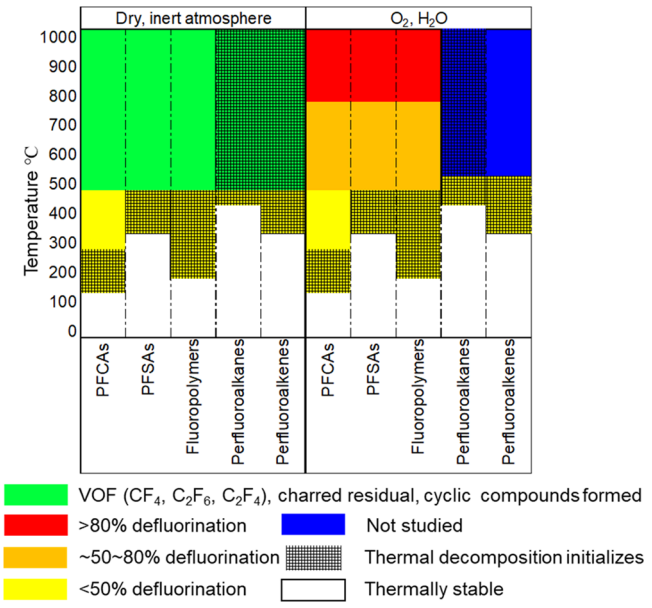

Figure 3. Summary of approximate thermal decomposition in inert and oxidizing atmospheres based on available data provided in Table S2.

Figure 4 illustrates several PFCA decomposition pathways based upon both experimental or computational studies.[95−99] It is worth mentioning that density functional theory calculations are generally carried out at zero Kelvin and that more rigorous ab initio molecular dynamics can simulate thermal effects.[100,101] Pathway 1 depicts the formation of 1*H*-perfluoroalkanes, which begins with HF elimination via a five-membered TS, resulting in the formation of CO_2 and a carbene (C_nF_{2n-1}−:CF). The carbene then reacts with HF to form a 1*H*-perfluoroalkane.[102] 1*H*-Perfluoroalkane formation via pathway 5 has also been proposed.[98] Further, 1*H*-perfluoroalkanes may not be the only products during PFCA pyrolysis. Perfluoro-1-alkenes via a six-membered TS2 may also be possible for long-chain PFCAs (pathway 2), and moderate amounts of perfluoro-1-heptene have been observed during PFOA pyrolysis.[102] Also, through TS2, PFPrA can form perfluoroacetyl fluorides, but this product is specific to PFPrA because it contains only two fluorinated carbons.[66]

Recently, Xiao et al.[66] proposed that thermal decomposition of PFOA on GAC surfaces is initiated by loss of a fluorine atom and −COOH to generate a perfluorocarbon radical (pathway 4), followed by loss of fluorine or CF_2 based on GC-MS identification of the organic fluorine products. There is, however, some debate over the decomposition pathway.[103,104]

Rayne and Forest[77] proposed a terminal perfluoroalkyl carbanion as an intermediate via thermal decarboxylation (pathway 3), yielding 1*H*-perfluoroalkanes by reacting with ambient protons or yielding perfluoroalkenes through loss of a fluorine. However, this pathway is more likely in polar solvents than the gas phase, because the dissociation energy of heterolysis is thought to be greater than homolysis for the same covalent bond in the gas phase.[105]

At least two computational studies of the pyrolysis of PFCAs indicated that direct decarboxylation is not likely to be the main pathway because of the high activation energy.[95,98] The primary decomposition pathway in these studies is HF elimination and the formation of an α-lactone intermediate (M1) via pathway 6, which is not thermally stable and is then degraded to a perfluoroacyl fluoride (M2) and CO at relatively low temperatures (<500 °C).[98] At high temperatures (>1000 °C), M1 tends to be degraded into CO_2 and M3.[98] The formation of M2 is supported by experimental studies of the pyrolysis of the simplest PFCA, TFA (CF_3COOH), which forms COF_2, likely first through the loss of HF and formation of a lactone, followed by loss of CO. This pathway is further supported by the observed

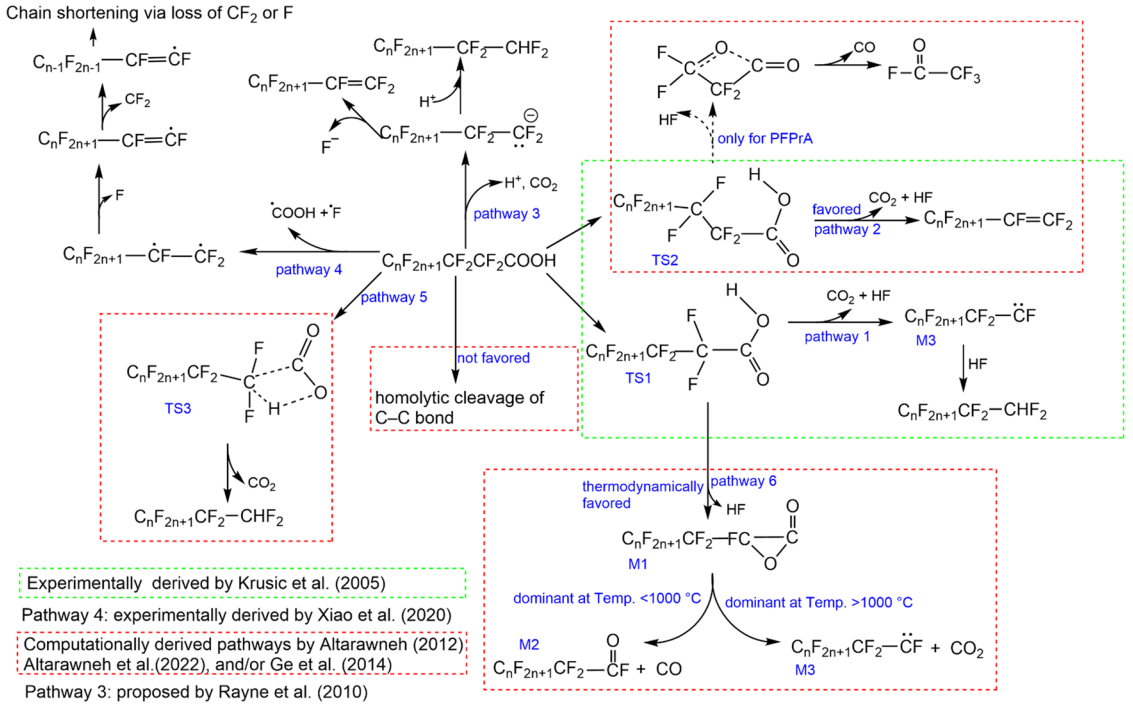

Figure 4. Published experimentally and computationally derived pyrolysis pathways of PFCAs. Dashed boxes indicate the literature source (see bottom left).

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2023, 57, 5355−5370

KD2863

formation of M2 during pyrolysis of PFCA metal salts, both agreeing well with the products in Table S2.

Although M2 has been computationally predicted to be the primary product of PFCAs and has been observed during the thermal decomposition of TFA and PFCA metal salts, M2 was not detected in other experiments of PFCA acids (Table S2). M2 (i.e., CF_3COF) is thermally stable up to ~600 °C (Table S2), and thus, the lack of detection is surprising. The lack of M2 detection may be because either the experimental conditions (e.g., reactor materials) altered the thermal decomposition pathway or because M2 readily reacts with HF and H_2O to form other compounds (Section 3.3.3).

Another poorly understood area of the decomposition of PFCAs is which pathway dominates the formation of the observed intermediates/products (e.g., 1*H*-perfluoroalkanes, perfluoro-1-alkenes). Pathways 1 and 2 support the observed formation of 1*H*-perfluoroalkanes and perfluoro-1-alkenes but fail to explain the traces of short-chained PFBA and perfluoropentanoic acid (PFPeA) present during PFOA pyrolysis.[82] Further, the carbene intermediate in pathway 1 does not explain why water promotes the decomposition of PFOA[77] or how the counterion influences PFCA thermal stability and product formation. Additional products not described well by these pathways have been observed during the pyrolysis of TFA,[106,107] further indicating that the mechanisms may be more complicated than current publications explain.

3.3.1.2. Perfluorosulfonic Acids. For PFSAs, only computationally derived decomposition pathways are available (Figure 5). HF elimination (hydrogen from the sulfonic acid and

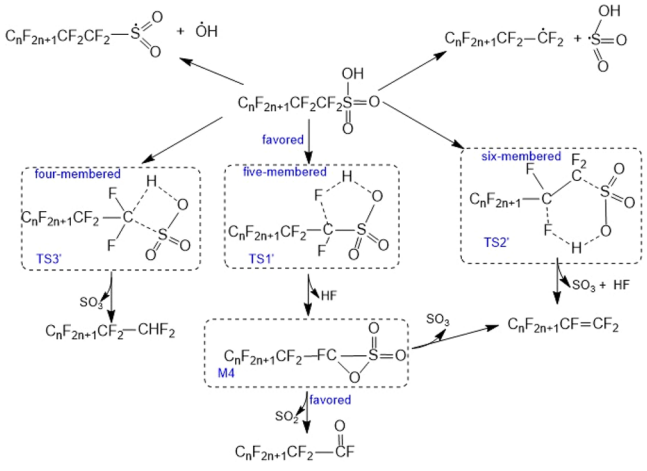

Figure 5. Computationally derived pyrolysis pathways of PFSAs.[96,99]

fluorine from the α carbon) via a five-membered TS1′ is thought to dominate, resulting in formation of an intermediate α-sultone (M4), which is then degraded to a perfluoroacyl fluoride and SO_2 at all studied temperatures.[96,99] Competing pathways include HF elimination leading to the formation of perfluoro-1-ene and SO_3 via six-membered TS2′ and 1*H*-perfluoroalkane formation via TS3′.[96,99]

3.3.1.3. Other Per- and Polyfluoroalkyl Substances. HF elimination is thought to also occur for other PFASs. HF elimination was confirmed experimentally and computationally during the thermal decomposition of 2*H*-heptafluoropropane (R1).[65,108,109] HF elimination was also demonstrated as a pathway for perfluoroalkanol pyrolysis.[110] Thus, HF elimination appears to be a component of multiple pathways of the pyrolysis of PFASs that contain hydrogen in the carbon chain or in a functional group. This is advantageous to incinerators that capture off gases using wet scrubbers, where HF would be captured and retained.

$$CF_3CHFCF_3 \rightarrow CF_3CF = CF_2 + HF \quad \text{(R1)}$$

3.3.2. Direct Cleavage of Intramolecular Bonds. The direct cleavage of intramolecular bonds has been demonstrated to be an initiating mechanism during thermal decomposition of PFASs. During pyrolysis of perfluoropolymers[89,92] and perfluorocarbons,[60,61,64,65,111] intramolecular C−C bond cleavage is dominant in initial reactions. The cleavage proceeds through (1) homolytic cleavage of C−C bonds resulting in the formation of perfluorocarbon radicals[60,61,64] and (2) radical recombination to form relatively thermally stable short-chain VOF or reactions with other matter (e.g., O_2, H_2O, •OH) if available.

