A HABITAT-BASED APPROACH FOR IDENTIFYING OPEN-SPACE CONSERVATION NEEDS IN SOUTHERN MAINE TOWNS

William B. Krohn

University of Maine, Orono

Abstract: A method to identify habitats that, if conserved, could be expected to maintain terrestrial vertebrates (= wildlife) currently breeding in southern Maine (i.e., lower half of state) into the future was developed with the Maine Department of Inland Fisheries and Wildlife (MDIFW). This method is based on digital maps and thus can be analyzed with a Geographic Information System (GIS). Southern Maine was selected for study because this region contains the greatest diversity of plants and animals in the state, has relatively few conservation lands, is experiencing sprawl into rural areas, and is projected to lose 569 mi² (1,473 km²) of agricultural and forest lands by 2050. The backbone of the method is the presumed conservation of habitats immediately adjacent to all waterways and water-bodies, termed Shoreland Zones. Added to this backbone are other habitats recognized by the Maine Legislature as worthy of conservation; these we termed Important Habitats. Although some upland vegetation occurs in the Shoreland Zones and Important Habitats, these areas are comprised mostly of lowland vegetation. Currently, 270 wildlife species (amphibians = 17, reptiles = 16, birds = 183, mammals = 54) are estimated to inhabit southern Maine, with 80% to 95% (median = 85%) having adequate habitat (defined as the types of habitats needed to support >10 individuals of that species in the town) in Shoreland Zones and Important Habitats. Wildlife not captured by Shoreland Zones and Important Habitats are those medium-to-large-bodied birds and mammals requiring large areas of uplands. To identify habitats for these species, blocks of agricultural and forest lands not intersected by roads, pipelines, powerlines, or railroads were mapped in the GIS. The conservation value of these relatively intact upland blocks, if maintained in current cover conditions, should be assessed in terms of size (i.e., the bigger the better) and location (i.e., the more connected to other habitats the better). Advantages of the method include that it deals with issues and habitats familiar to towns, and is computerized and hence cost efficient and practical to apply across southern Maine. Although the approach does have limitations (e.g., assumes complete data), these are addressed within this analysis method. The habitats identified by this method, if conserved, can reasonably be expected to maintain a town's wildlife well into the future.

Introduction and Background

The southern half of Maine is a conservation priority because it supports the highest diversity of plants and animals in the state, the highest number of endangered and threatened terrestrial vertebrates in Maine, and only scattered and small conservation lands (Krohn *et al.* 1998). In addition, this part of Maine supports the majority of the state's human population and is experiencing a repopulation of rural areas as people move out of the towns and cities into the less populated areas (O'Hara 1997, Krohn *et al.* 1998:6). While there is currently no conservation crisis *per se* in southern Maine, continued expansion of the human population will eventually negatively affect the region's wildlife unless land conservation measures are implemented. It has been estimated that by the year 2050 the eight counties of southern Maine will have an additional 428 mi² (1,109 km²) of urban lands while losing 569 mi² (1,473 km²) of agricultural and forest lands (Plantinga *et al.* 1999). Thus, preserving viable populations of all species of terrestrial vertebrates that regularly breed in southern Maine today requires that we identify and conserve the habitats needed to maintain these wildlife species.

Over 97% of the land in the southern portion of Maine is privately owned (Krohn et al. 1998: A9-1). Conserving wildlife habitats when lands are privately owned requires integration of local concerns in the broad context of open-space conservation where scenic, recreational and other values are considered (O'Hara 1997, Venno 1991). Town governments play an important role in land conservation in Maine. Specifically, Maine towns implement shoreland zoning ordinances, develop growth management plans, and enforce various land development laws [for details, see Venno (1991: Appendix A)]. State laws also play an important role in wildlife

habitat conservation in Maine. Specifically, under the Maine Natural Resources Protection Act (MNRPA), the MDIFW is responsible for identifying and conserving Significant Wildlife Habitat, defined as habitats for endangered or threatened species, high and moderate value deer wintering areas, high and moderate value waterfowl and wading bird habitats, along with some other specified habitats (Venno 1991:34). MDIFW is also responsible, under the Maine Endangered Species Act (MESA), for identifying and conserving Essential Habitats for endangered species (Venno 1991: Appendix A). Obviously, those habitats identified by the Maine Legislature are of special concern to the citizens of Maine, and thus should receive special attention in open-space conservation.

Assuming that the above habitats (hereafter called Important Habitats) along with shoreland and wetlands protected under state and Federal regulations (hereafter termed Shoreland Zones) are protected into the foreseeable future, the issues then become to (1) identify what species are, and are not, conserved by Important Habitats and Shoreland Zones; and (2) for species not conserved by these areas, identify what habitats need conserving and where.

Goal and Objectives

The goal of this project is to identify areas in southern Maine for towns to include in open-space conservation such that potential habitat is provided for all terrestrial vertebrates estimated to be regular breeding species in that town during the mid-1990s. To work toward this goal, we developed a GIS that can be used throughout the southern half of Maine to standardize the integration of wildlife habitat information into town planning, especially as related to long-

term planning for maintenance of open spaces (i.e., lands that are without human habitation).

Project objectives were (1) to identify, at the scale of individual towns, what wildlife species are, and are not, potentially conserved by Shoreland Zones and Important Habitats; and (2) for those species whose habitat requirements are not met within these habitats, to identify open-spaces where conservation would provide long-term habitat for these species.

Study Area and Method Development

Study Area

The portion of Maine used in this analysis extends from southernmost Maine, north to Coburn Gore, east to Lincoln, and southwest along the eastern shore of the Penobscot River. Three hundred and ninety-seven townships are included in our analysis (Figure 1), and the total size of this area (including water) is 13,623 mi² (35,280 km²). The southern part of the area has the mildest climate in Maine, with geomorphology ranging from rolling foothills in the west to the Atlantic Ocean in the east (Krohn *et al.* 1999). The coastal plain of this area, which comprises most of southern Maine (Krohn *et al.* 1998:7), consists of 64.7% forestlands, 17.3% agricultural land, 9.5% wetlands, 5.4% open water, and 3.1% developed lands (Krohn *et al.* 1998:A3-1).

Method Development

The landscape analysis method presented in this report was developed through close

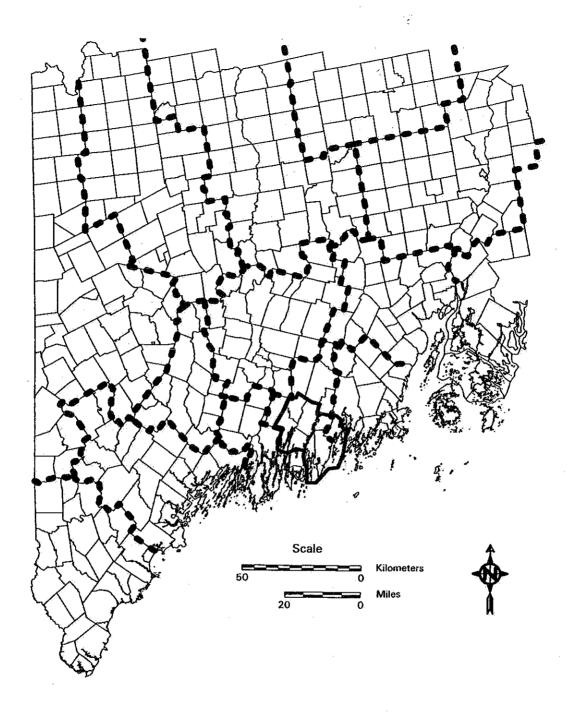

Figure 1. Location of towns (solid lines) and counties (dashed lines) in southern Maine for which the data were compiled. The heavy outline is the Damariscotta area (see Figure 2 for more detail of this area).

cooperation with the MDIFW. Specifically, the Department assigned personnel to a Wildlife Division Habitat Committee (see Acknowledgments) with whom we worked to establish objectives, define habitats of interest, and outline an analysis approach. The authors (i.e., WBK and JAH) would then assemble the appropriate data in a GIS, make preliminary tabulations and maps, and report back to the Committee for their critique and discussion. After revisions, the process would be repeated until the Committee was satisfied that the approach met their purpose. Two of the review meetings included, in addition to members of the Committee, representatives of the Maine Audubon Society (MAS), Maine Natural Areas Program (MNAP), and the U.S. Fish and Wildlife Service (USFWS).