One example of the direct cleavage of intermolecular bonds is the decomposition of perfluoroacyl fluorides, which proceeds initially through cleavage of the CF_2−COF bond (R2), leading to a perfluorocarbon radical and •COF.[99] Another example is the cleavage of C−F bonds, which has been observed during thermal decomposition of COF_2 (R3).[112]

$$C_nF_{2n+1}CF_2COF \rightarrow C_nF_{2n+1} - \bullet CF_2 + \bullet COF \quad \text{(R2)}$$

$$COF_2 \rightarrow \bullet COF + \bullet F \quad \text{(R3)}$$

Pyrolysis of perfluorocarbons also proceeds via cleavage of intramolecular bonds and generally yields similar gaseous products independent of the parent structure (Table S2). We summarize the potential pathways for the formation of the most common products (C_2F_6, C_2F_4, C_3F_8, C_3F_6, C_4F_8) with *n*-C_4F_{10} as an example in Figure 6. Additional information related to minor, high activation energy perfluorocarbon radical reactions is available in works by Buravtsev and Kolbanovskii[113] and Yu et al.[64]

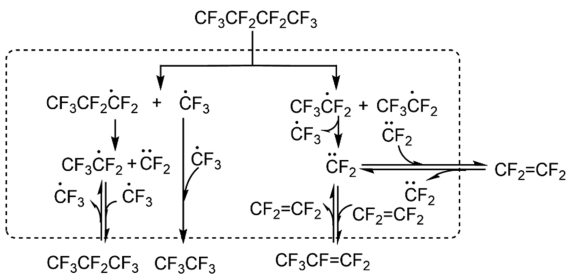

Figure 6. Summarized pyrolysis pathways of perfluorocarbons based on work by Yu et al.[64]

3.3.3. Intermolecular Reactions. 3.3.3.1. Reactions with Radicals and Oxygen. H_2O thermolysis yields •OH and •H at extremely high temperatures (>2000 °C).[114,115] Although the formation of radicals from water thermolysis at typical incinerator temperatures is likely to be low, we discuss their impact on decomposition during thermolysis because they promote decomposition of PFASs by allowing for new decomposition pathways and acting as a source of H for defluorination. In the presence of •OH and •H, abstraction of hydrogen is the dominant reaction pathway for *H*-fluoroalkanes (Figure 7, green box).[116] For sulfonic acids, H abstraction from the sulfonic acid group forms an intermediate M5 which is then decomposed into a corresponding perfluorocarbon radical and

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370

KD2864

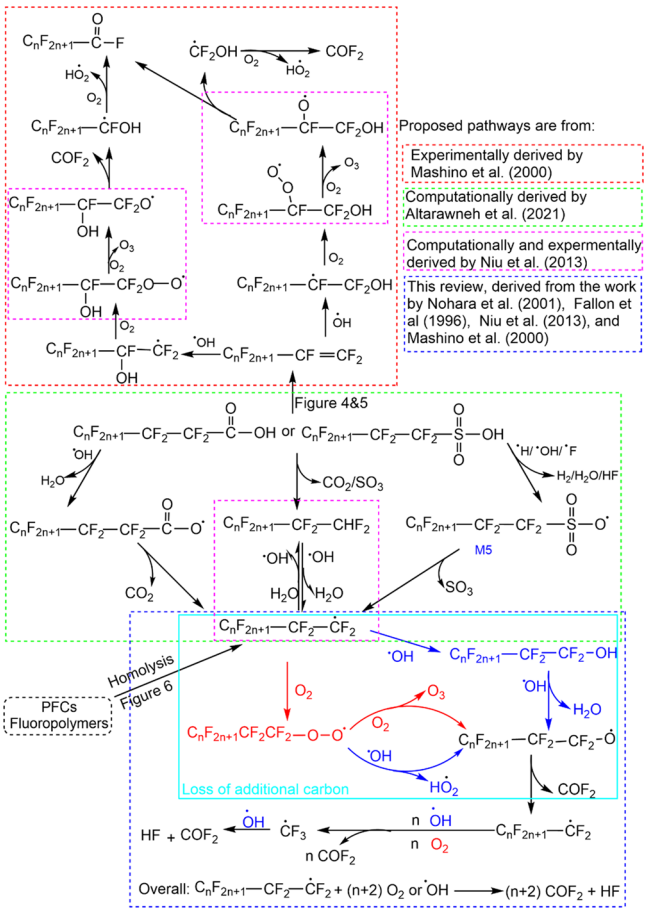

Figure 7. Reactions with •OH and O_2 with PFASs and PFAS decomposition products.[99,117−121] Pathways are generalized regardless of carbon chain length. Dashed boxes indicate literature source (see top right).

SO_3 (Figure 7, green box, right).[99] Similarly, •OH reacts with PFCAs to form a perfluorocarbon radical and CO_2 (Figure 7, green box, left), which has been experimentally observed during drinking water advanced oxidation processes.[117] Although fluorine abstraction is a possible pathway, it is not thermodynamically favored and therefore not illustrated.[116] •OH also attacks carbon−carbon double bonds, initiating the oxidation of perfluoroalkenes in the presence of O_2 to produce corresponding perfluoroacyl fluorides and COF_2 (Figure 7, red box).[118]

On the basis of the mechanisms depicted in the magenta and blue boxes of Figure 7, combined with the appearance of the corresponding expected products in Table S2, we find that the thermal defluorination of PFASs is promoted in the presence of O_2 and H_2O because they participate in reactions with perfluorocarbon radicals. O_2 reacts with perfluorocarbon radicals and the perfluorocarbon chain, and the carbon chain is shortened stepwise through release of COF_2. This has been demonstrated experimentally by the oxidation of PFOA by •OH in an electrochemical system[119] and a photochemical reaction system.[120] The observed formation of COF_2 during thermal decomposition of fluoropolymers provides additional experimental support for this pathway.[72,73]

3.3.3.2. Hydropyrolysis. Water promotes the thermal decomposition of PFASs by hydrolyzing the common intermediate products, perfluoroacyl fluorides (Figure 4, pathway 6; Figure 5, favored pathway; and Figure 7, red box). Perfluoroacyl fluorides are highly thermally stable but react with water to form corresponding PFCAs which are then decomposed to shorter-chain perfluoroacyl fluorides by HF elimination.[122,123] Alternating HF elimination and hydrolysis then occurs, forming shorter and shorter-chain PFCAs (Figure 8).[99,123] An example of such is the formation of PFBA and

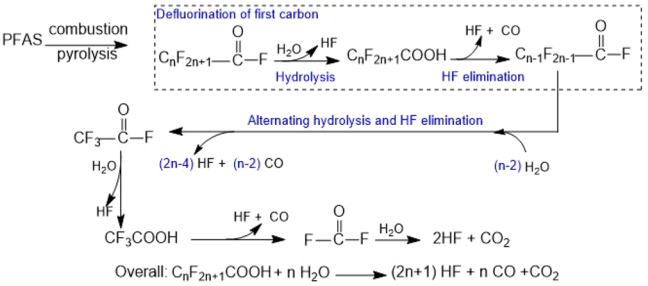

Figure 8. Mineralization of PFASs by alternating hydrolysis and HF elimination during hydropyrolysis.[99,122,123] Combustion and pyrolysis of PFASs to perfluoroacyl fluorides are described in Figures 4, 5, and 7.

PFPeA during PFOA/PFOS hydropyrolysis.[82] The final decomposition product, COF_2, readily reacts with water to produce CO_2 and HF.[124] These reactions have been shown to result in mineralization of F in seconds at temperature as low as 780 °C,[125] but the kinetics at varying temperatures have not been formally measured to our knowledge and are needed to inform hydropyrolytic thermal treatment processes. In the absence of water, the only mechanism which is known to decompose perfluoroacyl fluorides is direct cleavage of intramolecular bonds (Section 3.3.2, R2), resulting in relatively poor defluorination.

At alkaline pH, hydrothermal decomposition of PFOS occurs via OH^- attack of the C alpha to the $-SO_3$, forming a perfluorinated alcohol and SO_3^{2-} (R4).[110,126] The perfluorinated alcohol undergoes HF elimination to form a perfluoroacyl fluoride,[110] which is then hydrolyzed to a corresponding PFCA. The PFCA is ultimately mineralized by decarboxylation and releases F^- (see Figure 8).

$$C_nF_{2n+1} - CF_2 - SO_3^- + OH^- \rightarrow C_nF_{2n+1} - CF_2 - OH + SO_3^{2-} \quad \text{(R4)}$$

3.3.3.3. Reactions with HF. Perfluoroacyl fluorides react with water to form a corresponding PFCA and HF, and this reaction is reversible (R5).[106,127] This mechanism likely competes with those shown in Figure 8, where alternating HF elimination and hydrolysis result in PFAS chain shortening. As an example, perfluoroacyl fluorides have been shown to be formed during pyrolysis of TFA.[106,107,127]

Perfluoroacyl fluorides also react with HF to form perfluoroalkanols by R6.[99] HF may also reversibly react with perfluoroalkenes to form *H*−perfluoroalkanes (R7).[97] Finally, it has been demonstrated that addition of lime to PFAS-containing sludge sequesters F as CaF_2 at temperatures between 300 and 600 °C, but F is released back to the gas phase as HF or SiF_4 at higher temperatures (700−900 °C).[83] These products and decomposition pathways demonstrate that the mechanisms are complex and in many cases lead to the formation of new PFASs which are not part of routine monitoring analyses.

$$C_nF_{2n+1} - COOH + HF \rightleftharpoons C_nF_{2n+1} - COF + H_2O \quad \text{(R5)}$$

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370

KD2865

$$C_nF_{2n+1} - COF + HF \rightarrow C_nF_{2n+1} - CF_2 - OH \quad (R6)$$

$$C_nF_{2n+1} - CF = CF_2 + HF \rightleftharpoons C_nF_{2n+1} - CF_2 - CF_2H \quad (R7)$$

3.3.3.4. Surface Catalyzed Reactions. Some oxides (e.g., SiO_2 and Al_2O_3) used as thermolysis reactor materials can participate in the reactions of PFAS thermal decomposition. For example, during pyrolysis of cyclo-C_4F_8 in an inert atmosphere, Butler[87] demonstrated that CO, CO_2, SiF_4, and black solids were produced, and they also noted that the Pyrex reactor was etched. Notably, no oxygen is present in the parent compound, and CO_2 is not a known product of the direct cleavage of fluorocarbon intramolecular bonds (Figure 6). Thus, Butler postulated that R9 and R10 are responsible for the formation of the observed CO, CO_2, and SiF_4. Similarly, CO_2 was formed during the pyrolysis of *n*-C_4F_{10} in an alumina reactor, and once the surface alumina was completely reacted, the formation of CO_2 was significantly reduced.[64]

$$2SiO_2 + \text{cyclo-}C_4F_8 \rightarrow 2SiF_4 + 4CO \quad (R9)$$

$$2SiO_2 + \text{cyclo-}C_4F_8 \rightarrow 2SiF_4 + 2CO_2 + 2C \quad (R10)$$

However, the intermediates during these reactions and reactions of nonfluorocarbon PFASs are not completely resolved. A possible mechanism for fluorocarbons is that some fluoroalkane radicals are formed by direct cleavage of intramolecular bonds (e.g., $\bullet CF_2$, $\bullet CF_3$, and $\bullet C_2F_5$, see Section 3.3.2) which subsequently react with surface oxides.[64,128] This is supported by Ng et al.[129] who found that hydroxyl groups on an Al_2O_3 surface were necessary to degrade a model perfluoroether [$(C_2F_5)_2O$], suggesting that surface hydroxyl groups play a key role in the catalyzed oxidation of PFASs, particularly in inert atmospheres where decomposition of PFASs would typically terminate at the corresponding perfluoroacyl fluoride. This is relevant to incineration of contaminated soils, where surface hydroxyl groups are in abundance but there is a lack of water.