From the outset, the Committee had a number of characteristics they considered essential in defining a useful landscape analysis method. First and foremost, the method had to be comprehensive and designed to conserve all vertebrates native to southern Maine. The method should conserve plant as well as animal communities, and not only account for the different types of habitats used by each wildlife species, but should also meet their spatial needs. That is, not only should the appropriate habitat for each wildlife species be conserved, but this habitat must be in large enough blocks that it's functionally intact (i.e., likely to support a breeding unit). The method must allow for incremental analyses in that as habitats are identified and protected, users can determine what species are, and are not, likely to be conserved. Thus, as an increment of habitat covering the needs of one group of species is done, users can move on to identifying and protecting habitats for species groups previously under- or un-protected. The Committee recognized that over the long-term habitat fragmentation is a serious threat to many wildlife species (e.g., Robbins *et al.* 1989, Robinson *et al.* 1995), and that large-bodied and predatory

animals require large areas (e.g., bears and raptors). Thus, the method must include analyses of habitat block sizes and assess habitat patterns over multiple towns if habitats are to be conserved for the full range of wildlife species. In summary, the method must sequentially identify and conserve habitats, of the appropriate type and size, until the goal of providing habitats for the entire vertebrate wildlife community currently living in southern Maine is realized.

Data Sources and Methods

Following are descriptions of the data used in the development of the method reported on here, giving special attention to describing the data used and where it came from. See Hepinstall (2000) for additional technical details related to these data.

Predicted Wildlife Occurrences

Predictions of the presence of terrestrial (i.e., non-fish, non-marine) vertebrate species that regularly breed in Maine (hereafter referred to simply as wildlife) were derived from predictions made by Krohn *et al.* (1998) for the Maine Gap Analysis Project (ME-GAP). Species predictions were based on combining a vegetation and land cover map of Maine (Hepinstall *et al.* 1999) with species-habitat associations and species range maps to make spatially explicit predictions of where species are likely to occur on the landscape (Boone and Krohn 1998a,b). The species predictions were modeled at 295.3 ft (90 m) pixel resolution for ME-GAP, but we did all analyses at 98.4 ft (30 m) resolution to more precisely represent the edge of the Shoreland Zone. Expected species lists for each town based on ME-GAP predictions were calculated using

The Shoreland Zone GIS layers were merged into one file and converted into a raster format with 98.4 ft (30 m) pixel size. The state shoreland zoning regulations are more complex than the above list would indicate, not protecting first order streams, wetlands under 10 ac (4 ha) unless attached to other wetlands or water, or forested wetlands. We chose to include all water and wetlands in our database on the basis that we were attempting to ascertain the possible species list for each town. Wetland data at a 1:24,000 scale, in digital form, came from the USFWS National Wetlands Inventory (NWI). NWI data, in turn, come from interpreted color-infrared aerial photographs (for more details on the NWI data for Maine see Krohn *et al.* 1998: 12, Appendices, 1 and 2).

Important Habitats

The MDIFW provided a digital coverage of Important Habitats from habitats defined by the MNRPA. These data were added to the Shoreland Zone data and this layer was used with the species predictions from ME-GAP. Important Habitats included Biological and Conservation Data system (BCD) points and polygons (i.e., occurrences of rare invertebrates and vertebrates), wintering areas of White-tailed Deer (*Odecoileus virginianus*), seabird nesting islands, shorebird nesting, feeding, and staging areas and tidal waterfowl and wading bird habitats. Essential Habitat for the Bald Eagle (*Haliaeetus leucocephalus*) (MDIFW 1998), Roseate Tern (*Sterna dougallii*) and Least Tern (*S. antillarum*) was included in this data layer.

The percentage of species that inhabited Shoreland Zones (SZ) and Important Habitats (IH) were calculated by (1) the total habitat available for ≥ 1 individual of a species, and (2) ≥ 10 individuals of a species. Specifically:

(2) % of total potential species with > 10 = individuals per species missed No. of species with > 10 individuals in SZ + IH within a town

X 100.

Total no. of species predicted by ME-GAP with area for > 10 individuals

Blocks of Upland Habitat

To locate potential habitat for the species missed by the Shoreland Zones and Important Habitats, we developed a map of blocks of relatively unbroken, mostly upland habitats. Upland habitats were defined by the superclasses in Hepinstall et al. (1999) as Agricultural Lands and Forestlands (including forested wetlands). Blocks of agricultural and forest lands unbroken by roads (i.e., interstate, primary, secondary, and improved), pipelines, powerlines, and railroads were classified by sizes and color coded (i.e., larger the block, the darker the color). Road data came from MOGIS and were developed by the Maine Department of Transportation, and were mapped at a scale of 1:24,000. By visually inspecting the blocks of undeveloped habitats, and relating these blocks to the size and types of habitats needed to conserve upland species requiring large areas, habitat for species not adequately protected in Shoreland Zones and Important Habitats could be identified. To select upland blocks for conservation, we recommend that larger blocks be selected over small ones, and that blocks containing or connecting a variety of habitats (e.g., Shoreland Zones, Important Habitats, and conservation lands) be given special consideration. Additional factors, such as size of ownerships, land owner interest in conservation, and threat of development can also be considered.

Note that blocks of upland habitats are especially important to large animals with large spatial requirements, and to some smaller animals with population area requirements exceeding individual needs. For example, a minimum of 1,215 ac (3,000 ha) has been suggested to retain

breeding songbirds who do poorly along forest edges (Robbins *et al.* 1989); for some grassland breeders, fields should be at least 40.5 to 81 ac (100 to 200 ha) in size (Vickery *et al.* 1994).

Results - Damariscotta Area

To give the reader a sense of how to apply this landscape analysis method, we present data for the eight towns in the Damariscotta area of southcentral Maine (Figure 2). When not too unwieldy, data for the eight study towns are shown along with the data from all of the study area. When southern Maine data are too extensive, however, only data for the Damariscotta area are cited in the text; southern Maine results are given in the appendices.

Town Context and Characteristics

Most towns within the southern Maine study area are between 21 and 50 mi² (54.4 - 129.5 km²) in size. Compared to all of southern Maine, the towns in the Damariscotta study area are smaller, ranging from 11 to 40 mi² (28.5 - 103.6 km²) (Figure 3). Within these areas, the Damariscotta towns are covered mostly by forests, ranging from 61.2 to 77.3% of each town (Table 1) (see Appendix B for southern Maine data by town). The percentage of each town in agriculture generally ranges from 10 to 15%, with two towns (Bremen and Edgecomb) below 7% (Table 1). Wetlands occur over 11-15% of four towns, and the remaining four towns have only 7-10% of their total areas in wetlands (Table 1).

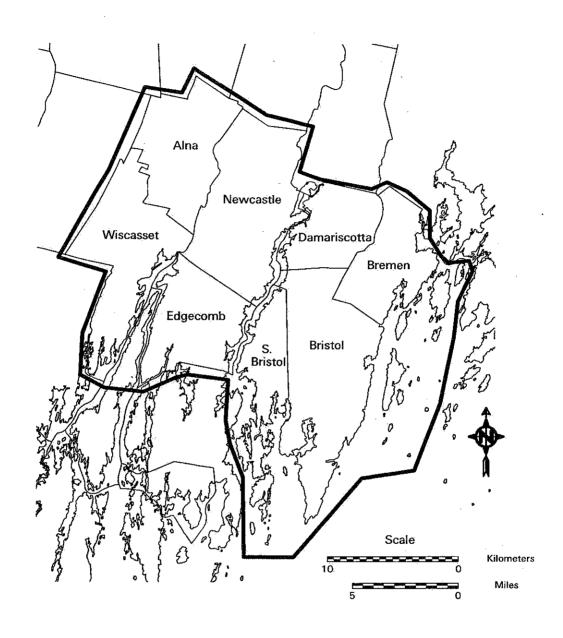

Figure 2. Location of eight towns in the Damariscotta area of southcentral Maine. Relation of this area to southern Maine is shown in Figure 1.

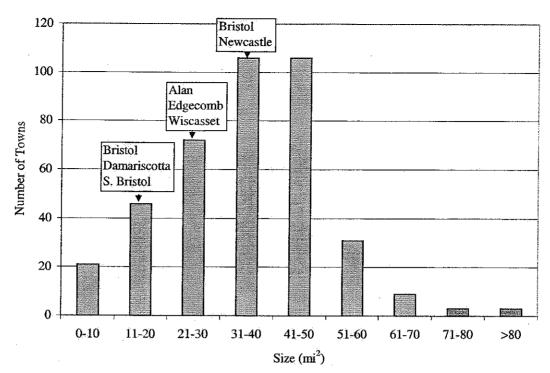

Figure 3. Frequency distribution of sizes (mi²) of towns in southern Maine (n = 397). Towns within the Damariscotta areas of southcentral Maine are skewed towards smaller towns than the regional average.