There is also emerging evidence that some metals catalyze thermal PFAS defluorination. For example, nickel catalyzed the decomposition of cyclo-C_4F_8, forming the decomposition product C_3F_8 ~55 times faster than in a Pyrex reactor.[87] Ag and Cu catalyzed the defluorination of perfluoropentacene at ~200 °C.[130] Platinum has been shown in one case to catalyze the pyrolysis of fluorocarbons.[61] Overall, research of catalyzed thermolysis of PFASs is not well studied.

3.4. Thermolysis Kinetics. Published kinetics data are limited, and we are not aware of measured kinetics in the presence O_2 or H_2O. From what has been published, it is evident that thermal unimolecular decomposition of PFASs follows first-order kinetics,[66,87,96] and the relationships between rate and temperature are explained well by the Arrhenius equation.[64,87,95,96,131] Temperature not only has a strong influence on the decomposition rates but also on reaction equilibria.[95] For example, HF elimination (Figure 4, M1) is endothermic, and the equilibrium constant of this reaction increases by approximately 11 orders of magnitude as the temperature is increased from 127 to 727 °C.[95]

Perfluorocarbons are relatively recalcitrant with likely the slowest decomposition rates during pyrolysis. This is evident for perfluoroalkanes (C < 5) which have half-lives greater than 1 h even at temperatures as high as 1000 °C,[61] compared to half-life of PFCAs and PFSAs (<1 s).[96] This is particularly relevant for incinerators because the half-lives of perfluoroalkanes far exceed the typical gas-phase retention time of incinerators (seconds). Perfluoroalkanes may be present in such systems in the feed stream or as decomposition products from other processes.

4. IMPLICATIONS FOR THERMAL TREATMENT PROCESSES

4.1. Treatment Processes. Thermal treatment processes use heat to initiate desorption and degradation of contaminants from a solid or liquid waste. They can be used as a targeted approach to remove PFASs from contaminated matrices such as soil or spent water treatment media (e.g., activated carbon, ion exchange brine), or they can be used as a broad approach to manage mixed municipal solid and hazardous wastes that contain PFASs and are not landfilled.

Thermal decomposition is part of thermal treatment, but thermal treatment encompasses the entire process of thermally treating PFASs, PFAS-containing materials, and the associated products. Thermal treatment processes are often associated generally with the term *incineration*, but incineration is a specific process that is outlined by the US EPA. Title 40 of the Code of Federal Regulations (CFR) Part 260.10 defines an incinerator as any enclosed device that uses controlled flame combustion and is not defined by the CFR as a boiler, sludge dryer, carbon regeneration unit, or industrial furnace, or it is an enclosed device that is operated as an infrared or plasma arc incinerator that has a controlled flame combustion afterburner. Thus, when discussing the thermal treatment of PFASs, one should use the specific terms (i.e., desorption, combustion, pyrolysis) and avoid the use of the term incineration, unless referring to a process described by the CFR.

Thermal desorption uses relatively low temperatures (<600 °C) to separate the contaminant from the solid or liquid waste matrix without the intent to degrade the contaminants, although in some cases they are incidentally decomposed.[132] Thermal desorption includes the energy required to overcome the interaction energy between the PFAS and the solid as well as the energy required to drive the PFAS to the gas phase (volatilization). Thermal desorption can be performed in situ or ex situ. In situ thermal desorption is a widely used method because it eliminates additional costs for transport and/or off-site treatment. It is effective for removing some contaminants at a lower temperature and thus at a lower cost, and those that may form more harmful degradation byproducts at higher temperatures. Although, with thermal desorption, a post-treatment process is always required, which incurs additional costs and complexities to the treatment train. Sörengård et al.[133] demonstrated the use of thermal desorption at temperatures ranging from 150 to 550 °C for a mixture of nine PFASs spiked into two soil types at temperatures ranging from 150 to 550 °C. Greater than 99% desorption of these PFASs from the soil was achieved at 550 °C. The temperature that PFASs desorb can be impacted by the matrix. For example, Crownover et al.[56] showed that desorption was minimal for both PFCAs and PFSAs when the soil was heated to 220 °C for 14 days, despite PFCAs having boiling points below 200 °C.[36] The soil needed to be heated to at least 300 °C to desorb 90% of the PFOA and 60% of the PFOS. Shorter-chain perfluorohexanesulfonic acid desorbed to a lesser extent than PFOS at temperatures below 350 °C. Specific matrix effects that change the required temperature to desorb PFASs are unknown and should be a topic of future studies.

Thermal degradation, which follows or is in conjunction with thermal desorption, is the process of using elevated temperatures (300−1000 °C), often in combination with other

Environ. Sci. Technol. 2022, 56, 5355−5370

KD2866

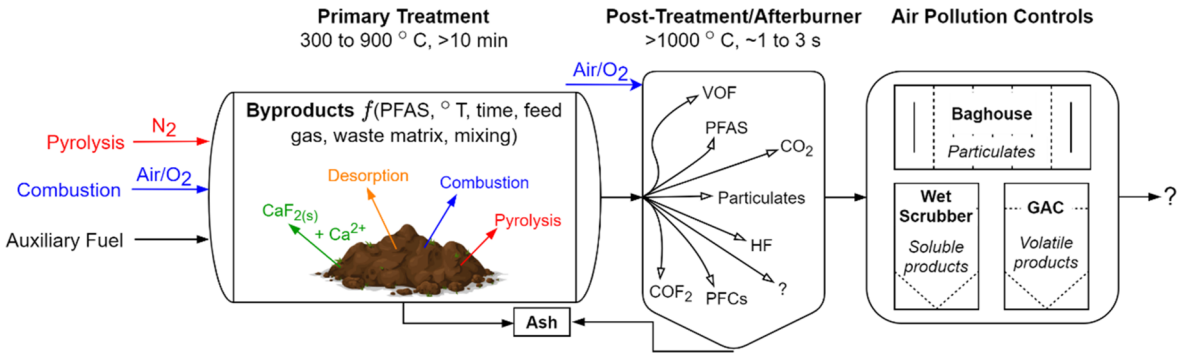

Figure 9. Schematic of a general two-stage thermal treatment system with air pollution control devices installed to treat the produced gases. Potential products and their potential to be captured in typical air pollution control devices are shown. Products formed will depend on temperature, gas mixture (e.g., pyrolysis, combustion), waste components (e.g., calcium), gas turbulence, and residence time.

compounds (e.g., oxygen, catalyst), to bring forth a chemical change in the contaminant. The primary variables that control the efficiency of thermal treatment methods are temperature, gas content, gas- and solid-phase mixing rates, and residence time. For PFASs, thermal degradation has been shown to lead to numerous complete and incomplete combustion products, whose formation depends on the operating conditions and type of PFAS (Table S2).

There are four major thermal degradation technologies: combustion, pyrolysis, gasification, and hydrothermal. Combustion is conducted at stoichiometric or excess oxygen ratios (i.e., excess air). Pyrolysis is performed in the complete absence of oxygen, and gasification is a starved air process performed below stoichiometric oxygen requirements. Hydrothermal treatment processes use water and heat to degrade solid waste at relatively low temperature (<375 °C) but higher pressure (4−22 MPa) and treatment times (>30 min) compared to other thermal processes.[134] It is typically used to treat wastes with a high liquid content, and the temperature and pressure limitations are related to the vapor−liquid critical point of water. Other thermal processes include plasma and microwave treatment. Plasma is an emerging heating technology for extremely high temperature pyrolysis and gasification,[135] but its use has not been specifically applied to PFAS treatment. Microwave heating is an emerging technology for generating rapid temperature changes internally.[136] Gagliano et al. demonstrated that relatively low power microwaves (<500 W) can be used to directly regenerate PFAS-spent GAC, reaching temperatures greater than 600 °C.[137] Combustion is the most commonly used thermal treatment process, and we depict a typical combustion or pyrolysis thermal treatment process treating PFASs in Figure 9, as well as the potential products and the likelihood of products to be captured by typical air pollution control measures.

For PFASs, most of the published combustion studies have involved controlled, laboratory-scale experiments involving the use of simple tube or muffle furnaces.[50,66,81,83,93,138] Lab-scale smoldering has also been investigated. Smoldering, which is a self-sustained combustion, was shown to remove at least 98% of six PFASs from GAC or soil when operated at temperatures above 900 °C.[139] The general consensus across these lab-scale studies is that even the most stable PFASs (e.g., long-chain sulfonates) desorb at temperatures less than 1000 °C, and they are destroyed in the gas phase at temperatures greater than 1000 °C. The critical questions that remain involve the effect of operating parameters (e.g., residence times, oxygen content), the effect of waste type/matrix, the identification of all fluorinated byproducts, and the ability to complete a fluorine mass balance on the system. These questions can be mostly answered at the lab scale with carefully planned experiments, but correlation of the outcomes to a larger scale is also critical. While some studies have confirmed the partial or full removal of PFASs from wastes in a full-scale thermal treatment process,[140−143] there is still a need for more detailed, specific, peer-reviewed studies that probe the impact of operating conditions and completely analyze inorganic and organic volatile fluorine compounds (including PFASs) and HF in the effluent stream.[144]

Further, there are no direct comparative studies on how differing types of full-scale incinerators impact the treatment of PFASs. The incinerator type is defined by the injection, mixing, and heating methods (e.g., fixed or open hearth, rotary film or kiln, fluidized bed, starved air modular). Complete combustion of PFASs will likely be most successful in incinerators that employ a two-stage process. In these, the waste is first fed into the primary combustion chamber where PFASs desorb and partially degrade. The gaseous byproducts are sent to a secondary chamber (the afterburner) that operates in excess air (stoichiometric excess of oxygen) at high temperature (>950 °C) and short residence times (1−3 s). These two-stage incinerators are likely to provide ample residence time to desorb PFASs in the primary chamber and then potentially sufficient temperature and time to mineralize gaseous fluorine products in the secondary chamber.