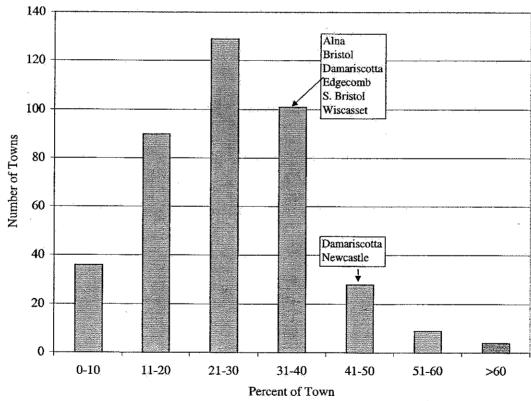

Figure 4. Frequency distribution of the percentages of towns in southern Maine (n = 397) in Shoreland Zones and Important Habitats combined. Towns within the Damariscotta study area tend to fall within the high end of this graph.

^a - Data from Hepinstall et al. (1999), which includes definitions of the above types of vegetation and land cover.

The land cover and land use characteristics of the eight towns in the Damariscotta area result in combined Shoreland Zones and Important Habitats (i.e., non-overlapping) covering 30.2 to 42.8% of each town (Table 2). These figures are high compared to the study area as a whole (Figure 4), primarily because of the relatively high amounts of water (salt- as well as fresh-water) and wetlands (Table 1).

Conserving Lowland Habitats

The total number of wildlife species potentially present in the Damariscotta area, by town, ranges from 146 to 151 (Table 3) (Appendix C for southern Maine data). Because we presumed that towns would fully conserve Shoreland Zones and Important Habitats, those wildlife species requiring open water, wetlands, riparian, or a combination of these areas, were now considered conserved and not given any additional analysis. However, if towns are interested in enhancing existing wetlands, or in creating new ones, detailed technical information is available (e.g., Whitman *et al.* 1995).

The majority of wildlife species in southern Maine have home ranges of $< 1.0 \text{ mi}^2 (2.59 \text{ km}^2)$ (Figure 5). All amphibians have home ranges $< 0.1 \text{ mi}^2 (0.26 \text{ km}^2)$ and no reptiles have home ranges $\ge 1.0 \text{ mi}^2 (2.59 \text{ km}^2)$ and only birds and mammals have home ranges $\ge 10 \text{ mi}^2 (2.59 \text{ km}^2)$ (Figure 5). The percentages of species potentially present but missed is similar for Shoreland Zones and Shoreland Zones plus Important Habitats (Figure 6), showing that shorelands are the most critical of the two in meeting conservation goals. Across the study area, 128 of 201 upland species of wildlife predicted as potentially occurring in a town were

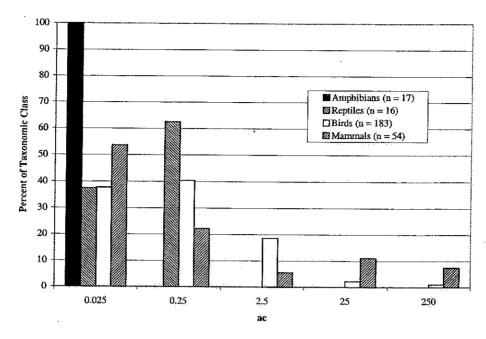

Figure 5. Frequency distribution of home ranges for terrestrial vertebrates that regularly breed in Maine.

 b SZ & IH = Shoreland Zones and Important Habitats

unprotected in \geq one town if only Shoreland Zones and Important Habitats were protected (Figure 7). When only those species unprotected by Shoreland Zones and Important Habitats in \geq 70 of the 397 towns are considered, the list drops to 22 upland species (Figure 8). Examining the spatial needs of these 22 species shows that medium to large-size birds and mammals (e.g., hawks, owls, and mammalian carnivores) with large home ranges are of special concern (Table 4). General types of upland habitats needing conservation are a mixture of forest and agricultural lands (Table 4).

Shoreland Zones and Important Habitats do an excellent job of providing habitats for amphibians and reptiles, both in terms of number of species (Table 5) and for species where enough habitat was provided for 10 or more individuals (Table 6). Shoreland Zones and Important Habitats in the Damariscotta area were estimated to not provide habitat for only 3.6-8.8% and 8.1-13.5% of the bird and mammal species, respectively (Table 5). When considering only those species for which enough habitat was provided for 10 or more individuals, more birds than mammals were missed with the town-specific data ranging from 10.1-25.2% and 5.9-9.1%, respectively (Table 6).