Although pyrolysis is a common alternative to combustion processes for treating solid waste,[145] there is limited full-scale data on the use of pyrolysis and gasification systems for treating PFASs. Pyrolysis of PFASs forms perfluoroalkanes, olefins, and VOF. Gasification (and combustion) will additionally form oxygenated fluorine compounds (e.g., COF_2). One pilot-plant study treating biosolids containing PFASs confirmed that pyrolysis coupled with combustion was potentially an effective treatment approach, achieving greater than 90% removal of PFOS and PFOA; although, complete defluorination and F mass balance were not achieved.[146]

Hydrothermal treatment is an emerging technology that could be useful for removing PFASs from solid wastes because of the ability of the high-pressure environment to promote defluorination.[134] Yu et al. investigated hydrothermal treatment for destroying PFOA, PFOS, 7:3 FTCA, 8:2 fluorotelomer sulfonate (FTS), and 8:2 fluorotelomer unsaturated carboxylic acid (FTUCA) from wastewater sludge.[147] At a reaction temperature of 350 °C for 90 min, greater than 99% of the carboxylic PFASs were decomposed, but only 34% and 67%

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370

KD2867

degradation occurred for PFOS and 8:2 FTS, respectively. Although complete mineralization was not achieved, these results were obtained at a temperature much lower than required for combustion (>700 °C).

One potential solution for the more recalcitrant sulfonates is to amend the liquid phase with acids/bases to catalyze the reactions. Wu et al.[110] showed that conducting hydrothermal treatment at basic conditions at 350 °C for 90 min achieved ∼80% defluorination of PFOS. This approach was confirmed with AFFF waste in a reactor amended with 5 N NaOH.[126] A similar behavior was observed for the hydrothermal treatment of plant biomass. At 300 °C, PFCAs were removed from the biomass to below the detection limit (50% defluorination), and less than 20% removal was observed for PFSAs.[148] The addition of 1 N KOH increased the removal efficiency of PFOS from the biomass beyond 80%, but the shorter-chain PFSAs were less susceptible to destruction (e.g., removal of PFBS was less than 50% observed). This aligns with other destructive technologies, where PFSAs and short-chain PFASs were more recalcitrant.[45,149]

4.2. Co-Occurring Constituents in Wastes. Solid wastes entering thermal treatment systems can be extremely complex, containing myriad co-occurring constituents that may affect the thermal behavior of PFASs. For example, simply changing the PFAS counterion influences both the degradation temperature and the resulting products (Section 3.2.1).[76] The presence of $Ca(OH)_2$ or CaO in the matrix has been shown to affect both the required desorption/degradation temperature and the fate of PFASs during thermal treatment.[83,94,150] In general, for PFAAs, the presence of Ca improved mineralization efficiency and reduced the temperature required for degradation,[83,150] and it prevented the formation of terminal PFAAs when PFAA precursors were treated.[94] In a smoldering column, Duchesne et al.[139] showed that the defluorination efficiency of PFASs was more effective for GAC (44%) compared to a soil (16%). The reason is unknown, but possible mechanisms may be linked to the high specific surface area and porosity of GAC, differing moisture conditions of the solids, differing surface chemistry of the solids, or effects of other constituents in the matrix. Given the complexity of solid waste, attempts to model the thermal behavior PFASs in real systems may prove to be too challenging. Even so, there is a critical need to study the specific effect of co-occurring waste constituents on the thermal behavior of PFASs.

From an operational perspective, the classification of the incinerator will also play a role in deciding what co-occurring constituents will be present during treatment. Municipal, hazardous, and medical waste incinerators are classified as either mass burn or refuse-derived fuel (RDF). For mass burn incinerators, the waste is processed as received, whereas the waste sent to an RDF incinerator is first processed to remove poorly combustible material (e.g., glass, metal), and combustible items are shredded to a uniform size. The removal of glass (i.e., silica) and calcium may alter PFAS degradation pathways because the combustion products (e.g., HF) will react directly with Si and Ca (i.e., Sections 3.3.3.3 and 3.3.3.4).[150] Thus, the thermal behavior of a PFAS is likely to be different in an RDF compared to a mass burn even under similar operating conditions (e.g., temperature).

4.3. Incinerator Solid and Gaseous Byproduct Control Measures. Waste byproducts of incineration include bottom ash, which contain noncombusted products, and gas, containing small particulate and volatile products. Ash, which contains mineralized fluorine but also some PFASs that remain bound to inorganic compounds such as calcium,[150] is typically sent to a landfill or repurposed (e.g., fly ash for concrete). For the gas, there are numerous air pollution control methods available. Particulates that remains in the gas are captured with electrostatic precipitators or baghouses. Numerous methods exist for removing acid gases, including HF that is formed from PFAS thermal conversion. All involve the use of a calcium or sodium salts, such as calcium hydroxide or sodium bicarbonate, forming a corresponding salt (e.g., CaF_2). Escaped HF or volatiles products are presumably captured in the alkaline wet scrubbers, although there is a substantial gap in our understanding of the gas/liquid partitioning (Henry's Law constants) for nearly all PFASs and their combustion products.[53,54] In general, an abundance of information is known about how to capture HF in the gas stream, but very little knowledge exists for removing VOF.

5. IDENTIFYING ANALYTICAL NEEDS TO EVALUATE THERMAL TREATMENT SYSTEMS

The anticipated goal of thermal treatment processes is to completely remove PFASs from the solid/liquid waste and/or mineralize PFASs to CO_2 and inorganic fluorine. Many publications to date report the removal of PFASs from solid or liquid waste matrices but fall short in quantitatively accounting for all fluorine in the system. Reporting a complete F mass balance on thermal treatment systems is important to assess the relative risk of the released products but is challenging because of the following: (1) Numerous fluorinated byproducts are formed (i.e., Table S2). (2) There is no robust analytical method for their quantification. (3) Analysis of multiple phases (gas, surfaces, ash, scrubber liquids) is required.

For targeted PFAS analysis, liquid and gas chromatography−tandem mass spectrometry (LC-MS/MS and GC-MS/MS) can be used to quantify specific PFASs that are present in the produced gas or extractable from the ash.[12,58] However, targeted analysis of PFASs is incapable of quantifying all products, and it has been shown that greater than 50% of postcombustion fluorine is not captured by the sum of LC-MS/MS and HF measurements.[139] Additional compounds can be identified using nontarget analysis, which typically employs high-resolution mass spectrometry (HRMS).[2,151,152] However, this technique is laborious and poorly or not quantitative and does not capture all fluorinated or nonfluorinated products. Achieving a complete mass balance in thermal treatment processes requires total F methods beyond mass spectrometric techniques and measurements of HF.

Common total F analytical approaches include combustion ion chromatography (CIC), particle-induced gamma-ray emission (PIGE), instrumental neutron activation analysis (INAA), and ^{19}F nuclear magnetic resonance (^{19}F-NMR). Schultes et al.[153] showed that CIC, PIGE, and INAA yield similar results when measuring homogeneously packaged samples, but each has advantages and disadvantages. CIC and PIGE have emerged as the most reported methods because of their ease of use, but CIC is more readily available than PIGE.[125] One critical issue for CIC is that it cannot be used to quantify F in solids remaining after combustion (i.e., ash) because CIC requires F to be combusted to HF gas, and ash has already been through a combustion process. PIGE has been used to regularly quantify total F in numerous matrices,[6,153−156] and because it is a direct solid-phase analysis, quantification of total F in all matrices of thermal treatment processes is possible. ^{19}F nuclear magnetic resonance spectroscopy (^{19}F-NMR) has been used to

https://doi.org/10.1021/acs.est.2c02251
Environ. Sci. Technol. 2022, 56, 5355−5370
KD2868

measure total F and distinguishes between organofluorine and inorganic F in solids,[157] but poor detection limits (ppm levels) impede its broad application.

Gas-phase compounds may be captured by activated carbon, hydrophobic−lipophilic balance media, or polyurethane foam/XAD samplers[58,158] and then analyzed by LC-MS/MS or GC-MS/MS for targeted compounds or by various total F methods. These methods are validated for well-studied PFASs. However, the capture and recovery of PFAS thermal decomposition products is unknown, and there is a lack of knowledge regarding how sampling procedures may bias the results (i.e., formation of dioxins during cooling of combustion gases).[159] Additionally, GC-MS/MS measurements of gas-phase PFASs using electron impact ionization results in fragmentation spectra that are similar for most PFASs, with prominent product ions representative of the fluoroalkyl chain (e.g., 69 m/z CF_3^+, 119 m/z $CF_2CF_3^+$, 169 m/z $CF_2CF_2CF_3^+$).[58] Chemical ionization reduces fragmentation, but not all GC-MS are equipped with chemical ionization sources.[160,161] Volatile fluorine products can also be measured by Fourier transform infrared spectroscopy (FTIR), and it has been used to quantify COF_2, HF,[162] and CF_4, and C_2F_6.[163] The greatest challenge of employing FTIR to measure such compounds in the gas phase is calibrating the instrument, as pure gas-phase standards used for generating calibration curves are not widely available.

Applying these various capture and analytical schemes is challenging but represents a meaningful first step toward closing the fluorine mass balance. Knowledge of important gaseous products is essential to design and operate next-generation incineration processes that truly achieve complete mineralization of PFASs.

6. KNOWLEDGE GAPS AND RESEARCH NEEDS

The thermal decomposition of only a limited group of mostly pure-phase PFASs under pyrolysis conditions have been thoroughly investigated to date. The implications of such a limited range of studies are relevant to industries, municipalities, and regulators interested in using thermal treatment processes to manage PFAS wastes. Past research focused primarily on determining temperatures that initiate desorption and degradation, as measured by mass loss of the PFASs from the waste. Other studies, to a more limited extent, include measurements or computational predictions of likely decomposition mechanisms and expected products. There are significantly more studies that used computational chemistry to make such conclusions than there are those that used experimental measurements. Some of the coinciding experimental and computational studies do not agree, and several differ significantly. Thus, there is a critical need to conduct studies that incorporate both computation and experimental measures.

A major weakness of existing mechanistic studies is that they do not mimic full-scale thermal treatment systems, which have operational variations that are significantly different than lab-scale systems. There is also a lack of knowledge about the efficiency of full-scale effluent treatment processes for the thermal degradation products of PFASs. While these processes should capture the numerous products, additional studies are required to confirm this hypothesis. Closing the fluorine mass balance on ash, scrubber solutions, and gaseous emissions should be a priority in the near term to understand the fate of PFASs in incinerators having been operated for the past several decades and to understand how to modify incinerator processes in the future.

To adequately assess the fate of PFASs in thermal treatment systems requires analytical techniques that can close the F mass balance. Key to this will be total fluorine measurements because mass spectrometry-based methods do not have readily available standards for the numerous products that may form. Further, measurements of PFASs in the produced ash is a significant challenge, as the detection limits for total fluorine instrumentation (CIC, PIGE, NMR, INAA) are high, and thus, sample preparation and concentration methods are needed if trace levels are to be reached.

To improve upon the understanding of the fate of PFASs during thermal treatment, we propose the following ranked research needs:

(1) Experimental studies of relevant mixtures of PFASs during combustion on different types of surfaces (soils, activated carbon, ion exchange, liquid brines). Although some PFAS decomposition pathways in oxidizing atmospheres are provided in this review, most of the experimental literature focuses on pyrolysis, and therefore, more knowledge relevant to commercial incinerators is needed.
(2) Measurements of Henry's Law constants of organofluorine compounds. Henry's Law constants include interactions with water and better represent environmental systems and incinerator air pollution control measures than vapor pressure (pure compound). These measurements will lead to an understanding of which PFASs are the most likely to elude air pollution control measures. Such constants are not generally available, and combined with the first research need, will provide knowledge of which PFASs are the most likely to be released in flue gases during thermal treatment.
(3) Experimental confirmation of computational studies. Select studies have focused on experimentally derived decomposition, and there is some divergence published between computation and experimental results. Robust studies are needed that incorporate experiments used to validate computational models.
(4) Development and validation of instrumentation and sampling and analytical methods capable of measuring products identified in research needs 1, 2, and 3. These methods will help to close the mass balance on fluorine during thermal treatment and better understand the fate of PFASs.
(5) Experimental research of PFAS decomposition products and temperature-dependent kinetics and pathways of formation of less studied PFASs (e.g., fluorotelomers, iodinated PFASs, PFPAs, perfluorophosphinic acids).

Glucose homeostasis
Obese status

ABSTRACT

Background: Humans are widely exposed to environmental perfluoroalkyl substances (PFAS), which may affect glucose homeostasis. However, research linking PFAS exposure to glucose homeostasis during pregnancy is limited and the results were inconsistent. We aimed to investigate the association between PFAS exposure and glucose homeostasis in pregnancy in a large prospective cohort.

Methods: A total of 2747 pregnant women who participated in the Shanghai Birth Cohort, had blood samples in early pregnancy and completed a 75 g oral glucose tolerance test (OGTT) at 24–28 gestational weeks were included. 10 PFAS were determined by high-performance liquid chromatography/tandem mass spectrometry (HPLC/MS-MS) in the plasma samples in early pregnancy. Logistic regression was used to explore the associations between PFAS concentrations and gestational diabetes mellitus (GDM), while multiple linear regression was used to model the associations between PFAS and OGTT fasting, 1-h and 2-h glucose levels. Potential confounders were adjusted. Bayesian kernel machine regression (BKMR) and a quantile-based g-computation approach (qgcomp) were employed to explore the joint and independent effects of PFAS on glucose homeostasis.

Results: The incidence of GDM was 11.8%. One log-unit increment in plasma concentrations in early pregnancy was associated with an increased risk of GDM for perfluorobutane sulfonate (PFBS) (adjusted odd ratio (aOR) = 1.23, 95% confidence interval (95% CI): 1.05, 1.44) and perfluoroheptanoic acid (PFHpA) (aOR = 1.25, 95% CI: 1.07, 1.46). Perfluorooctane sulfonic acid (PFOS), perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluorohexanesulfonate (PFHxS) and PFHpA were positively correlated with 1-h and 2-h glucose levels. Results of the mixed exposure model showed that the joint effects of PFAS were significantly associated with abnormal glucose homeostasis; In the BKMR model, PFAS mixture exposure was positively associated with the GDM incidence, 1-h and 2-h glucose levels and negatively correlated with FBG level. A similar trend could be observed in qgcomp and the positive correlation between PFAS and 2-h glucose level was significant ($\beta = 0.12$, 95% CI: 0.04, 0.20). PFOS, PFNA and PFHpA may be the main contributors after controlling for other PFAS congeners. PFOS was significantly correlated with GDM incidence and 2-h glucose level, and PFHpA was significantly associated with FBG and 2-h glucose levels. The above associations were more prominent among women with a normal prepregnant BMI.

Conclusions: Environmental exposure to PFAS may affect glucose homeostasis in pregnancy and increase the risk of GDM, especially in normal weight women.

1. Introduction

Gestational diabetes mellitus (GDM) is a common pregnancy complication. The reported prevalence varies substantially worldwide, ranging from 5% to >30% (Chiefari et al. 2017). Developing countries tend to have higher GDM incidence than developed countries. For instance, the incidence is around 15% in the Middle East, North Africa, South-East Asia and China (Gao et al. 2019; McIntyre et al. 2019). GDM increases the risk of adverse birth outcomes (Johns et al. 2018). The offspring of GDM pregnancy are at a higher risk of metabolic diseases in adulthood (Blotsky et al. 2019; Lowe et al. 2019).

Per- and polyfluoroalkyl substances (PFAS) are a group of synthetic chemicals and have been used extensively in industrial and consumer products due to their thermal stability, hydrophobic and oleophobic properties (Wang et al., 2017b). They are commonly used as additives in oil- and water-resistant textiles, nonstick cookware, greaseproof food packaging and personal care products. They may be absorbed by human body through foods and drinking water (Domingo and Nadal 2019). Even though perfluorooctane sulfonic acid (PFOS) and perfluorooctanoic acid (PFOA) were listed in the Stockholm Convention as persistent organic pollutants for restricted use or elimination in 2009 and 2019, respectively, they are still universally detectable in humans worldwide due to their persistence and bioaccumulation (Lee et al. 2020). Moreover, it was reported that the total production of PFAS has been increasing rapidly in Asian countries, especially in China, due to the transfer of production line from North America and Europe to Asia (Wang et al. 2019; Zhang et al. 2012). China is currently the main producer of PFOS and PFOA in the world. It is estimated that about 250 tons of PFOA and its salts were discharged into the environment between 2004 and 2012 (Wang et al. 2020). Coupled with the persistence in the environment, the exposure concentration of PFOA and PFOS has been maintained at a high level. In addition, the replacements for PFOS and PFOA have been increasingly produced in recent years, despite that the toxicity of many PFAS remains unclear. As PFAS have been linked to a variety of health outcomes (Pelch et al. 2019), the potential effects on human metabolism are gaining more attention (Timmermann et al. 2014; Wang et al., 2017a; Yang et al. 2018).

Some epidemiologic studies showed that exposure to PFAS may increase the risk of type 2 diabetes mellites (T2DM) (Conway et al. 2016; Donat-Vargas et al. 2019; Lin et al. 2009). Animal experiments demonstrated that PFAS may cause metabolic disorders and insulin resistance through inflammatory response and endocrine disruption, and increase the risk of diabetes (Fang et al. 2012; Yan et al., 2015). Peroxisome proliferator-activated receptor (PPAR) activation is considered to be an important pathway (Ammazzalorso et al. 2019; Corrales et al. 2018; Liu et al. 2018). However, it is unclear whether and how PFAS may affect glucose metabolism in pregnant women who have high metabolic rates. The limited number of epidemiologic studies have generated inconsistent results. Null or even negative associations were also reported, which may be attributable to variations in sample size, study design and inadequate information of potential confounders in previous studies (Shapiro et al. 2016; Valvi et al. 2017; Wang et al., 2018b; Zhang et al. 2015).

In addition, high pre-pregnant BMI is a risk factor for GDM (Giannakou et al. 2019). PFAS exposure may be associated with abnormal gestational weight gain during pregnancy and excessive weight gain could increase the GDM incidence (Marks et al. 2019; Mitro et al. 2020). PFAS exposure may induce child obesity through disturbing the metabolic processes (Braun 2017). These evidence indicate that the adiposity status of pregnant women may modify the health effects caused by PFAS exposure. More evidence is needed.

We aimed to examine the association between PFAS levels in early pregnancy and glucose homeostasis and the risk of GDM in later pregnancy in a large prospective cohort in China. The effects of the joint exposure and the independent effect of PFAS congeners were further explored. We also sought to evaluate whether the associations vary by pre-pregnancy weight status.

2. Material and methods

2.1. Study population

The present study used data from the longitudinal Shanghai Birth Cohort (SBC). SBC recruited women in early pregnancy from six participating hospitals in Shanghai, China during 2013–2016. Detailed description of the cohort was provided elsewhere (Zhang et al. 2019). In brief, eligible women were those who were at least 20 years old, registered Shanghai resident or married to a Shanghai resident; planned to seek prenatal care and give birth at the collaborative hospitals; were willing to sign a consent form and have follow-up visits regularly in the following 2 years. The participant provided the following information in questionnaire survey: demographic characteristics (e.g. maternal age, race/ethnicity, height, pre-pregnancy weight, education, family economic status), behavior and lifestyle (e.g. smoking and drinking status in early pregnancy, physical activities in early pregnancy) and reproductive characteristics (e.g. parity), disease history (e.g. diabetes). Medical records were retrieved and reviewed by trained research staff for information on the pregnancy.

A total of 3046 pregnant women had both PFAS measurements and pregnancy outcomes of interest. 67 subjects were excluded due to pre-pregnancy diabetes mellitus. We further excluded women who had previous GDM (n = 7) or missing data on GDM diagnosis (n = 225), leaving 2747 subjects in the final analysis (see Fig S1). GDM was diagnosed based on a 75 g oral glucose tolerance test (OGTT) between 24 and 28 gestational weeks according to the International Association of Diabetes and Pregnancy Study Groups (IADPSG) criteria (Basri et al. 2018): the glucose concentration met any of the following 3 thresholds: a) fast plasma glucose (FPG) $\geq$ 5.1 mmol/L; b) 1-h plasma glucose $\geq$ 10.0 mmol/L; or c) 2-h plasma glucose $\geq$ 8.5 mmol/L. The blood glucose detection is carried out by an automatic blood glucose meter. The detection mechanism is that the glucose dehydrogenase on the test paper will convert the blood glucose into glucose lactone and then generate changed current. The accuracy is above 95% and the variation coefficient of repeated measurements is less than 5%.