Neither the percentage of total species protected (Figure 9), nor species with > 10 individuals each protected (Figure 10), were correlated with the amount of land occupied by humans (= urban lands). This suggests that conserving Important Habitats and Shoreland Zones will work equally well in both urban and rural towns, with few exceptions (see outliers on left side of Figure 9). However, the percentage of total species that could be protected by the conservation of Important Habitats and Shoreland Zones rises sharply as the amount of Important Habitats and Shoreland Zones increases beyond 5 mi² (13.0 km²) (Figure 10).

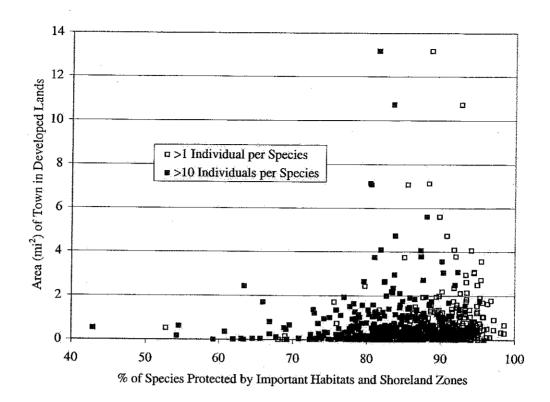

Figure 9. The percentage of species protected by Important Habitats and Shoreland Zones potentially present in a town against the amount of developed land (mi²) in the town for southern Maine towns.

South Bristol	0	0	25.2	(27)	9.1	(3)

^a - Total species potentially present per town. Because this total varies by town, a range is shown where appropriate.

Thus, towns with $\leq 5 \text{ mi}^2$ (13.0 km²) of Important Habitats and Shoreland Zones (i.e., mostly lowland habitats), should consider conserving more upland habitat than in towns with $> 5 \text{ mi}^2$ (13.0 km²) of lowland habitats (Figure 10).

Conserving Upland Species

Wildlife not captured by Shoreland Zones and Important Habitats are those medium-to-large-bodied upland species requiring large areas of agricultural and forest lands (Table 4). To identify habitat for these species, blocks of agricultural and forest lands not intersected by roads, pipelines, powerlines, or railroads were mapped in the GIS. Relatively unbroken blocks of habitat are presumed to have higher value for some species by limiting negative edge effects such as dry conditions (e.g., DeMaynadier and Hunter 1998, 1999) or nest parasitism/predation (e.g., Robbins *et al.* 1989, Robinson *et al.* 1995), and the potential disturbance and mortality (e.g., Krohn *et al.* 1994) related to ease of access by humans or their pets.

Thus, we next identified upland habitats, of adequate size, to provide habitat for those species missed if only Shoreland Zones and Important Habitats were conserved. Most blocks of agricultural lands in the Damariscotta area are in the 0.25 to 25 ac (0.10-10.1 ha) range compared to 25-2,500 ac (10.1-1,012 ha) for forestlands (Table 7). The locations of blocks of relatively intact uplands as well as Shoreland Zones, Important Habitats, and conservation lands for the town of Alna are shown in Figure 11.

To develop a landscape that conserves a full compliment of species, carefully review the available conservation lands data to ensure that all new acquisitions, conservation easements, land trust parcels, and water district lands are included. Next, look for opportunities where, if conserved, the blocks of undeveloped land would link conservation lands, Important Habitats, and Shoreland Zones.

^a - Includes Forested Wetlands.

Because larger blocks provide habitat for more species, the larger the block the higher the conservation value of the parcel. Once blocks are selected, numerous options are available to conserve open-space (Milne 1985). Thus, the vision is to create a landscape with a series of large, open-space blocks, connected by corridors linking Shoreland Zones and Important Habitats, that then function as a continuous landscape for wildlife. By considering linkages to adjacent towns, a regional landscape can be created to provide habitat for species with the largest spatial requirements.

The methodology reported here emphasizes the values of wildlife habitats. Other values that must be considered when selecting parcels include exemplary and rare plant communities, scenic views and sites (e.g., waterfalls), recreational values, and others (i.e., number of parcel owners, interest of landowners in conservation).