2.2. Plasma PFAS assessment

Blood samples were collected in early pregnancy at a median gestational age of 15 weeks [interquartile range (IQR): 13–17 weeks] and centrifuged at 4000 rpm for 10 min. Plasma and blood cells were separated and stored at −80 °C until assays. A 100 μl plasma was used for PFAS quantification using high-performance liquid chromatography / tandem mass spectrometry (HPLC/MS-MS; Agilent1290–6490, Agilent Technologies Inc., USA). Detailed methods of PFAS measurement have been described elsewhere (Zhou et al. 2017). Both intra- and inter-assay coefficients of variation (CV) were below 10% for all PFAS congeners. The 10 measured PFAS congeners were PFOS, PFOA, perfluorononanoic acid (PFNA), perfluorodecanoic acid (PFDA), perfluoroundecanoic acid (PFUnDA), perfluorohexanesulfonate (PFHxS), perfluorododecanoic acid (PFDoA), perfluorobutane sulfonate (PFBS), perfluoroheptanoic

KD2876

acid (PFHpA), perfluorooctane sulfonamide (PFOSA). The limits of detection (LOD) were 0.09 ng / mL for PFOA and PFOS, 0.02 ng / mL for PFDA, PFNA, PFUnDA and PFHxS, 0.03 ng / mL for PFHpA, 0.05 ng / mL for PFDoA, 0.009 ng / mL for PFBS and 0.12 ng / mL for PFOSA, respectively. PFAS concentrations below the LOD were replaced by the LOD/ $\sqrt{2}$ (Hornung 1990).

2.3. Covariates

Data on maternal age, weight, height, education, smoking, alcohol consumption, physical activity, economic status, parity and disease history were collected using a standardized questionnaire. Pre-pregnant body mass index (BMI) was calculated as weight in kilograms divided by height in meters squared. Maternal education was grouped into high school or below, college and postgraduate. In this study, only 3 women were current smokers. Thus, we combined active with passive smoking into a single category. Since only a few women drank alcohol (1.3%) in pregnancy, alcohol consumption was thus not included in the final analyses. Parity was classified into nulliparous and parous. Maternal economic status was grouped into four levels based on the question "How do you feel about your family financial situation currently": very good, fairly good, fairly poor and very poor. Physical activity was measured using the short version of the International Physical Activity Questionnaire (IPAQ) (Patterson 2005). We calculated each individual's weekly physical activity level (MET-min/w), combined the frequency of activities and further divided the physical activity intensity into low, middle and high groups. Potential confounders were selected based on previous studies and a directed acyclic graph (DAG) (see Supplementary Fig S2) (Chen et al. 2015; Shrier and Platt 2008; Zheng et al. 2017).

2.4. Statistical analysis

We assessed the distribution of all PFAS and relevant covariates. PFAS were reported as medians and interquartile range. Other continuous and categorical covariates were reported as mean and standard deviation, number and percentage, respectively. All PFAS concentrations were natural logarithm (ln) transformed for further model analyses. Differences in PFAS, characteristics and glucose parameters between GDM and non-GDM groups were tested using Wilcoxon's rank sum test (skewed distribution) or Chi squared test (categorical variables) where appropriate. Spearman rank correlation analysis was conducted to explore the pairwise correlation among PFAS original value. Multiple imputation with fully conditional specification (FCS-MI) method was used to impute missing values of the covariates before regression analyses. This method can specify the multivariate imputation model on a variable-by-variable basis and offers a principled yet flexible method to address missing data (Liu and De 2015). Ten datasets with imputations for missing data were created and modeled separately. Results were pooled to obtain the final effect parameters in single pollutant analyses and PFAS mixture exposure analyses.

We applied logistic regression and multiple linear regression models to assess the associations of PFAS with GDM and continuous outcomes (FBG, 1-h and 2-h glucose levels), respectively. PFAS congeners were analyzed one at a time in relation to glucose homeostasis. Tolerance and variance inflation factor (VIF) values were calculated to evaluate multicollinearity between covariates, with tolerance <0.1 and VIF > 10 being considered indicative of multicollinearity. All models adjusted for maternal age, pre-pregnant BMI, maternal education, smoking status, parity, physical activity and economic status. PFOSA was not included in our regression model due to the low detection rate. Restricted cubic spline (RCS) models with knots at the 5th, 27.5th, 50th, 72.5th and 95th percentiles of each PFAS were fitted to further identify potential nonlinearities between plasma PFAS and glucose homeostasis. Odds ratios (ORs) with 95% confidence intervals (CIs) were used to report the relative increase in the risk of GDM for every log unit increase in PFAS, while β-coefficients with 95% CIs were used to report the change in glucose concentration.

Bayesian kernel machine regression (BKMR) was used to estimate individual and overall effects of PFAS on GDM incidence, FBG, 1-h and 2-h glucose levels. BKMR is a semi-parametric method that can be used to estimate the effects of individual mixture components, the overall mixture effect and interactions between mixture components (Bobb et al. 2015). A Gaussian kernel was adopted to support flexible exposure–response shapes for continuous outcomes. A probit link function was used to fit the exposure–response relationship for binary outcome (i.e., GDM). For all BKMR analyses, PFAS were ln-transformed and centered to a mean of 0 and scaled to a standard deviation of 1 to account for skewness and to reduce the influence of extreme values and different value scales in the variables. Each of the BKMR models was adjusted for the corresponding covariates as described above. The overall mixture effects of PFAS were estimated by subtracting the mean value of the outcome when the PFAS concentrations were at their 25th percentile with the mean value of the outcome when all the PFAS concentrations were at their 75th percentile. Similarly, individual effects of each PFAS mixture component were estimated by subtracting the mean outcome value when the specified PFAS was at its 25th percentile with the mean value of the outcome when the specified PFAS was at the 75th percentile and. Other PFAS congeners were fixed at their medians and all covariates held constant. Plots were used to evaluate the overall associations of PFAS mixture with different glucose homeostasis indicators and visualize the exposure–response relationship for each PFAS isomer while holding the other exposures to their 50th percentile and covariates constant (Lebeaux et al. 2020). The group posterior inclusion probability (groupPIP) and the conditional posterior inclusion probability (condPIP) were calculated, representing the probability of a mixture group and a particular PFAS within the group, respectively. All BKMR models were fit 50,000 iterations using the Markov Chain Monte Carlo (MCMC) sampler.

Even though BKMR benefits from the flexibility of modeling the exposure–response function and allowing for the nonlinear and non-additive association between multiple PFASs and glucose levels, it cannot provide parsimonious parametric inference (e.g., a single coefficient corresponding to the change in the outcome per unit of joint exposure). We further applied a recently developed quantile-based g-computation method to explore the joint effects based on parameter inference. This approach combines the inferential simplicity of weighted quantile regression (WQS) with the flexibility of g-computation and also allows for nonlinearity and non-additivity of BKMR, which appears to be less biased and more robust (Keil et al. 2020). We used this method to model the joint and individual effects of exposure to all nine PFAS on the categorical GDM outcome and continuous glucose levels. Binomial and gaussian distributions were specified as link functions, respectively. Parameter q represents the specified quantile and was set to 4 as most of the dose–response relationships did not show a significant nonlinear pattern. 500 bootstrap iterations were performed to calculate the CIs. In addition, stratified analyses were conducted in BKMR and qgcomp models by pre-pregnant weight status (BMI). We grouped the study subjects into normal weight and overweight or obese with the BMI cutoff at 24 kg/m^2, since this cut-off value is appropriate for Chinese (Xia et al. 2019).

Several sensitivity analyses were performed to test the robustness of our results. 1) In our pre-analysis, only a few PFAS showed non-linear relationships with glucose related outcomes. In order to better evaluate the accuracy and stability of the linear model, PFAS were categorized by tertiles and then included in the binary logistic or multiple linear model one PFAS at a time. 2) Multicollinearity due to high correlation among PFAS congeners may bias the parameter estimates between exposure and outcome. We applied the elastic net regression (ENR) model to address this issue and to evaluate the robust and stability of BKMR and qgcomp modeling results. This method combines the properties of least absolute shrinkage, selection operator and ridge penalty and has a better performance in addressing multiple-collinearity

KD2877

(Friedman et al. 2010). α value was set from 0 to 1 by 0.01 and λ value equal to 100. A 10-fold cross-validation was performed to obtain the optimal combination of α and λ (Huo et al. 2020). We further modeled the PFAS selected by ENR to estimate the joint and individual effect in qgcomp and obtained the estimate parameter. 3) We added the interaction analysis between PFAS exposure and pre-pregnant BMI to the single pollutant models and mixed exposure models to quantitatively evaluate their possible relationship. 4) Considering that there is substantial missingness in some of the covariates, e.g., physical activity. We performed an additional analysis among those with complete information. We further created dummy variables for those with missing information. As for values below the limit of detection, we further adopted a left censored log-normal regression model to impute them and the results across different datasets were combined using Rubin's rule. All of these analyses helped to assess the stability and reliability of our results. 5) When assessing the outcomes with high prevalence, odds ratio may not be an appropriate measure as it may overestimate the possible effects. Therefore, we also calculated the relative risk (RR) of PFAS exposure on GDM by using the marginal parameters to yield estimates of the population average exposure effect. 6) GDM group and normal women significantly differ in glucose homeostasis. After modeling the pooling data, we further conducted an analyses using data stratified by GDM status and explored whether there existed metabolic vulnerability in pregnant women. 7) We restricted the study subjects to nulliparous women to eliminate the influence of excluding women who had previous GDM on parity.

All statistical analyses were conducted in SAS V9.4 (SAS Institute Inc., Cary, NC, USA) and R (version 3.6.1, R Development Core Team 2019). The BKMR model, qgcomp and ENR model were implemented using the R package "bkmr", "qgcomp" and "glmnet", respectively (Bobb et al. 2015; Friedman et al. 2010; Keil et al. 2020). An α level of 5% (two-sided) was considered statistically significant. This project was approved by the Research Ethics Committees of Xinhua Hospital affiliated to Shanghai Jiao Tong University School of Medicine.

3. Results

3.1. Population characteristics

Table 1 presents the demographic characteristics of the study cohort. The mean maternal age was 29.1 years. The average pre-pregnant BMI was 21.40 kg/m^2. 15.8% of the subjects were overweight or obese. The distribution difference in BMI status between GDM and non-GDM groups is statistically significant ($P < 0.01$). The majority of subjects had university education. Nearly 36% of women were passive smokers. Over 80% were nulliparous. Most pregnant women had low to mid intensity physical activity (73%). 63% of pregnant women had fairly good family economic status. The incidence of GDM was 11.8%. The average FBG, 1-h and 2-h glucose levels were 4.45 (SD: 0.48), 7.55 (SD: 1.63) and 6.52 (SD: 1.35) mmol/l, respectively. The incidence of GDM increased with maternal age ($P < 0.01$). The differences in other variables beside maternal age, pre-pregnant BMI and glucose measurements between GDM and non-GDM groups were statistically non-significant.

3.2. Maternal plasma PFAS

Table 2 describes the LOD and detection rate of each PFAS congener, the median and interquartile range (IQR). PFOSA had a low detection rate (21.6%) and, therefore, was not analyzed further. PFOA was the dominant compound detected with the median concentration at 11.56 ng/ml, followed by PFOS at 9.40 ng/ml. PFBS and PFHpA concentrations were significantly higher in GDM group compared to non-GDM group, while PFUnDA showed an inverse trend. Pairwise correlation analysis shows significant correlations between PFAS congeners. The correlation coefficients of different PFAS ranged from −0.02 to 0.94 and there were strong correlations among several long-chain PFAS (PFNA, PFDA and PFUnDA), with r ≥ 0.6 (Fig S1).