Discussion

Cautions

This method is spatially explicit and thus presumes that all data elements are completely mapped (i.e., census data, not samples). We know this is not the case and thus users must be careful. Streams, a key element in Shoreland Zones, were represented at a scale of 1:100,000, and if one examines the 1:24,000 scale coverage, more small streams and brooks will be found. Unfortunately, the completeness (i.e., uniformity) of the 1:24,000 stream coverage varied greatly among quadrangles and thus could not be used. Similarly, deer wintering areas, an element in the Important Habitats, were not uniformly mapped across southern Maine (see Figure 17, Krohn et al. 1998:89). We also suspect that occurrence records for many rare animal species, mapped as part of the Important Habitats, are incomplete. Finally, we note that not only is the existing

GIS coverage of conservation and public lands dated (Krohn and Kelly 1997), it is incomplete in terms of lands such as conservation easements, local land trusts holdings, water district lands, and the many small parcels of public lands scattered across southern Maine towns (Krohn *et al.* 1998:66-67). To counter the above deficiencies, users must supplement the regional data provided with up-to-date local knowledge.

The preceding method is habitat-based and if someone wants to conserve a representative sample, say 10-15%, of the major landform types that occur in southern Maine, an entirely different analysis would be used (e.g., Orndorff, In Preparation). Similarly, if interest was focused on rare or exemplary plant communities instead of wildlife habitat, different areas could be selected for conservation. However, when we overlaid plant data from the MNAP onto the Shoreland Zones and Important Habitats for some areas of southern Maine, we found a high spatial coincidence suggesting that multiple conservation targets (i.e., plants and animals) would be conserved, with some exceptions (i.e., dry sandy areas, or mountain tops). Users of this wildlife habitat-based system should not be surprised if landscape analyses using different methods yield different results, but instead should view alternative analyses as opportunities to identify and obtain multiple conservation goals.

To ensure that the analysis method outlined above encompasses landscapes at the level necessary for conserving vertebrates requiring large areas, users must regularly apply the method on a multi-town basis. For example, consider the fisher (*Martes pennanti*), a medium-sized forest carnivore that is territorial with adult females living apart from adult males (Arthur *et al.* 1989a). Radio-telemetry work in southcentral Maine suggests that it takes approximately 12 mi² (31.1 km²) and 6 mi² (15.5 km²) per adult male and adult female, respectively (Arthur *et al.* 1989a). Because fishers do not use urban/industrial lands, open water, or forested wetlands

(Arthur *et al.* 1989b), we can assume that only 30 mi² (77.7 km²) of an average town of 40 mi² (103.6 km²) (Figure 3) is suitable. Furthermore, if like American marten (*M. americanus*) (Bissonette *et al.* 1997), fishers can tolerate ≤ 30% of non-forested habitats within their territories, then the average amount of suitable habitat per town is less than 30 mi² (77.7 km²). However, staying with the optimistic estimate of a mean of 30 mi² per town of suitable fisher habitat, this is enough space for only 7-8 adults (2-3 males, 5 females). Such small populations over such large areas are vulnerable to random mortalities (let alone high road-kills in the towns with dense human populations and roads). Thus to maintain viable fisher populations in southern Maine, fisher habitat must be analyzed and managed over multiple town areas (i.e., in blocks of ≥9 towns).

Advantages

The landscape analysis method presented here is based on information that MDIFW has collected, and these data relate to issues towns deal with (i.e., including shoreland zoning, wetland protection, and endangered species protection), and can be applied in a framework familiar to towns (i.e., comprehensive planning). Specifically, Maine's Comprehensive Planning and Land Use Regulation Act has ten goals that include such topics as protecting the state's rural character, safeguarding agricultural and forest resources, protecting water resources and wetlands, protecting wildlife and fisheries habitats, and promoting and protecting opportunities for outdoor recreation and the many benefits of open space (Venno 1991:30-31). Thus, this method reinforces existing mandates to give water, wetlands, and certain habitats special consideration in town planning, and acknowledges multiple solutions to conserving habitats in the context of open-space planning.

Inputs to the method such as home range sizes and habitat associations can be updated as new information about wildlife ecology is developed. The method is not based on a fixed set of rules and thus can be adapted as new developments occur in the rapidly expanding fields of conservation biology and landscape ecology. Because an area's hydrology forms the skeleton of methods conservation strategy, implementation of this method conserves the full range of aquatic and semi-aquatic vertebrates as well as terrestrial wildlife. This method provides biologists and planners with flexibility to account for factors not in a GIS, such as patterns in land ownership and land owner attitudes. Finally, this method has many of the attributes amenable for working with local governments as suggested by Hobbs (1999).