3.3. PFAS, GDM and blood glucose levels

Table 3 illustrates the associations between individual PFAS, GDM risk and glucose levels in different models after controlling for potential confounders. Significant positive associations were observed between PFBS and PFHpA exposure and GDM risk (OR = 1.23; 95% CI: 1.05, 1.44 for PFBS; and OR = 1.25; 95% CI: 1.07, 1.46 for PFHpA), which were consistent with the significant difference in their concentrations between the GDM and non-GDM groups. PFOS, PFNA, PFDA and PFHxS were significantly associated with increased 1-h glucose concentrations (by 0.11–0.22 mmol/l per log unit increment). Similar results were observed for the 2-h glucose level.

Note: All models adjusted for maternal age, pre-pregnant BMI, maternal education, smoking status, parity, averaged physical activity and economic status.
[a] Binary logistic regression was used to estimate the associations. Effect estimate was expressed as odds risk (OR) and 95% confidence interval (95% CI).
[b] Multiple linear regression was used to estimate the linear associations. Effect change was expressed as Beta coefficient (β) and 95% confidence interval (95% CI).

3.4. PFAS joint and individual exposure with glucose homeostasis based on BKMR

The overall associations between the PFAS mixture and glucose homeostasis are shown in Fig. 1. The risk of GDM increased significantly with increasing total PFAS mixture levels. Similar results were observed between PFAS exposure and 1-h and 2-h glucose levels but not with FBG level. We further examined individual PFAS exposure–response functions of early pregnancy exposure and glucose homeostasis (Fig S3). Positive relationships between PFNA exposure and FBG, 1-h and 2-h glucose levels were observed. PFHpA exposure was positively associated with GDM and 1-h glucose level, while PFDA exposure was positively associated with FBG level. The condPIP of PFHpA was relatively high within this group and stable with outcomes (GDM, FBG, 1-h and 2-h glucose levels), whereas the groupPIPs of PFDA for FBG and PFNA for 2-h glucose level were all above 0.5 (Table S2).

When the results were stratified by pre-pregnant BMI in BKMR, PFAS mixture was positively associated with 1-h and 2-h glucose levels and negatively associated with FBG level, while the trend weakened in overweight/obese subjects (Fig S4). The condPIP of PFHpA was relatively stable with an extremely high value at 0.98 in normal weight pregnant women. The condPIPs of PFNA, PFBS and PFDoA were >0.5 whereas in the overweight/obese group, only PFHpA showed relative more importance.

3.5. Mixture analyses by quantile-based g-computation method

Table 4 presents the quantile-based g-computation analyses for GDM, FBG, 1-h and 2-h glucose levels. PFAS as a whole was significantly associated with increased 2-h glucose level, with β = 0.12 (95% CI: 0.04, 0.20) for every quantile increase in PFAS concentrations. PFOS and PFHpA had a larger association with glucose homeostasis while PFDoA exposure was negatively associated with FBG and 1-h glucose levels. PFAS with significant associations had higher weights than the others.

Furthermore, we observed that the joint effects of nine PFAS on GDM risk were more pronounced in normal weight women. A similar pattern was observed for independent effects of PFOS, PFHpA and PFDoA on glucose homeostasis. PFNA was associated with higher 1-h and 2-h glucose levels among women with normal weight.

3.6. Sensitivity analyses

Table S3 shows the results of logistic regression and multiple linear regression with PFAS included as an ordinal variable. Overall, the results were consistent with Table 3. The highest tertiles of PFBS and PFHpA exposure were positively associated with GDM risk (OR = 1.54; 95% CI: 1.15, 2.07 for PFBS and OR = 1.44; 95% CI: 1.09, 1.95 for PFHpA, respectively). The highest tertiles of PFOS, PFDA and PFHpA exposure were also significantly associated increased 1-h and 2-h glucose levels. High exposure of PFHxS and PFUnDA were associated with increased 1-h and 2-h glucose levels, respectively. In addition, PFUnDA and PFHpA were found to be significantly associated with increased FBG level. Meanwhile, negative correlations were observed between PFDoA or PFBS exposure and FBG level.

To validate the results of mixed exposure models, ENR was used (Table S4). The mixed effects of the selected PFAS were associated with increased GDM risk and increased 2-h glucose level. PFNA had independent effects on FBG and 1-h glucose levels. PFHpA exposure was significantly correlated with increased FBG and 2-h glucose levels, while PFDoA showed an inverse association. In the interaction analysis, the product terms of PFHpA and pre-pregnant BMI were statistically significant for GDM and 1-h glucose level in single pollutant analyses and significant for 2-h glucose level in mixed exposure analyses (Table S5 and S6).

Results of completed data analyses showed that PFAS mixture exposure was positively associated with 2-h glucose level. PFHpA, PFBS, PFUnDA and PFDoA have significant effects on glucose homeostasis after controlling for other PFAS (Table S7). In the analyses that including missing information as a dummy variable, the PFAS mixture was significantly associated with GDM incidence, 1-h and 2-h blood glucose levels (Table S8). PFNA, PFBS, PFHpA, PFHxS and PFDoA showed significant associations with various outcomes. PFAS mixture

KD2879

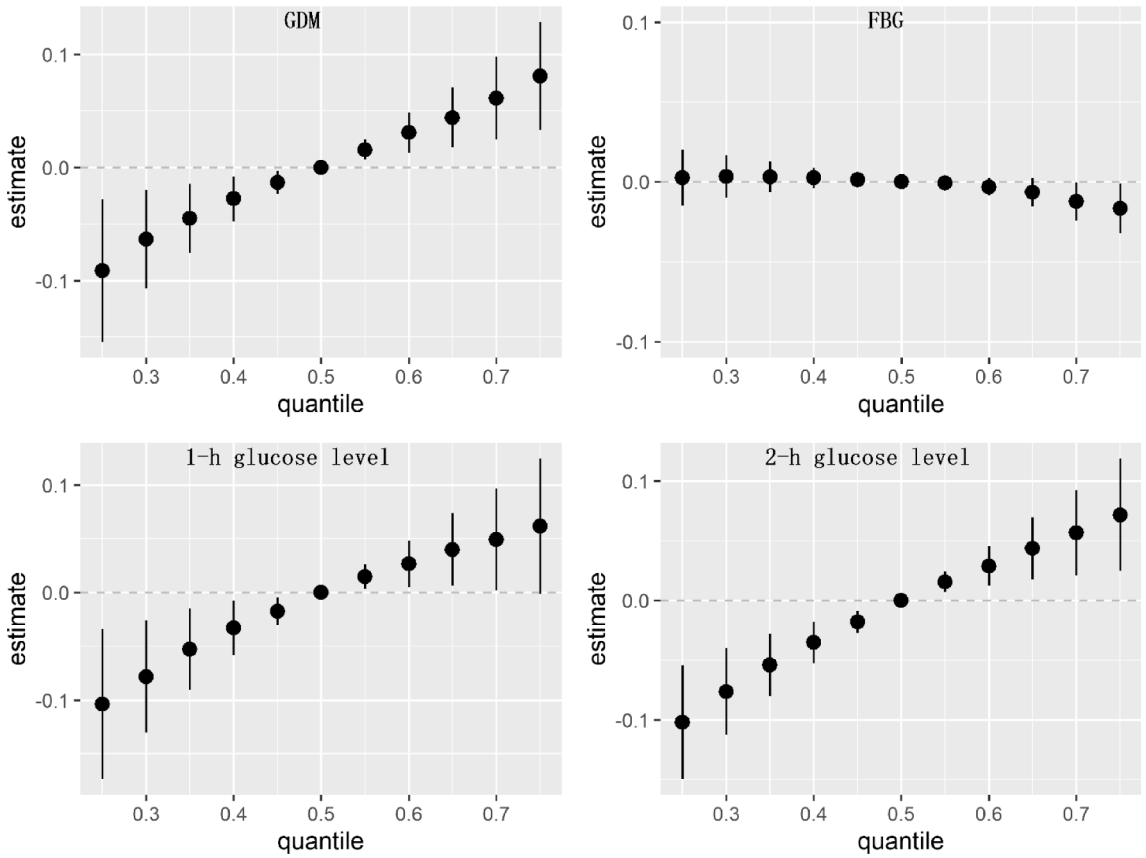

Fig. 1. Joint effect estimates with 95% CI for the PFAS mixture total exposure in relation to glucose homeostasis in the hierarchical BKMR models; all the chemicals at particular percentiles (from 0.25 to 0.75 increment by 0.05) were compared to all the chemicals at their 50th percentile.

exposure were associated with increased 2-h glucose level. PFOS, PFDoA and PFHpA were the identified PFAS with significant effects on glucose homeostasis (Table S9). Although the results in Table S7, Table S8 and Table S9 were somewhat different, the specific PFAS with significant effect may vary, the overall trend and direction of the effect of PFAS on glucose outcomes were basically consistent. Results of estimated RR values showed that PFOS exposure may increase the GDM incidence after controlling other PFAS exposures (OR = 1.24; 95% CI: 1.02, 1.51), which is more pronounced in normal weight group (OR = 1.30; 95% CI: 1.03, 1.63) compared to overweight/obese group (OR = 1.23; 95% CI: 0.86, 1.77) (Table S10). The associations estimated by the RR value were consistent with which by the OR value. In the stratified analysis by pre-pregnant BMI, although there were certain differences, they had the same trend. PFAS mixed exposure may affect the 2-h glucose level in the non-GDM group, among which PFNA, PFHpA and PFDoA were the significant pollutants (Table S11). These effects were attenuated in GDM group, which indicated that non-GDM pregnant women may be more sensitive to PFAS exposure. Table S12 shows that PFAS mixture exposure may increase the risk of GDM incidence (OR = 1.22, 95%CI: 1.01, 1.46) and the effects of PFOS and PFBS are significant. PFHpA exposure is positively correlated with 1-h and 2-h glucose levels.

The RCS analysis indicates that the association between PFAS exposure, GDM and 2-h glucose level was linear, while some of the PFAS congeners exposure, FBG and 1-h glucose levels show some evidence of non-linear associations (Fig S5-S8).

4. Discussion

In this large prospective cohort, we explored the associations between PFAS exposure and glucose homeostasis during late pregnancy using multiple statistical models. Overall, PFAS mixture exposure may affect the glucose homeostasis by increasing 2-h glucose level. The joint effects of multiple PFAS congeners were more pronounced in women with normal weight. As for specific PFAS congeners, PFOS may increase the risk of GDM while PFNA and PFHpA may increase the glucose levels, especially for FBG and 2-h glucose levels.