Major Steps

The methodology, summarized by its major steps, works as follows:

- (1) Obtain an overview of the cover and land characteristics of the study town and adjoining towns. Examine the locations of water (running and standing), wetlands and habitats of concern to the MDIFW. Water and wetlands should be examined for completeness, and modified as needed. Note also the locations of Important Habitats; these are species-specific (e.g., white-tailed deer), or group-specific (e.g., wading birds) habitats.
- (2) Examine the buffers that were created along shorelands. They should be 250 feet on each side of rivers, lakes, ponds, and wetlands; 75 feet on each side of streams. Collectively, these are termed Shoreland Zones and roughly correspond to Maine Shoreland Zoning Ordinances. (Note: If waters and wetlands were added in Step 1, those areas will have to be buffered in this step).
- (3) The potential number of terrestrial vertebrates regularly breeding in each town during the mid-1990s was estimated from Maine Gap Analysis. Based on the habitat and home range (i.e., spatial) needs of these species, data are provided on the number of species potentially inhabiting Shoreland Zones and Important Habitats. Review Important Habitats and add on needed new data or rare plants and exemplary plant communities. Assuming that the town fully conserves the Important Habitats and Shoreland Zones, the town next needs to consider conserving habitats for upland species requiring large blocks

- of undeveloped lands.
- (4) Examine the maps of (a) conservation lands, and (b) blocks of agricultural and forest lands. Give special attention to completeness of the conservation lands map, especially with regard to parcels in land trusts, conservation easements and water district land (the statewide data are known to be incomplete, so add areas as appropriate).
- (5) Identify blocks of agricultural and forest lands to provide habitat for upland species not adequately addressed by conservation of Shoreland Zones and Important Habitats (e.g., wild turkeys, fishers). When identifying blocks for potential conservation as part of open space plan, special attention should be given to the larger blocks, and blocks that connect conservation lands, Important Habitats, and Shoreland Habitats.
- (6) Once open-space needs for conserving upland wildlife with large spatial needs are identified, conserve these areas through voluntary purchase, easements, or cooperative agreements. In each step consider how habitats are distributed in all adjacent towns, as well as distribution patterns within the town of primary interest.

When applied, it must be emphasized that Shoreland Zones are the skeleton of habitat conservation. This method fails if large blocks of agricultural and forest lands are not conserved, and thus to maintain large, upland blocks in current cover conditions, willing land owners must be identified. Land owner cooperation will also be critical to maintain connectivity among watersheds, conservation lands, Shoreland Zones, Important Habitats, and open spaces. Because this process is not anti-development, lands suitable for development should also be identified within the framework presented.

Acknowledgments

We thank all the MDIFW biologists who spent countless hours in the field identifying and mapping the Important Habitats used in this study. The analysis method developed here would not have been created if it were not for the time and input provided by the Department's Wildlife Habitat Committee. Specifically, we would like to thank the following persons: R. Bradford Allen, Philip A. Bozenhard, James M. Connolly, Richard L. Dressler, Eugene A.

Dumont, Walter Jakubas, Douglas M. Kane, John S. Kenney, George J. Matula, Mark A. McCollough, Amy L. Meehan, Sandra L. Richie, Sandra M. Schaefer, G. Mark Stadler, and MaryEllen Wickett. In addition, we appreciate the constructive criticism provided by the following: Arnold Banner, USFWS; Barbara Charry and Sally Stockwell, MAS; and Daniel R. Coker and Molly T. Docherty, MNAP. We also want to thank Ken Elowe, Director of MDIFW's Bureau of Resource Management, for the vision to see the value of this methodology; Mark Stadler, MDIFW's Wildlife Division Director, was gentle yet firm in keeping the process moving forward; and Rich Dressler, Maine's Wildlife Habitat Committee Chair, for arranging meetings, making data available, and keeping on top of all the details that if not done, this project would never have been completed. We also acknowledge the Gap Analysis Program, Biological Resources Division of the USGS, whose earlier funding of the Maine Gap Analysis Project permitted the creation of many of the data layers used in this work. This project was funded by the MDIFW and is a contribution of the Maine Cooperative Fish and Wildlife Research Unit (MDIFW, University of Maine, and the Wildlife Management Institute, cooperating). This report was reviewed by R. L. Dressler, K. D. Elowe, S. M. Schaefer, and G. M. Stadler.