A number of studies have reported a positive link between PFAS exposure and T2DM in non-pregnant individuals (Domazet et al. 2016; Donat-Vargas et al. 2019; Duan et al. 2020). For example, a nested case-control study in the USA and another cross-sectional study conducted in elderly Swedish population showed that higher PFAS exposure was associated with an elevated risk of T2DM, insulin resistance and may damage beta cell function (Cardenas et al. 2017; Lind et al. 2014; Sun et al. 2018). So did two other epidemiologic studies (Christensen et al. 2016; Mancini et al. 2018).

Compared to healthy adults, pregnancy leads to a series of physiological changes in order to support the demands of the growing fetus, including adaptations to the cardiovascular, renal, hematologic, respiratory and metabolic systems (Plows et al. 2018). Insulin sensitivity is one important metabolic adaptation during this period and may promote a state of insulin resistance together with a series of local and placental hormones (Catalano et al. 1991). The glucose homeostasis fluctuation during pregnancy makes it more sensitive to the interference of environmental pollutants, especially pollutants with estrogen-like effects (Rahman et al. 2019; Zhang et al. 2020).

A total of 9 studies so far have examined the association between PFAS exposure and GDM in pregnant women, but only 3 of them were conducted in developing countries. Seven of them reported positive associations between specific PFAS congeners and glucose homeostasis, which is consistent with our findings. For example, both our study and the Odense Child Cohort study conducted in Denmark found that PFNA was associated with glucose homeostasis (Jensen et al. 2018). A study

[a] Quantile-based g-computation model adjusting for maternal age, pre-pregnant BMI, maternal educational level, smoking status, parity, averaged physical activity and economic status.

[b] Quantile-based g-computation model adjusting for maternal age, maternal educational level, smoking status, parity, averaged physical activity and economic status.

from the Spanish INMA Birth Cohort and a cross-sectional study in China found that PFOS and PFHxS were positively associated with impaired glucose tolerance and GDM (Matilla-Santander et al. 2017; Wang et al., 2018b). Another cross-sectional study in the USA found that certain PFAS such as PFOS may alter glucose homeostasis (Preston et al. 2020). Both of these two studies can support our findings on the effect of PFOS. A positive effect of PFHxS was also observed in the MIREC study in Canada (Shapiro et al. 2016). The LIFE study in the USA and another prospective study with repeat measurements in China found that PFOA was positively associated with increased GDM risk and impaired insulin sensibility, which was not repeated in our study (Wang et al., 2018b; Zhang et al. 2015).

In addition, our study suggests that short-chain PFAS such as PFHpA might affect glucose homeostasis during pregnancy. This is supported by a recent nested case-control study showing that PFBS level in early pregnancy was associated with a substantially higher GDM risk (Xu et al. 2020). Given the increasing use of short-chain PFAS as a replacement for long-chain ones, further research on this issue is urgently needed. Besides, no obvious association between PFAS and GDM was observed in another longitudinal study in Denmark (Valvi et al. 2017). Incidentally, we found that PFDoA seemed inversely associated with glucose metabolic outcomes, which was inconsistent with results of previous studies (Rahman et al. 2019; Seo et al. 2018). This finding may be due to chance as many comparisons have been made in the analysis. But the possibility that the disturbance of PFAS on glucose homeostasis might vary by PFAS congeners cannot be ruled out. The inconsistent results may also be attributable to differences in regional variation in PFAS concentrations (higher PFOA in China and higher PFOS in Europe and North America), study design (longitudinal and cross-sectional), sample size, study population and control of confounding factors. More population-based studies, especially from developing countries with high PFAS exposure, are needed to verify these associations.

Our study showed that prepregnant BMI may be an important modifier in the effects of PFAS. A similar modification was also observed in two previous studies (Radesky et al. 2008; Wang et al., 2018a). Both of them treated prepregnant BMI as an important modifier in the exploration of factors affecting the pathogenesis of GDM. In our study, pre-pregnant BMI was associated with GDM and PFAS exposure, but the effect of PFAS on GDM was attenuated in overweight or obese women. This is in contrast to a previous study in which the effects of PFAS were more pronounced among obese children than in normal weight children (Timmermann et al. 2014). Evidence from the non-obese diabetic mice model found that PFUnDA exposure could increase apoptosis in pancreas and reduce macrophage function as well as accelerate the development of insulitis, thus promoting the development of type 1 diabetes (Bodin et al. 2016). PFAS seems more likely to directly interfere with the glucose homeostasis. As obesity is a risk factor for diabetes, the chronic inflammation state in adipose tissue may induce insulin resistance (Roden and Shulman 2019). The effects of environmental factors, therefore, may be masked in overweight and obese pregnant women. Consequently, these associations appeared to be more pronounced in normal weight women. Although PFHpA and pre-pregnant BMI have a significant interaction effect on glucose homeostasis in this study, more evidence is needed to clarify its role in the PFAS exposure- outcome

KD2881

relationship.

How PFAS might affect glucose homeostasis remains unclear. PPARs are the most interested metabolic pathway. They are a subfamily of three ligand-inducible transcription factors, belonging to the superfamily of nuclear hormone receptors with three different isoforms: PPAR-α, PPAR-β/δ and PPAR-γ (Botta et al. 2018). *In vivo* and *in vitro* studies showed that PPAR could control a group of genes involved in adipogenesis, lipid metabolism, inflammation and maintenance of metabolic homeostasis. Among them, PPAR-α is mainly expressed in energy-demanding tissues that show high rates of β-oxidation and ketogenesis. Likewise, PPAR-β/δ are ubiquitously expressed in humans and found to be associated with an increase in fatty acid β-oxidation and antioxidant factors and a decrease in nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB). PPAR-γ is expressed at high levels in the adipose tissue (Chen and Yang 2014; Dubois et al. 2017; Saluja et al. 2001).

Some PFAS were found to be able to activate human PPAR-α and weakly bind to human PPAR-γ (Behr et al. 2020). The expression of PPAR-α and PPAR-β may lower glucose uptake, suppress pyruvate transition to acetyl-CoA and promote gluconeogenesis, specifically from glycerol (Botta et al. 2018; Takacs and Abbott 2007). Besides, PFAS may affect insulin resistance by inhibiting phosphorylation and activating protein kinase B (AKT) (Qiu et al. 2016). The AKT pathway involving cellular insulin signaling may be another important mechanism to enhance insulin sensitivity and inhibit hepatic glycogen synthesis and, thus, alter glucose homeostasis (Yan et al., 2015).

A recent study showed that PFOS could stimulate insulin secretion and intracellular calcium level via GPR40. Six compounds (PFHxS, PFOA, PFNA, PFDA, PFUnA and PFDoA) could bind with human GPR40; PFOA and PFDoA could enhance the insulin secretion by β-TC-6 cells (Qin et al. 2020). GPR40-mediated increase in intracellular calcium levels could promote the fusion of insulin-containing vesicles to plasma, resulting in the secretion of insulin, disturb glucose homeostasis and, finally, aggravate insulin resistance (Ghislain and Poitout 2017). However, more studies are needed to elucidate the possible mechanisms.

In addition, previous studies on the associations between environmental contaminants and GDM were mostly cross-sectional in design and the contaminants were evaluated one by one, which may introduce bias by reverse causation and miss the correlations between pollutants (Bobb et al. 2015; Preston et al. 2020; Tanner et al. 2020). Furthermore, the effects of different pollutants on health outcomes may show directional heterogeneity. This calls for a mixed exposure analysis to assess the effect of multiple PFAS exposures. Mixture effects of 30 environmental contaminants on incident metabolic syndrome were assessed in the Prospective Study of the Vasculature in Uppsala Seniors (PIVUS) and found that a mixture of contaminants were associated with future development of the metabolic syndrome in an additive fashion (Lind et al. 2017). To our knowledge, only the Viva Project assessed the joint effects of PFAS on GDM using the BKMR and found that certain PFAS may alter glucose homeostasis during pregnancy, but may not be associated with clinically diagnosed GDM (Preston et al. 2020).

Our study used BKMR and the novel quantile-based g-computation, which allows estimation of parsimonious mixture dose–response parameters by a joint marginal structural model (Keil et al. 2020). The results of these two models showed consistent findings. Compared to the Viva Project, we included a larger sample size and adding stronger evidence to the effect of PFAS on glucose metabolism. The mixed exposure analysis also took into account the non-linear associations between pollutants and health outcomes and the estimation error caused by the insufficient sample size. These methods helped to better assess the overall health effects of specific types of environmental pollutants.

In this study, multiple statistical models provided mutual validation on our findings. The BKMR model fits the nonlinear relationship between PFAS mixture exposure and glucose homeostasis and identify key pollutants better while the qgcomp model can generate the parameter estimate of mixed exposure effects. Both the weight of individual PFAS calculated in the qgcomp model and the specific PFAS congener selected by the ENR can help to assess the main contributors that affect glucose homeostasis. Generally, the results of BKMR and qgcomp were consistent and can be mutually verified. In addition to the robustness of the models, a series of sensitivity analyses such as completed data analysis, data analysis that includes missing information as dummy variables, data analysis using multiple imputation for small values that below the LOD and stratified analysis based on GDM status can help us to assess the stability and reliability of the results and the rationality of the modeling data. The stratified analysis can quantitatively test the possible interaction between PFAS and pre-pregnancy BMI.

Our study has several strengths. First, to our best knowledge, this is the largest study on this topic in the literature, particularly in a developing country with high PFAS exposure level and GDM incidence. Second, our study was a prospective cohort study with a clear temporal relationship between exposure and outcome. Still, our study has some limitations. First, although we have adjusted for as many potential confounders as possible, other important factors such as diet and nutritional supplements have not been included. We could not completely rule out the possibility of residual confounding. Second, only a single estimate of plasma PFAS concentrations in early pregnancy was determined in our study. However, previous studies demonstrated that PFAS concentration during pregnancy was relatively stable due to its long half-life (Papadopoulou et al. 2015). Last, the lack of information on some important metabolic factors such as insulin and C-peptide makes it difficult to evaluate the insulin resistance and pancreatic function.

5. Conclusions

Our study indicates that exposure to PFAS was associated with disturbance of glucose homeostasis in pregnancy and an increased risk of GDM. PFOS, PFNA and PFHpA may be the major contributors. The effect of PFAS on glucose homeostasis in pregnancy is more pronounced in women with normal weight. As PFAS are ubiquitous and GDM not only is common but also has long-term impact on women and their offspring, our findings may have important public health implications.

Credit authorship contribution statement

G-Q Y and J Z did the background research and conceptualization. G-Q Y, Y H and M-F J contributed to the data curation. G-Q Y conducted the formal analysis. M-F J and Y H helped to validate and interpret the results. R A and M N did the PFAS detection, and took responsibility for the integrity and accuracy of the exposure data. T Z, Y T, W-Y W, Z-C L, L-S S and X-P W helped to the data collection. G-Q Y drafted the manuscript. Q D, W-P X and J Z supervised the project, carefully reviewed and edited the manuscript. Each author contributed important intellectual content during manuscript drafting or revision. All authors accept accountability for the overall work.

Declaration of Competing Interest

The authors declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.
